**Fig. 4** (LEFT) Audiograms for Bighead, Silver, and Common carp. Each data point represents the minimum sound pressure level (SPL; dB re 1 µPa $SPL_{rms}$) necessary to invoke an *auditory* evoked potential (AEP) response (tested range: 100 Hz to 5000 Hz). (RIGHT) Particle acceleration thresholds (dB re 1 µPa $ms^{-2}$) for the Bighead, Silver, and Common carp. Data are reported as mean (±S.D.). (Accessed 2023 Jan 13; Vetter et al. 2018)

projector vessel for signal transmission, and the signal was recorded on a receiver vessel using an AMAR, set to 24-bit, with three M36-100 hydrophones (GeoSpectrum Technologies Inc., Dartmouth, Canada) and one M20 vector sensor (GeoSpectrum Technologies Inc., Dartmouth, Canada). With these components, the spectral noise floor is 20 dB re 1 $\mu Pa^2$/Hz and the nominal ceiling is 171 dB re 1 µPa. To reduce vessel generated noise on the receiver and projector vessels, the sound production (CDi 2000, Crown Audio, Lake Mary Florida), communications (i.e., radios), and data collection systems (i.e., water quality, GPS, chart plotters, laptops, etc.) were powered by uninterruptable power supplies (SMT2200C, American Power Conversion, West Kingston, Rhode Island). Campaign data was used on four projector locations along the top of the 5th discharge lateral and one location within the 5th discharge lateral and recorded the signals at 28 locations 1 m off the lock floor, and at 28 locations mid-water column.

The final deployed uADS consists of a "soundbar" in which 16 transducers were co-located in a discharge channel (patent pending COE-789 [USACE-ERDC 2022]) (Fig. 5). The projector cables are placed in a series of cuts to a control station. The noise generated by the soundbar is recoded using a series of 8104 hydrophones, Lan-XI Data Acquisition System, and Tescia 2022.0 (Hottinger, Brüel and Kjær [HBK], Virum, Denmark). The Lock No. 19 evaluation is ongoing and primarily conducted between typical navigation season (March through early December) to examine navigation and seasonal impacts on the operation and effectiveness of the uADS (Brey et al. 2023).

## Brandon Road Interbasin Project (BRIP)

Currently, the USACE, federal and state partners, and stakeholders are developing the Brandon Road Interbasin Project (BRIP, Fig. 6). The project is a complex ecosystem protection effort to prevent invasive carp and other aquatic nuisance

**Fig. 5** (TOP) Deployment of the soundbar (which hangs over in the photo) in the 5th discharge lateral at Lock No. 19 in the Mississippi River (Keokuk, IA, Photo credit: Mark Cornish, USACE). (LEFT) Photo of silver carp over the uADS (powered off) at Lock No. 19 with the miter gates closed (Photo credit: Christa M. Woodley, USACE). (RIGHT) Deployment of two types of acoustic receiving systems at Lock No. 19 to study fish movements (Hydroacoustic Technology Incorporated [HTI; 307 kHz]; Innovasea Systems Inc., Boston, MA, USA) and sound events (8104, low noise shield cable, Hottinger, Brüel and Kjær [HBK], Virum, Denmark)

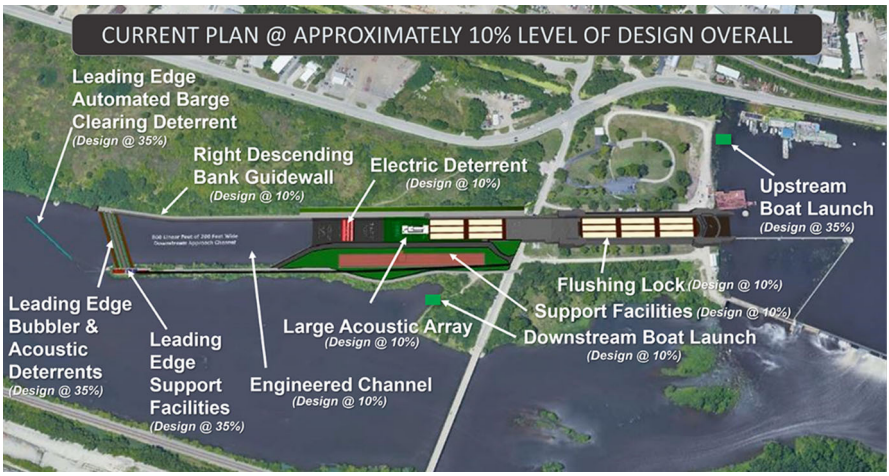

**Fig. 6** Brandon Road Interbasin Project (BRIP) Proposed 10% Design. This is the current proposed design of the multi-deterrent system proposed for Brandon Road Lock and Dam (BRLD; Joliet, IL, USA) as of August 2022. The BRIP proposal includes an automated barge clearing deterrent, two underwater acoustics deterrent systems, an electric deterrent, and a flushing lock to prevent the passage of adults, juveniles, and larvae of invasive species. (Accessed 13 Jan 2023; http://www.mvr.usace.army.mil/Missions/Environmental-Stewardship/BR-Interbasin-Project/)

species movement into the Great Lakes via the Illinois Waterway (USACE 2018). Bandon Road Lock and Dam (Joliet, Illinois, USA) has been identified as the critical pinch-point where layered technologies could be used to prevent the movement of invasive carp populations into the Great Lakes. The pre-construction engineering design phase of the BRIP was initiated in December 2020 when the state of Illinois signed an agreement with the USACE. The BRIP approach involves a layered system of deterrents that include flushing the locks with water, an engineered channel to reduce hiding places for species while providing infrastructure for an electric deterrent, underwater acoustics, dispersal bubble curtain, and an automated barge clearing deterrent. In addition, the project supports public education and outreach, regional fish monitoring, integrated pest management, state-regulated pesticide treatment, and manual removal (USACE 2018). The conceptual idea for the multi-deterrent system proposed is to prevent INNS from passing through BRLD. However, much like the electric barrier in the CSSC, the BRIP will allow for hydrological connection, but significantly limit migration through the lock by native and desirable species.

## Next Steps

To date, there are many assumptions on the potential impacts of NSDs, in particular, the impacts of underwater acoustic deterrents on the environment, community, and even infrastructures. In terms of the most needed unknown, yet least studied, are the potential

long-term impacts of NSDs and the impacts of underwater acoustics. Most long-term studies have focused on near-term impacts, such as ontogenetic developments, physiological stress, audio impairments, and behavioral alteration or disruptions in movement-migration patterns. Without understanding the long-term consequences of underwater acoustic deterrents, there are unrevealed and potentially insidious risks to T&E and native species, community ecology (including fishes, turtles, mammals, invertebrates, plants, and microbiology), biodiversity, and ultimately on, ecosystems health (Hawkins et al. 2015; Popper and Hawkins 2019; Popper et al. 2020). The cumulative effects of long-term exposures to underwater acoustic deterrents may even force evolutionary pressure (e.g., ontogenetic shifts, hearing shifts, hair loss, behavioral responses). Furthermore, most research on underwater acoustic noise or impacts on biota tends to be coastal and ocean-based studies (Murchy et al. 2019; Popper and Hawkins 2019; Popper et al. 2020), resulting in inferences on impacts for freshwater systems. While this does not detract from the quality of the studies, it leaves a significant gap in understanding the impacts on riverine and shallow-water environments.

Hand in hand with biology-based assessments are needed within rivers and lakes that focus on understanding soundscapes, propagation of sound and particle motion through locks, commercial navigation waterways (i.e., areas dredged, or receiving greater than expected flushing flows), and riverine systems. Similarly, the production of sounds from underwater acoustic NSDs is also needed to estimate the impacts of the sound production and refine the sounds for the desired impact or targeted species. Ultimately, the considerations of more complex multi-deterrent deployments, efficacies, and impacts both near- and long-term are critical and should include large science groups of multi-disciplines from regional and global points of view.

**Acknowledgments** The authors would like to thank the Great Lakes Restoration Initiative, US Army Corps of Engineers, Chicago and Rock Island Districts, for supporting several of the studies mentioned in this research. We thank the states of Michigan, Illinois, and Iowa who have been supportive of this research and the other efforts underway to deter the movement of invasive carp into the naïve waterways and the Laurentian Great Lakes. In addition, field support, data collection, and model analyses included the following team members from Jasco Sciences, Sam Denes, Robert Mills, and David Zeddies; US Army Engineer Research and Development Center, Charles Ellis and William Butler; US Army Corps of Engineers, Mark Cornish, Kelly Granberg, Felcia Kirksey, and Johnna Pothoff; and from US Geological Survey, Marybeth Brey and Kelsie Murchie.

**Abstract**

Fish commonly respond to anthropogenic noise through behavioral changes. There are limitations to replicating noise and observing behavioral responses in controlled lab or cage experiments, which make observing behaviors in natural environments a preferred option. Acoustic telemetry offers advantages in providing the ability to monitor behavior of wild, individual fish in their natural environments while exposed to realistic sound from anthropogenic sources. In recent years, acoustic telemetry has been used in several studies to address questions about the behavioral responses of marine fish to various types of anthropogenic noise. Despite several benefits to the use of acoustic telemetry, there are logistical and analytical challenges to consider, and for some research questions, combining field studies using acoustic telemetry with experiments in more controlled environments may be most appropriate.

## Introduction

Anthropogenic noise is increasingly being recognized as an important pollutant of marine environments, with the potential to impact a wide variety of marine taxa in diverse ways (Williams et al. 2015; Carroll et al. 2017; Duarte et al. 2021). Sound can be produced by many human activities, including seismic surveys, pile driving, offshore wind farms, sonars, fishing vessels, and shipping (Duarte et al. 2021). These sounds contribute to the "acoustic scene" or "soundscape" of marine environments, which are composed of sounds of biotic and abiotic origin related to specific times and locations (Duarte et al. 2021).

Marine vertebrates detect and analyze the acoustic scene to gather important information about their environment (Popper and Hawkins 2019). Hearing is thus an important sense for fish, which use acoustic information for a variety of purposes (Popper and Hawkins 2019). For example, fish use sound to gather cues about their environment, to detect prey and predators, and to communicate with conspecifics (Popper and Hawkins 2019). Increased anthropogenic noise levels can interfere with the ability of fish to detect and respond to biologically relevant sounds, impacting this large, diverse group of marine organisms in several ways (Slabbekoorn et al. 2010; Popper and Hawkins 2019).

Reported effects of anthropogenic noise on fish have ranged from physical injury caused by loud, impulsive sounds at close ranges (McCauley et al. 2003; Popper et al. 2005; Halvorsen et al. 2012; Smith et al. 2022) to no apparent response to noisy human activities such as seismic surveys (Peña et al. 2013; Meekan et al. 2021). Fish are often reported to exhibit behavioral responses to anthropogenic noise (Carroll et al. 2017), for example, changes in swimming depth and activity levels in response to seismic surveys (Davidsen et al. 2019; van der Knaap et al. 2021), changes in small-scale swimming behaviors in response to pile driving (van der Knaap et al. 2022), and changes in schooling behavior and swimming depth in response to playback of impulsive sounds (Hawkins et al. 2014).

Studying behavioral responses of fish is relevant for understanding large-scale impacts of noisy human activities at sea, as behavioral responses are likely to be the most widespread and may affect fitness-related behaviors such as feeding, reproduction, or migration (Popper and Hawkins 2019). Therefore, although not resulting directly in injury or death, behavioral changes caused by anthropogenic disturbance can lead to population level consequences (Pirotta et al. 2018), though this has so far been difficult to quantify for sound disturbance of fish due to lack of necessary data (Slabbekoorn et al. 2019).

Detecting realistic behavioral responses of marine fish to anthropogenic noise is not straightforward. It is perhaps easiest to observe fish behavior in a laboratory setting, but problems associated with exposing fish to realistic sound in tanks are well documented (Duncan et al. 2016; Popper and Hawkins 2019). Net pen or cage

experiments, where fish are contained within, for example, a floating net pen in the sea, largely avoid the problems associated with achieving realistic sound exposures that hamper tank experiments. However, fish confined to a net pen have limited scope for displaying realistic behavioral responses, such as dispersal away from the area (Hawkins et al. 2020; Slabbekoorn 2016). Additionally, fish reared in captivity can respond differently to stimuli than wild fish (e.g., Meager et al. 2011). Monitoring free-ranging, wild fish exposed to real sound sources provides the highest chance of observing realistic behavioral reactions. However, observing and recording behaviors of free-ranging fish within marine environments can be challenging.

In this mini-review, various methods for observing responses of free-ranging fish to anthropogenic noise are presented. Acoustic telemetry is introduced as a relatively novel method for observing behavior of free-ranging fish that avoids some of the limitations of the other methods. An overview of published studies that have applied acoustic telemetry is presented, and advantages and limitations of this method are discussed.

## Methods for Observing Behavioral Responses of Free-Ranging Fish

Available methods for detecting behavioral responses of free-ranging fish to anthropogenic noise include video observation, direct visual census using divers, active acoustic methods to detect fish and schools, analysis of catch data, and tagging. Each method has some strengths and limitations.

### Visual Observation

Visual observation of fish responses to anthropogenic noise can be achieved through video recordings (Wardle et al. 2001; Paxton et al. 2017; Meekan et al. 2021) or direct observations made by divers (Miller and Cripps 2013). Visual observation can be used to directly observe instantaneous individual behavioral reactions to noise (Wardle et al. 2001) or changes in abundances and species distributions in an area over longer timescales (Miller and Cripps 2013; Paxton et al. 2017; Meekan et al. 2021). However, visibility is limited in most marine environments, and use of additional lighting to improve visibility, or use of bait to attract fish to the observable range, will likely influence natural behaviors. Direct visual observation by divers requires good visibility and favorable conditions for diving, so it is unlikely to be suitable in all environments. For safety reasons, dive surveys cannot be conducted during very loud activities like seismic surveys, so this method is limited to before-after-type surveys.

### Active Acoustic Methods

Active acoustics can be used to monitor fish abundance and swimming behavior in real time. Fishery sonars that can be tilted 180 degrees can be used to follow highly mobile fish schools over time to provide information about swimming depth, speed,

and direction and have been used to study responses of herring schools to seismic surveys (Peña et al. 2013). Fishery sonars are appropriate for highly mobile, pelagic, schooling fish.

Downward-looking echosounders are used in fishery acoustics and provide information about abundance and depth distribution of fish and, through additional sampling, information about species composition. This type of sampling has been used to study the before-during-after composition of fish in response to seismic surveys (Engås et al. 1996; Slotte et al. 2004; Løkkeborg et al. 2012). These methods generally require a vessel to follow the fish schools or to collect data along transects.

It is also possible to detect changes in fish schooling behavior without a vessel, for example, using moored upward looking echosounders (De Robertis and Wilson 2011; Kok et al. 2021); however a limitation with this approach is that species identification may not be possible (Kok et al. 2021). Echosounders are most appropriate for measuring abundance and biomass, as well as depth distribution, though tracking individual behaviors with echosounders can also be achieved (Handegard 2007).

## Catch Data Analysis

Analysis of catch data can allow detection of changes in abundance or catchability in relation to anthropogenic noise (Skalski et al. 1992; Engås et al. 1996; Løkkeborg et al. 2012; Bruce et al. 2018). Catch sampling studies can be relatively simple to conduct, as they do not require additional equipment (such as tags, video equipment, etc.) beyond what is already available on fishing or fishery research vessels, and samples can be taken opportunistically around real sound sources, such as seismic surveys.

Desktop studies using fishery data may also be able to detect changes in catch related to anthropogenic sound sources such as seismic surveys (e.g., Soldal and Løkkeborg 1993; Vold et al. 2012; Bruce et al. 2018). However, such methods need to consider possible confounding factors such as market forces, catchability, environmental variation, discarding, and variation in time of landings in relation to the disturbance (Vold et al. 2012; Bruce et al. 2018). It is also important to consider that observed changes in catch may be gear specific (e.g., Løkkeborg et al. 2012). Importantly, analysis of catch data can only provide indirect evidence of behavioral responses. It may be difficult in practice to directly link changes in catch rates to the physical, behavioral, or physiological responses that drive them (Bruce et al. 2018).

## Tagging Methods

Various methods of tagging are available and commonly used for studying fish behavior and population dynamics. Tagging methods include marking fish with unique identification tags (e.g., external T-bar tags (conventional tagging)) or

tagging fish with archival or data storage tags (DSTs) that record information about the fish's environment and/or behavior during its time at liberty.

Conventional tagging provides limited information on fish behavior, providing information only on release and recapture position, with no information on the fish's location and behavior during time at liberty. There is at least one example of an attempt to detect fish behavior in relation to a seismic survey using conventional tagging, with this method able to indicate that there was no obvious dispersal of bass from the study area in the year of the seismic survey compared to previous years (Pickett et al. 1994).

DSTs can provide detailed and high-resolution data on fish behavior and environmental variables. However, post hoc geo-positioning is required using recorded variables such as light levels or combinations of other factors such as depth and salinity. This can result in uncertainty in position estimates, which can make matching fish location to noisy human activities challenging, as evidenced by a study that tried to relate behavior of tagged tuna to seismic surveys (Evans et al. 2017).

## What Is Acoustic Telemetry?

Acoustic telemetry is an approach that can be used to monitor behavior of free-ranging fish in their natural environments, while avoiding many of the limitations of the methods described in section "Methods for Observing Behavioural Responses of Free-Ranging Fish." Acoustic telemetry studies involve the use of electronic tags that transmit a unique identification code through an ultrasonic signal. These tags are attached to individual fish, usually through surgical implantation into the body cavity. Study fish therefore need to be large enough to carry the tag. Tags may also be equipped with additional sensors, which transmit information about variables such as depth, acceleration, and temperature.

Tagging of fish is combined with deployment of receivers in the area of interest. These receivers can record time-stamped detection information from the fish tag when the animal is within range, thus collecting individual-specific information on fish presence in the study area. Receivers can be deployed in dense arrays that allow precise positioning of fish within the study area or can be spread out to cover a larger area to gain coarser-scale movement information.

Acoustic telemetry has been used to study fish movement and behavior since at least the 1990s (Abecasis et al. 2018). The use of acoustic telemetry in marine fish research has been greatly increasing in recent years, partly due to technological advancements leading to reduced tag size and increased battery life and memory size (Hussey et al. 2015). A recent review promotes acoustic telemetry as a suitable method to gather data on a range of topics relating to sustainable use of the oceans, including monitoring the impacts of various types of pollution (Alós et al. 2022). This highlights the potential for acoustic telemetry to become more widely used in research into the impacts of anthropogenic noise on fish.

## Using Acoustic Telemetry to Investigate Behavioral Responses to Noise

Acoustic telemetry is increasingly used to study behavioral responses of marine fish to anthropogenic noise, with an overview of published studies on this topic provided in Table 1. All but one of these studies are from the past 6 years, highlighting the very recent application of this technology to anthropogenic noise-related questions. Most of these studies have opportunistically investigated the effects of noisy human activities that were occurring in the environment, such as seismic surveys (Bruce et al. 2018; Meekan et al. 2021), pile driving (Iafrate et al. 2016; van der Knaap et al. 2022), and shipping (Ivanova et al. 2020; Rider et al. 2021). Others have used experimental sound treatments that nonetheless used realistic sound sources (Wardle et al. 2001; van der Knaap et al. 2021; McQueen et al. 2022, 2023).

The species of fish tagged in the studies in Table 1 have been limited to a handful of families, including gadoids (Wardle et al. 2001; Ivanova et al. 2020; van der Knaap et al. 2021, 2022; McQueen et al. 2022 2023), snappers (Iafrate et al. 2016; Meekan et al. 2021), porgies (Iafrate et al. 2016), and flatheads (Bruce et al. 2018), with two studies conducted on various shark species (Bruce et al. 2018; Rider et al. 2021) (full species names are provided in Table 1). Notably, these examples are mostly relatively hardy, large-, and round-bodied fish, which are therefore robust to the tagging procedure.

Acoustic telemetry studies have so far been used to infer a variety of large- and fine-scale behavioral responses to anthropogenic noise. The studies listed in Table 1 have been used to investigate changes in residency at an area of interest (Iafrate et al. 2016; Ivanova et al. 2020; Rider et al. 2021; McQueen et al. 2022; van der Knaap et al. 2022), home ranges (Ivanova et al. 2020; Meekan et al. 2021; McQueen et al. 2023), and various swimming behaviors such as step lengths, swimming depths, and acceleration (Wardle et al. 2001; Bruce et al. 2018; Ivanova et al. 2020; van der Knaap et al. 2021, 2022; McQueen et al. 2023) and behavioral states inferred from combinations of these behavioral metrics (Ivanova et al. 2020; van der Knaap et al. 2021). This level of detail about behaviors in situ, at an individual level and tracked for relatively long periods of time, would be difficult to achieve with the methods described in section "Methods for Observing Behavioural Responses of Free-Ranging Fish."

## Advantages and Limitations of Acoustic Telemetry

Acoustic telemetry is well suited to monitoring residency of fish at a specific site and has therefore proven particularly useful for assessing whether anthropogenic noise causes abandonment of habitats, feeding or spawning sites (Iafrate et al. 2016; Bruce et al. 2018; Ivanova et al. 2020; Meekan et al. 2021; Rider et al. 2021; van der Knaap et al. 2021, 2022; McQueen et al. 2022). Finer-scale changes in behavioral metrics

**Table 1** Overview of published studies investigating behavioral responses of marine fish to anthropogenic noise, using acoustic telemetry

| Species | Noise source | Behaviors studied | Responses observed | Combined with other method | References |
|---|---|---|---|---|---|
| Arctic cod (*Boreogadus saida*) | Ships | Home ranges, behavioral states (inferred from variables relating to step length, swimming speed, and bearing) | Home range displacement and change in swimming activity | No | Ivanova et al. (2020) |
| Bull shark (*Carcharhinus leucas*) | Boats | Residency | No change in residency related to boat density | No | Rider et al. (2021) |
| Great hammerhead shark (*Sphyrna mokarran*) | Boats | Residency | No change in residency related to boat density | No | Rider et al. (2021) |
| Nurse shark (*Ginglymostoma cirratum*) | Boats | Residency | No change in residency related to boat density. Hourly presence decreased with increasing boat traffic | No | Rider et al. (2021) |
| Atlantic cod (*Gadus morhua*) | Pile driving | Residency, spatial behavior within study area (step lengths, distance to scour bed, relative distance to piling event) | Moved closer to turbine bases, movement away from piling locations | No | van der Knaap et al. (2022) |
| Gray snapper (*Lutjanus griseus*) | Pile driving | Residency | Decrease in residency, potential displacement from area | No | Iafrate et al. (2016) |

(continued)

**Table 1** (continued)

| Species | Noise source | Behaviors studied | Responses observed | Combined with other method | References |
|---|---|---|---|---|---|
| Sheepshead (*Archosargus probatocephalus*) | Pile driving | Residency | No decrease in residency | No | Iafrate et al. (2016) |
| Atlantic cod (*Gadus morhua*) | Seismic survey | Residency, behavioral states inferred from step lengths and acceleration | Decrease in activity, change in daily patterns of behavioral states, displacement after survey | No | van der Knaap et al. (2021) |
| Gummy shark (*Mustelus antarcticus*) | Seismic survey | Step lengths, acceleration | Not enough data | Analysis of CPUE from commercial fisheries | Bruce et al. (2018) |
| Swell shark (*Cephaloscyllium laticeps*) | Seismic survey | Step lengths, acceleration | Not enough data | Analysis of CPUE from commercial fisheries | Bruce et al. (2018) |
| Tiger flathead (*Neoplatycephalus richardsoni*) | Seismic survey | Step lengths, acceleration | Some increase in movement, no change in residency | Analysis of CPUE from commercial fisheries | Bruce et al. (2018) |
| *Lutjanus sebae* | Seismic survey | Residency, home ranges | High residency, no long-term displacement | BRUV surveys | Meekan et al. (2021) |
| Pollack (*Pollachius pollachius*) | Air gun | Daily behavior patterns, movement | Interruption of daily behavior patterns, movement away from air gun | Video observations | Wardle et al. (2001) |
| Atlantic cod (*Gadus morhua*) | Air gun | Residency, home ranges, swimming depth, acceleration, step lengths | No change in residency, slight increase in swimming depth | No | McQueen et al., (2022, 2023) |

*CPUE*, catch per unit effort; *BRUV*, baited remote underwater video

detected on telemetry receivers have additionally been used to infer changes in movement behaviors and behavioral states within the study site (Ivanova et al. 2020; van der Knaap et al. 2021; McQueen et al. 2023).

The advantages of using acoustic telemetry over the methods described in section "Methods for Observing Behavioural Responses of Free-Ranging Fish" include the possibility to gather longitudinal behavioral data at an individual level, which would be difficult using active acoustic, visual observation, and catch sampling methods. Additionally, data can be collected over longer periods than would be possible using visual observation methods. The behaviors can be spatially resolved, which is a limitation of conventional or DST tags. Despite these advantages, there are also a number of limitations of this method that should be considered.

Acoustic telemetry is probably not an appropriate method for studying all fish species in all environments. The most successful of the studies reviewed in this chapter targeted species that showed high site fidelity to the study region. In studies that tagged more than one species, it was easier to draw conclusions about the responses of fish showing high site fidelity to the telemetered area, thus providing large sample sizes of data (Iafrate et al. 2016; Bruce et al. 2018; Rider et al. 2021). The situation reported in Bruce et al. (2018), where every tagged shark left the array before the seismic survey began, returning only occasionally and thus providing only a handful of data points, exemplifies the problems that can arise from tagging a species whose spatial movement ecology substantially exceeds the telemetry array.

Most studies listed in Table 1 were conducted in some kind of semi-enclosed environment such as bays (Ivanova et al. 2020; Rider et al. 2021; McQueen et al. 2022, 2023) or harbors (Iafrate et al. 2016) or around structures such as wind turbines (van der Knaap et al. 2021, 2022) which simplifies the designing of receiver arrays and may encourage retention of tagged fish within the system. Conducting studies offshore, with a lack of physical boundaries, could be riskier and increase the possibility that tagged fish quickly leave the area (as in Bruce et al. 2018). However, this risk is species specific, as shown by the high detection rates of tiger flathead and *L. sebae* in the offshore telemetry grids of Bruce et al. (2018) and Meekan et al. (2021), respectively.

In general, a key aim of studies that investigate the effects of anthropogenic noise on fish behavior is often to assess whether fitness-related behaviors such as feeding, reproduction, or migration are impacted by anthropogenic noise (Popper and Hawkins 2019). Dispersal from key foraging or spawning habitats is relatively simple to detect using acoustic telemetry (e.g., van der Knaap et al. 2021; McQueen et al. 2022). Detecting changes in actual spawning or feeding behavior is more challenging using acoustic telemetry, as behaviors cannot be directly observed. Some studies have attempted to translate behavioral metric data, such as step lengths and acceleration, to specific behaviors such as foraging (Ivanova et al. 2020; van der Knaap et al. 2021). However, it is difficult to assess the reliability of these categorizations using only the telemetry data. Ground-truthing behavior categorization using data from captive fish may be a means to improve the reliability of this approach (e.g., Clarke et al. 2021).

Telemetry studies generally produce large amounts of high-resolution data that often require statistically complex and computationally expensive analysis. It is important to consider structure in the data, for example, most telemetry data are serially autocorrelated and detections from the same fish are non-independent.

Spatial correlation, measurement error and false absences are also likely (Whoriskey et al. 2019). Fortunately, there are statistical tools available for dealing with such data, and new methods are being developed actively (Lennox et al. 2017; Whoriskey et al. 2019).

The most appropriate statistical method for analyzing telemetry data depends on the research question, but options include generalized linear mixed effects models, mark-recapture models, network analysis, and survival analysis (Whoriskey et al. 2019). Hidden Markov models are also becoming increasingly popular for analyzing aquatic telemetry data. These stochastic time-series models are well suited to telemetry datasets and can be used to infer hidden behavioral states from animal tracking data (Leos-Barajas et al. 2016; Pohle et al. 2017; Bacheler et al. 2019). There are also many studies that use telemetry data to estimate fish home ranges (e.g., Meager et al. 2010; McMahan et al. 2013; Dean et al. 2014), which can be relevant for asking questions about changes in space use (e.g., Ivanova et al. 2020; McQueen et al. 2023). In general, using complementary methods to analyze the same telemetry data can increase confidence in the conclusions drawn (Bacheler et al. 2019).

## Some General Field Study-Related Challenges

Some challenges associated with studying free-ranging fish were exemplified through this review, though are not unique to acoustic telemetry studies. For example, it may be challenging to disentangle behavioral responses to anthropogenic noise from the many other variables that influence behavior in natural settings. Movement of fish is the outcome of a complex interplay of different factors, including individual-specific factors and external factors (Cooke et al. 2022). Many variables must be taken into account when analyzing field data, including environmental variables (e.g., temperature, salinity, time of day, sun angle, tide, current speed (van der Knaap et al. 2022; McQueen et al. 2023) and presence of predators like marine mammals (Ivanova et al. 2020). Individual variation, variation between sexes, and variation between study years may also be important to consider (McQueen et al. 2023). Fish responses may also vary depending on time of year and motivational state (e.g., Fernö et al. 1998). Accounting for the numerous variables influencing fish movement behavior is another reason why analyses of telemetry data tend to be necessarily complex.

### Replicates and Control Sites in Field Studies

A key advantage of studies that have used acoustic telemetry is that the fish were exposed to realistic sound sources, such as full-scale seismic surveys (Bruce et al. 2018; Meekan et al. 2021; van der Knaap et al. 2021). In several studies, the sources were opportunistic, for example, pile driving (Iafrate et al. 2016; van der Knaap et al. 2022) or shipping and boat traffic (Ivanova et al. 2020; Rider et al. 2021). However,

this benefit may also make it difficult to conduct replicates or select appropriate control sites. This is an issue related to study design rather than acoustic telemetry and has also been highlighted in studies using other methods to monitor behavioral changes (Løkkeborg et al. 2012; Bruce et al. 2018). Given that fish behavior can vary according to a large variety of factors, as discussed previously, a lack of replicates and controls can limit the conclusions drawn from such studies.

In the studies included in this mini-review, experiments using large-scale exposures like seismic surveys did not include replicates (Bruce et al. 2018; van der Knaap et al. 2021). Conversely, studies focusing on shipping noise or pile driving were able to include replicates by analyzing results over several events (Ivanova et al. 2020; van der Knaap et al. 2022). Studies that used an experimental treatment, rather than an opportunistic exposure, were able to incorporate replicates into study design (McQueen et al. 2022, 2023).

Control sites were not included in some of the studies included in this review (Ivanova et al. 2020; van der Knaap et al. 2021, 2022). It can be extremely challenging to find suitable control sites in spatially and temporally dynamic marine environments, as control sites should be far enough away from the test site that they are not affected by the disturbance, yet as similar as possible in terms of habitat and species composition (Methratta 2020). In some studies, nearby, suitable control sites unaffected by the sound exposure were identified and exploited (Iafrate et al. 2016; Bruce et al. 2018; Meekan et al. 2021; McQueen et al. 2022). If it is not possible to establish suitable control sites, a gradient design may be an alternative, as has been recommended for studying effects of offshore wind farms on fish (Methratta 2021).

Overall, this indicates that acoustic telemetry does not avoid all limitations associated with conducting behavioral response studies in the field. In many situations it remains expensive and logistically challenging to incorporate replicates and control sites into large-scale field studies using realistic sound sources. Careful study design is required to ensure effects of anthropogenic noise can be disentangled from natural variation and confounding variables.

## Conclusions

Acoustic telemetry provides an opportunity to gather behavioral data at relatively long temporal scales and large spatial scales, with high temporal and spatial resolution. These data can be used to assess behavioral responses of wild fish to exposure to realistic sources of anthropogenic sound.

As with the other methods included in this mini-review, there are some limitations to the use of acoustic telemetry, for example, due to the inability to directly observe behaviors. Therefore, depending on the research question, it may be necessary to combine lab and field studies, as also promoted by Slabbekoorn (2016), or to combine observation methodologies, as in Wardle et al. (2001), Bruce et al. (2018), and Meekan et al. (2021).

Sample size can also be limited in acoustic telemetry studies, due to cost and practical limitations of tagging many fish, the possibility that tagged fish leave the

study area, and due to some methods of signal transmission resulting in signal interference if too many tags are transmitting within a limited area. Combining acoustic telemetry with other methods like catch sampling or visual observation can allow for increased sample sizes and sampling of additional species, providing at least some information on species and individuals that were not tagged (Wardle et al. 2001; Bruce et al. 2018; Meekan et al. 2021).

Not all species or life stages of fish are suitable for tagging, for example, due to size or fragility. However, as tag sizes continue to decrease through technological advancements, the variety of fish that can be tagged increases (Lennox et al. 2017). Extremely mobile species may also be unsuitable for behavioral response studies using acoustic telemetry, unless nationwide or international tracking networks are established (Abecasis et al. 2018; Lennox et al. 2022).

Overall, acoustic telemetry studies can provide data on wild fish behavior in unprecedented detail. Carefully designed acoustic telemetry studies can contribute to our understanding of the behavioral responses of free-ranging, marine fish to anthropogenic noise.

**Abstract**

Introduction of silver (*Hypophthalmichthys molitrix*) and bighead (*Hypophthalmichthys nobilis*) carp to the Mississippi River drainage has created ecological and economic distress. These species, collectively known as bigheaded carp, are closely related, and silver carp are well known for their jumping behavior in response to motorboats. Therefore, the impact of boat motor sound on bigheaded carp behavior has important implications for controlling range expansion. We examined the effect of broadband boat motor sound on the schooling behavior of bigheaded carp. In a two-choice shuttle tank, broadband sound (0.06–10 kHz; 140 dB re: 1 μPa) was played via an underwater speaker,

and bigheaded carp responses were recorded using overhead cameras. The schooling behavior of silver and bighead carp during broadband sound playback was compared to a no-sound period. Broadband sound playback elicited negative phonotaxis and increased swim speed in all trials. However, the carp continued to school ($n = 5$ individuals swimming in the same direction and one body length apart) the majority (57.2% $\pm$ 11.2%) of time during the broadband sound playback periods. These results indicate that schooling could contribute to the consistent negative phonotaxis observed in previous studies reporting the efficacy of broadband sound in deterring bigheaded carp swimming.

## Introduction

Silver (*Hypophthalmichthys molitrix*) and bighead (*H. nobilis*) carp, collectively known as bigheaded carp, pose ecological and economic threat to North American waterways. Since accidental introduction in the 1970s, both species have migrated north, establishing populations throughout much of the Mississippi River Basin. These invasive fish compete with native species for resources and physically damage watercraft and boaters (Kolar et al. 2007). Continued upstream migration could endanger the Laurentian Great Lakes, and the ecological stability of the largest freshwater system in North America could be compromised (Cudmore et al. 2012).

Bigheaded carp are otophysans and possess morphological specializations (Weberian ossicles) that connect the swim bladder to the inner ear and allow for detection of sound pressure. On the proposed continuum of hearing abilities in fishes, otophysans are well adapted for detection of sound pressure (Popper et al. 2021). Physiological studies (using auditory evoked potentials) report that bigheaded carp can detect frequencies up to 5 kHz (Vetter et al. 2018), while native non-otophysans are limited to lower frequencies (e.g., lake sturgeon *Acipenser fulvescens* and paddle fish *Polyodon spathula*; Lovell et al. 2005).

Acoustic barriers have been recommended to deter carp upstream migration (Putland and Mensinger 2019). When exposed to broadband acoustic stimuli (0.06–10 kHz), wild silver carp jump in large numbers (Vetter et al. 2017a), and captive bigheaded carp exhibit consistent negative phonotaxis (Murchy et al. 2017; Vetter et al. 2015, 2017b). However, schooling behavior in response to acoustic signals has not been directly evaluated in these species. This project examined the impact of broadband sound playback on the schooling behaviors of bigheaded carp in a controlled setting.

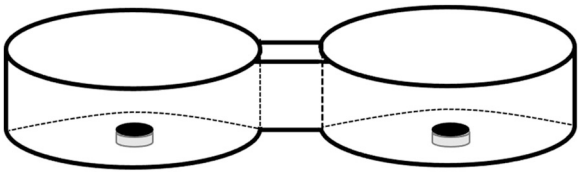

**Fig. 1 Two-choice shuttle tank.** Experiments were performed in a two-choice shuttle tank with a single speaker placed in the center of each side. Only one speaker was active at a time. An overhead camera mounted above the tank recorded fish behavior during pre-sound and broadband sound playback

## Materials and Methods

Experiments were conducted at the Minnesota Aquatic Invasive Species Research Center (MAISRC) at the University of Minnesota in St. Paul, Minnesota. All procedures were approved by the University of Minnesota Institutional Animal Care and Use Committee (Protocol: 2103-38930A).

### Animal Husbandry

Juvenile silver ($n = 15$ individuals; SL: 61.3 ± 1.3 mm SE) and bighead ($n = 15$ individuals; SL: 75.0 ± 1.5 mm) carp were maintained in 500 L circular holding tanks and fed a mixture containing equal parts *Spirulina* algae and dry feed (Starter Crumble, Skretting USA, Tooele, UT) once a day. Food was withheld from fish for 24 h prior to the testing period. Trials were conducted between 20 and 24 July 2021.

### Experimental Design

Experiments were conducted in a two-choice shuttle tank (Loligo Systems, Viborg, Denmark). The tank consisted of two circular chambers (50 cm diameter, 25 cm depth) connected by a central channel (10 cm length, 7 cm width, 25 cm depth), allowing fish to access both chambers (Fig. 1). Water depth was maintained at 20 cm. A single underwater Bluetooth speaker (JBL Clip 4, Harman International Industries, Inc., Stamford, CT) was placed in the center of each of the chambers. The speakers were situated in a PVC ring 5 cm from the bottom of the tank. An overhead camera (Model UI-1640SE-C-GL; IDS Imaging Development Systems, Inc.; Stoneham, MA) 2 m above the tank provided a full view of the tank to record fish position and behavior. A black curtain was placed between the experimental tank and the researcher to prevent interference with fish behavior.

## Sound Stimulus

The sound was broadcast through one of the two underwater speakers placed centrally within the tank chambers, selected at random. The inactive speaker remained in the other chamber as a control to keep the visual environment consistent. The acoustic stimulus consisted of a broadband sound (0.06–10 kHz; 140 dB re: 1 μPa) recorded underwater in the Illinois River from an outboard boat motor (100 Hp Honda four-stroke; Vetter et al. 2015). Sound was played from a laptop computer (VLC Media Player, Lenovo 80MK).

## Sound Mapping

Sound pressure levels (SPL) were measured throughout the two-choice shuttle tank using a hydrophone (HTI-96-Min, High Tech, Inc., Long Beach, MS) plugged into a PowerLab (Model 26T, AD Instruments, Sydney, Australia) data acquisition system, and the SPL was determined from the root mean square (RMS) voltage calculated in LabChart8 (AD Instruments). The hydrophone was placed at points distributed evenly throughout the tank. The tank was mapped under ambient conditions and during broadband sound playback. The entire mapping process was performed twice: with a single active speaker in each side of the tank. During each mapping process, the tank was mapped at two depths: 5 cm above the tank bottom and 5 cm below the water surface. A total of eight mapping locations were selected throughout the tank. The ambient sound level was 85–100 dB re: 1 μPa throughout the tank. During playback of the broadband sound stimulus, the maximum sound pressure level was 140 dB re: 1 μPa at the source (hydrophone placed 2 cm directly above each speaker). This SPL was chosen as it was at least 40 dB over the ambient sound (to act as an acoustic deterrent) but still allowed for a gradient of sound pressure levels in the tank such that the SPL was 20 dB lower in the opposite side (SPL was 120 dB re: 1 μPa directly above the inactive speaker in the chamber opposite to the active speaker).

## Behavioral Trials

Behavioral phonotaxis experiments were conducted for each school ($n = 3$ for both species). Before the beginning of the trial, either the right or left speaker was randomly selected for sound playback. A school ($n = 5$ individuals) of bighead or silver carp was placed in the experimental tank and allowed to acclimate for 30 min prior to the testing period. The last 5 min of acclimation was recorded via the overhead camera to serve as a control for fish movement and schooling. This period will be hereafter referred to as the "pre-sound period." After acclimation, testing began 5 s after the majority of the school (at least three fish) entered the chamber with the speaker selected for sound playback. The broadband sound was played for 5 min, and the school was allowed to swim freely throughout the shuttle during the

playback period. Fish behavior was recorded via the overhead camera (18 fps). After the 5-min playback period, the fish were removed and placed into holding tanks.

## Data Analysis

*Schooling Behavior:* Video data were analyzed for group size and behavior throughout the 5-min pre-sound and broadband sound playback periods. Schooling was characterized as all five individuals swimming with the same directionality while being within one body length from another individual. Smaller grouping behavior (e.g., majority groups of three or four fish swimming in the same direction within one body length) and no grouping behavior (e.g., fish swimming in pairs or individually) were also evaluated. Both pre-sound and broadband sound playback videos were evaluated for the total time the fish swam in schools of five fish or smaller groups of three or four fish (or a "majority" group) or demonstrated no group swimming. These values are reported as the percent of the total 5-min period spent in each condition. The percentage data were arcsine transformed for statistical analysis. To compare schooling behavior during the pre-sound swimming, a one-way ANOVA was performed on these residuals. A one-way ANOVA was also performed on the residuals for the broadband playback to compare schooling during broadband sound playback period.

*Behavioral Response to Broadband Sound:* During all broadband sound playback periods, the fish always swam in groups of three or more (or a "majority" group) and left the chamber during the first 10 s of sound playback. Therefore, the video data were further analyzed to assess the swimming velocity (m/s) of the majority groups (three or more) to the broadband sound stimulus using Noldus EthoVision software (EthoVision XT Version 11.5.1026; Noldus; Wageningen, the Netherlands). As a control, velocity also was evaluated during the pre-sound period. All statistical analyses were performed using SigmaPlot for Windows (version 12.5).

## Results

*Behavioral Response to Broadband Sound:* During the pre-sound period, the fish explored both sides of the shuttle tank while swimming at a consistent pace. During broadband sound playback however, a majority (a group of at least three individuals) exited the chamber with the active speaker and often remained in the other side (Fig. 2). There was no significant difference between the two species of carp for average swimming velocity during the first 10 s of the pre-sound or broadband sound playback periods (t-test, $p > 0.10$). Thus, these data were pooled to evaluate bigheaded carp response behavior ($n = 6$ schools). During broadband sound playback, a majority swam away from active speaker and increased swimming velocity (playback, 8.86 $\pm$ 0.46 cm/s; pre-sound, 6.86 $\pm$ 0.41 cm/s; mean $\pm$ SE; t-test, $p > 0.05$; Fig. 3).

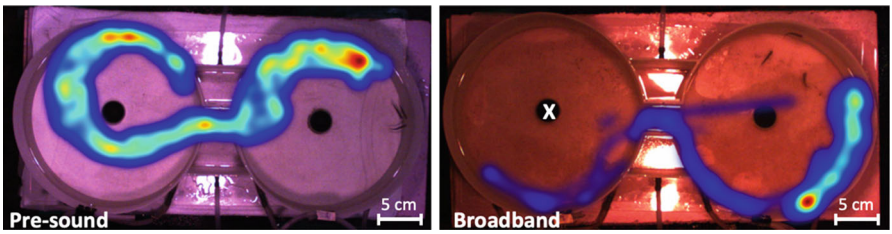

**Fig. 2 Negative phonotaxis in bigheaded carp.** Representative heat maps showing the pattern of swimming for a silver carp school during the 5-min pre-sound versus the 5-min broadband sound playback. The active speaker in the broadband sound playback period is denoted by an X. The colors represent the location of the school during the trial, with red indicating where the school spent the most time and blue representing minimal time in that location. During the pre-sound period, the school swam freely between the two chambers, while the school exited the chamber with the active speaker during the first 10 s of playback and spent the rest of the broadband period in the opposite chamber

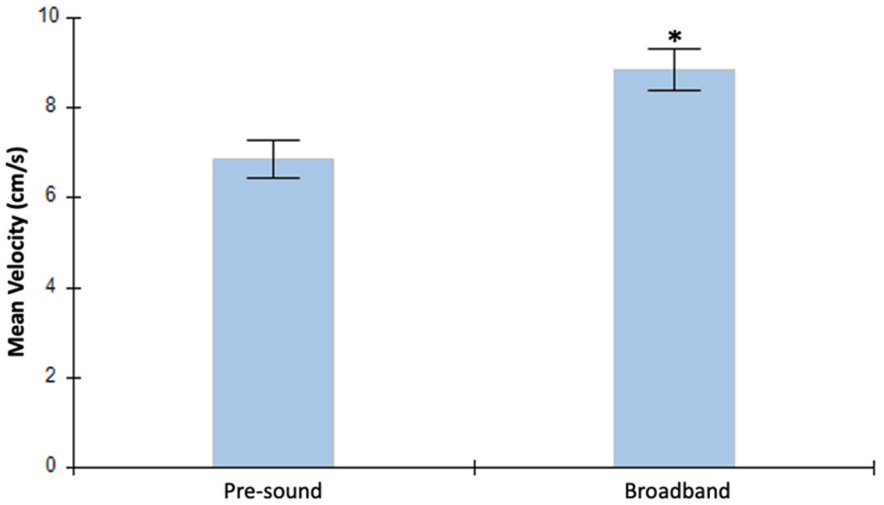

**Fig. 3 Mean swimming velocity during broadband sound playback vs. pre-sound period.** Mean velocity increased during the first 10 s of broadband sound playback compared with 10 s of pre-sound (control) swimming. Mean ± SE; asterisk indicates significant difference (t-test; $p < 0.05$)

*Schooling Behavior:* During both the pre-sound and the broadband sound periods, the carp continued to school the majority of the time (Fig. 4). Fish schooled in groups of five 48.0% ± 16.1% (mean ± SE) of the 5-min pre-sound and 57.2% ± 11.2% of the 5-min broadband sound playback periods. For the pre-sound period, smaller group swimming behavior was observed 23.2% ± 8.2% (group of four) and 18.2% ± 5.6% (group of three) of the time or not at all (10.6% ± 6.2% of the time). During the broadband sound playback, fish spent less

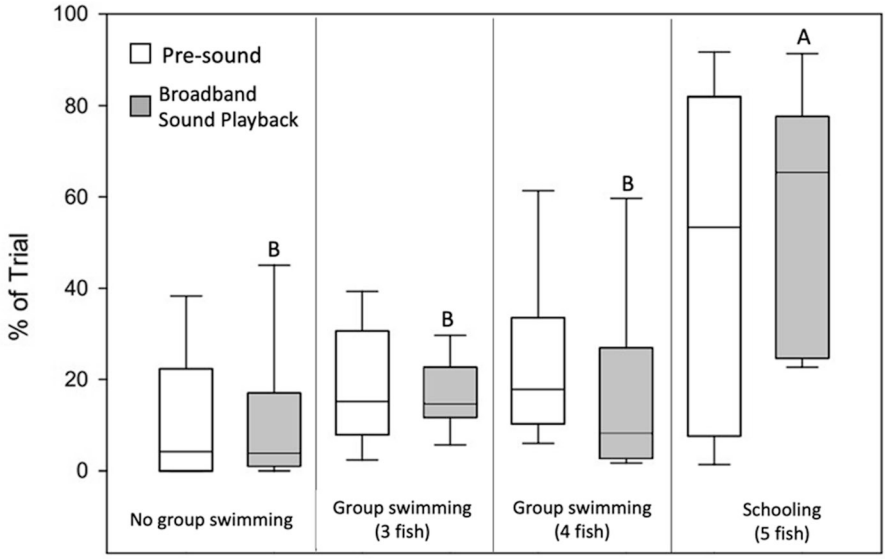

**Fig. 4 Group swimming behavior in bigheaded carp during the pre-sound and broadband sound playback periods.** During both the pre-sound and broadband sound playback periods, fish were most often in a school of five (though this relationship was not significant during the pre-sound period, ANOVA: $p > 0.05$). Letters above the gray bars (broadband sound playback) indicate significantly different groups (ANOVA: $p < 0.05$). For the statistical tests, the percentage data were arcsine transformed

time schooling in smaller groups (group of four, 16.1 ± 9.0%; group of three, 16.4 ± 3.3%) but spent a similar 10.3% ± 7.0% time not in a group.

The arcsine-transformed data for the pre-sound period were normally distributed (Shapiro-Wilk $p = 0.663$), but the variances were unequal ($p = 0.026$), so a one-way ANOVA on ranks was performed on the residuals and found no significant differences between the median values ($H_3 = 5.1$; $p = 0.162$; Fig. 4).

The arcsine-transformed data for the broadband sound playback period were normally distributed (Shapiro-Wilk $p = 0.139$) with equal variance ($p = 0.602$), and a one-way ANOVA found that fish were significantly more likely to school (group of five) during broadband sound playback than swim in the smaller groups (three or four) or exhibit no group swimming behavior ($F_{3,20} = 7.22$, $p = 0.002$; Fig. 4).

## Discussion and Conclusions

Similar to previous studies (Murchy et al. 2017; Vetter et al. 2015, 2017b), bigheaded carp avoided broadband sound. Furthermore, the present results show that carp schooling behavior is more likely to occur when fish are responding to a broadband sound stimulus. During sound playback, carp consistently remained in

schools of five. These results suggest that schooling could contribute to the consistent negative phonotaxis responses observed in previous studies. As individual fish cluster together, their negative phonotaxis responses result in strong schooling behavior. From a management standpoint, these results may indicate that deterrent strategies involving acoustic stimuli could be successful if they consider a school of fish as a single entity instead of considering the behaviors of individual fish; however, additional research is needed to evaluate schooling behavior under more naturalistic conditions (e.g., a larger tank or a field study). Further, the finding that fish prefer to school even under conditions of an active deterrent has interesting management implications. If a school is repelled after encountering a deterrent, it is possible that this could promote deterrence by other fish in the area. Finding deterrent methods that strengthen these negative group effects could help to maximize the number of fish affected by a single deterrent, ideally increasing the efficacy of the deterrent.

The sound mapping indicated that there was a gradient of sound pressure levels from ~40 dB above ambient at the active speaker to ~20 dB above ambient levels in the center of the opposite side of the tank, thus providing a "quieter" retreat for the bigheaded carp schools during playback periods. However, this study was done in a relatively small tank which poses a challenging acoustical environment, especially regarding the particle acceleration component of sound (Gray et al. 2016; Rogers et al. 2016). Particle acceleration was not evaluated and could have impacted the fish's behavioral responses. It is important that future research characterize particle acceleration, especially the acoustic impedance of the tank (Popper and Fay 2011).

Acoustic barriers have been evaluated to prevent the spread of invasive fish species (Putland and Mensinger 2019), and this study suggests that schooling could contribute to the negative phonotaxis behavior observed in species such as bigheaded carp. Future research includes evaluating schooling behavior in a more naturalistic setting and determining if a subset of individuals can influence the swimming behavior of an entire school.

**Abstract**

Vertebrates exposed to intense or long-duration loud sounds often show a temporary loss of hearing (temporary threshold shift, TTS). TTS has been examined in a number of fish species after exposure to white noise, pure tones, and impulsive sources, leading to the concern that TTS has the potential to impact fitness and survival of fishes exposed to anthropogenic sound. This chapter focuses on whether TTS is of real concern with regard to developing

criteria for sound exposure for fishes. It starts with a review of the literature on TTS and ear damage as a result of exposure to various sounds and shows that the data are highly variable and that most of the significant TTS occurs in species that are defined as having specializations to enhance hearing sensitivity. The chapter then argues that TTS is not likely for free-swimming fishes since they can leave the areas of the most intense sounds and that most fish in a population exposed to such sounds will receive levels that are well below those that could produce TTS. At the same time, since data are limited, it is proposed that further studies using approaches that allow comparison between species and sounds be conducted.

Noise · Hearing loss · Sensitivity · Impulsive sound · Continuous sound

## Introduction

In developing criteria for potential effects of anthropogenic sound on marine animals, a frequently cited issue is whether the sound has the potential to cause temporary loss of hearing, something referred to as temporary threshold shift (TTS). As discussed below, TTS is a change in hearing sensitivity as a result of temporary damage to the sensory hair cells of the inner ear and/or their innervating nerves as a result of exposure to intense or long-term sounds (e.g., Finneran 2016; Liberman 2016; Ryan et al. 2016). While the greater consideration has been for TTS in marine mammals (e.g., Finneran 2016; NMFS 2018; Thomsen et al. 2021), TTS has also been considered in developing interim criteria for effects of anthropogenic sound in fishes (Popper et al. 2014).

Popper et al. (2014) defined TTS as a change in hearing threshold of at least 6 dB and proposed that exposure to 186 dB re 1 $\mu Pa^2 \cdot s$ cumulative SEL (sound exposure level) would potentially result in TTS in all fishes for exposure to seismic air guns and pile-driving, while a level of 193 dB re 1 $\mu Pa^2 \cdot s$ cumulative SEL would be likely for low-frequency sonars. The likelihood of TTS for lower intensity continuous signals such as shipping was not thought to be great, and no criteria were proposed.

The purpose of this chapter is twofold. First it discusses what is known about TTS in different species exposed to a variety of sound sources. This includes consideration of the results from TTS studies, as well as the likely physiological mechanisms that result in TTS. Second, based on these data, the chapter considers the likelihood of TTS occurring in wild fishes and whether TTS is even an issue of any importance in developing criteria to protect fishes from anthropogenic sounds. Finally, since TTS data are very limited for fishes, the chapter

proposes additional areas of study that will help confirm if TTS is or is not an issue for most fishes.

## Anthropogenic Sound and Fish Hearing

### Potential Effects of Anthropogenic Sound

Within the last two decades, there has been a significant increase in research examining how sound from anthropogenic sources may potentially affect marine organisms. These sound sources include, among other things, powered vessels, pile-driving for marine construction, high-intensity low-frequency sonars, and geophysical research and energy exploration and production using seismic air guns. While the preponderance of earlier work focused on marine mammals, there is a substantial, and growing, interest on potential effects of anthropogenic sound on fishes and aquatic invertebrates (Scholik-Schlomer et al. 2023). Indeed, as fishes and invertebrates provide key components to aquatic ecosystems and both marine and human food chains, there is a need to fill the many research gaps in our understanding of how anthropogenic sound affects these organisms.

The potential negative effects of anthropogenic sound can be measured at various levels of impact on an animal's fitness. The most extreme effect is immediate death or physical injury ultimately leading to death (e.g., Halvorsen et al. 2012b; Dahl et al. 2020). Other potential effects include masking of important natural and biologically relevant sounds such as acoustic communication signals between individuals (Popper and Hawkins 2019) and behavioral changes such as displacement from the current impacted area which may be important feeding or spawning grounds (e.g., Engås et al. 1996; Carroll et al. 2017). Other potential effects include physiological impacts that produce hearing loss in fishes that could result in reduced fitness associated with an inability to hear biologically relevant sounds, even if masking does not occur.

### The Role of Hearing in the Lives of Fishes

Within vertebrates, hearing first evolved in the ancestors of fishes (e.g., Fay and Popper 2000; Clack et al. 2016). The selective pressures thought to have resulted in the evolution of hearing were the detection of distant sounds in the "auditory scene" such as those made by predators, prey, or sound-producing locations such as coral reefs (Fay and Popper 2000). Over 800 species of fishes have been reported to produce species-specific sounds (Kaatz 2002; Rice et al. 2022) for a variety of reasons including, but not limited to, agonistic signaling, stress response, alarm

calling, predator avoidance, and reproduction-associated displays (e.g., Hawkins and Myrberg 1983; Ladich 2019).

Since sound is so important to fishes, it can be expected that a reduction in their ability to detect such communication signals and the auditory scene in general will reduce the animal's fitness. Therefore, hearing loss is one of the adverse effects of anthropogenic sounds that has been focused on in fishes.

## Effects of Acoustic Overstimulation on Fish Hearing

The earliest studies documenting sound-induced hearing loss in fishes were done in the laboratory using tones or white noise as stimuli. The first report of hearing loss in fishes was done in goldfish, *Carassius auratus*, which were exposed to tones of 300, 500, 800, or 1000 Hz at approximately 149 dB re 1 μPa for 4 h, followed by determining behavioral hearing thresholds at 500 and 800 Hz (Popper and Clarke 1976). This exposure resulted in temporary threshold shifts (TTS) that depended upon stimulation and test frequency, but hearing returned to normal within 24 h.

Most subsequent experiments tested hearing loss by the recording of auditory evoked potentials (AEP), an electrophysiological method which allowed relatively rapid measurement of TTS in fishes compared to standard behavioral methods (e.g., Corwin et al. 1982; Kenyon et al. 1998). While using AEP recording only represent the responses of the ear or brainstem and do not measure hearing (Sisneros et al. 2016; Popper and Hawkins 2021a), they do provide a good indication of the function of the ear and are useful in determining if exposure to anthropogenic sound alters ear sensitivity.

Sound-induced hearing loss has been examined in very few of the more than 34,000 extant fish species. Table 1 lists these species, but does not consider the degree of hearing loss. The table also includes a number of species for which there was little or no hearing loss.

A general explanation for why some species are more prone to TTS than others is that there is considerable variation in hearing sensitivity between species. As can be seen in Table 1, most species that showed TTS are those that have anatomical specializations that enhance the frequency range of hearing and lower the sound level that can be detected (sensitivity threshold) (Popper et al. 2021). Most commonly, such specializations connect gas-filled chambers (e.g., swim bladders, suprabranchial chambers, and otic bullae) to the inner ear. For example, otophysan fishes (all species in the top section of Table 1) have modified vertebrae, the Weberian ossicles, that contact the swim bladder on one end and the inner ear on the other, allowing sound pressure-induced vibrations from the swim bladder to be transmitted directly to the inner ear (Popper and Hawkins 2021b). Such specialization allows for the detection of the pressure component of sound and results in lower hearing thresholds over a much broader frequency range compared to species without specializations (Popper and Hawkins 2021b).

Thus, it is important to note that the majority, but not all, of the species listed in Table 1 for which sound-induced hearing loss have been reported are otophysans,

**Table 1** Fish species for which TTS has been tested. Note that, the table does not include species where fish were exposed to intense sounds and ear damage, but no tests of hearing (e.g., McCauley et al. 2003; Smith et al. 2022)

| Common name | Species | Type of sound | Citations |

[a]Fish from some broods did not show hearing loss

most likely because their greater hearing sensitivity makes them more sensitive to sound exposure. In contrast, the species in Table 1 for which no or minimal hearing loss was reported have no specializations for hearing.

## Predicting Threshold Shift

One predictive model of fish hearing loss that considers the differences in frequency-specific hearing sensitivity between species is the linear threshold shift (LINTS) hypothesis (Smith et al. 2004b; Smith and Monroe 2016). This model predicts that the best indicator of potential TTS is the sound pressure level difference (SPD) between the intensity of the anthropogenic sound stimuli at a specific frequency and the baseline hearing threshold level of the species at the same frequency. Thus, the LINTS hypothesis predicts that fishes will have the greatest TTS at frequencies at which they are most sensitive (i.e., have the lowest hearing thresholds), but only if the anthropogenic sound is a certain level above that threshold. Or, put another way, an anthropogenic sound has to be a certain level above the hearing threshold to induce TTS.

This, in fact, is the case for goldfish and other otophysan fishes that have been tested (Smith et al. 2004a, 2006, 2011). In all cases, the anthropogenic sound was sufficiently above threshold to result in TTS. However, fishes without specializations and thus poorer hearing sensitivity may not show TTS to the same extent since the anthropogenic sound is not sufficiently above threshold. The only likely way to induce TTS in those species is to raise the level of the anthropogenic sound so it is the same level above threshold as in the hearing specialists.

While more work is needed to test and refine the LINTS model, it was able to predict TTS in three species of fishes that were exposed to a seismic air gun array (Popper et al. 2005). In that study, lake chub (*Couesius plumbeus*), an otophysan, exhibited the greatest TTS; northern pike (*Esox lucius*), a species without known specializations, were intermediate; and broad whitefish (*Coregonus nasus*), a species only likely to detect particle motion since it is a salmonid (Hawkins and Johnstone 1978), exhibited no hearing loss. As predicted by the LINTS model, this pattern was the inverse of the three species baseline hearing thresholds. That is, TTS was greatest in lake chub with the best hearing sensitivity and lowest in the broad whitefish with the poorest hearing thresholds. Whether this LINTS model is useful for species without hearing specializations is unclear since of those species tested so far (e.g., Nile tilapia, bluegill sunfish, rainbow trout, broad whitefish, sailfin mollies, northern pike), only northern pike and sailfin mollies showed TTS (Coffey 2014; Smith et al. 2004b; Wysocki et al. 2007; Popper et al. 2005).

An important issue, however, is that SPD has been reported in terms of sound pressure level (SPL) with units of dB re 1 μPa. The problem is that most fishes without hearing specializations only detect the particle motion component of sound; thus, pressure is not the most appropriate measure of hearing in those species (Nedelec et al. 2016; Popper and Hawkins 2018). Thus, the levels to which fish were exposed, in terms of particle motion, may be very different than the sound

pressure levels, particularly since the studies were done in tanks where the sound field is very complex and particle motion hard to measure (Radford et al. 2014; Rogers et al. 2016; Jézéquel et al. 2022).

## TTS and Sound Duration

While TTS increases linearly with SPL of the sound stimulus in goldfish and carp (Smith et al. 2004a; Nissen et al. 2019), TTS also increases with the duration of noise exposure (Popper et al. 2004; Smith et al. 2004b) or, in the case of a seismic air gun array, with an increase in the number of air gun shots (Popper et al. 2005). As anthropogenic sound sources like air gun shots and pile-driving produce transient impulsive signals with rapid increases and decreases in pressure that are very short in duration, measures other than the root-mean-square (RMS) of the SPL may be required to predict hearing loss in fishes. For example, cumulative sound energy and sound exposure level (SEL) are potential alternate measures that would account for both the amplitude and duration of a sound source (Popper and Hastings 2009).

## Recovery from TTS

While it is clear that anthropogenic sounds have the potential to produce hearing loss in fishes, the few studies that have performed hearing tests at multiple days post-sound exposure have shown that fish can recover to control hearing levels. For example, goldfish exposed to white noise (160–170 dB re 1 μPa) for 21 days exhibited significant threshold shifts in hearing up to approximately 28 dB. After 14 days, the fish fully recovered to control hearing levels (Smith et al. 2004b). In a subsequent study, goldfish were exposed to white noise (170 dB re 1 μPa RMS) for 48 h. By 7 days postexposure, goldfish hearing recovered significantly (mean TTS $< 4$ dB) (Smith et al. 2006).

Similar results have been found for zebrafish which were exposed for 24 h to white noise at various amplitudes (130, 140, and 150 dB re 1 μPa), and their hearing was tested at different times post-treatment (after 3, 7, and 14 days) (Breitzler et al. 2020). Recovery of hearing occurred within 3 d for fish exposed to 130- and 140-dB noise, while fish exposed to 150 dB took 14 days to recover to control levels. Thus, hearing recovery from TTS depends upon the intensity and duration of the sound stimulus. This is likely because the auditory sensory cells in the inner ear, referred to as hair cells, exhibit greater damage with increased intensity and duration of acoustic overstimulation (discussed below).

Recovery was also found after exposure to shorter and more intense signals. Rainbow trout (a non-specialist) exposed to low-frequency active sonar at a maximum received RMS sound pressure level of 193 dB re 1 $Pa^2$ for 324 or 648 s recovered from TTS within 24–48 h (Popper et al. 2007), and similar results were found for channel catfish (an otophysan) exposed to the same stimulus (Halvorsen et al. 2013) and to mid-frequency active sonar at 210 dB re 1 μPa. Similarly, both

lake chub (an otophysan) and young northern pike showed TTS to exposure to blasts from a seismic air gun at a sound exposure level of about 178 dB re 1 $\mu Pa^2$•s and recovered within 24 h (Popper et al. 2005).

## Effects of Acoustic Overstimulation on the Fish Ear

### The Inner Ear of Fishes

The inner ear of fishes consists of three semicircular canals and three otolithic end organs, the utricle, lagena, and saccule (reviewed in Popper and Hawkins 2021b). Within each end organ is a sensory epithelium (or macula) that contains large numbers of sensory hair cells surrounded by supporting cells and overlain by a dense calcareous otolith which is connected to the macula by a gelatinous matrix. The sensory hair cells are specialized mechanoreceptors with stereocilia and a single microtubule-based kinocilium in their apical surfaces. When sound passes through a fish, the differential density between the otolith and the underlying hair cells causes the stereociliary bundles to be deflected, opening up cation channels and producing receptor potentials that are transmitted to the brain (Flock 1971; Popper and Hawkins 2021b).

### Damage to Sensory Cells from Sound Exposure

One of the problems in studying hearing loss and TTS in many fish species is that it is difficult to measure hearing when animals have been exposed to sounds in the field or in some laboratory conditions (McCauley et al. 2003; Casper et al. 2013; Smith et al. 2022). To at least get some indication of potential hearing damage in these species, investigators have used microscopy to examine inner ear tissues. This approach, while not necessarily indicating hearing loss, parallels work in humans and other vertebrates that have shown close correlation between damage to sensory cells or the innervating nerves of the inner ear and hearing loss (e.g., Le Prell et al. 2012; Liberman 2016). Indeed, this approach has been validated in several studies in fishes that demonstrated close correlation between hair cell damage and hearing loss, followed by hair cell recovery and return of hearing (Smith et al. 2006, 2011; Uribe et al. 2013; Breitzler et al. 2020; Lara et al. 2022).

Sound-induced sensory hair cell loss in fishes was first reported for Atlantic cod (*Gadus morhua*) that were exposed to tones between 50 and 400 Hz that were 100–110 dB above the most sensitive hearing threshold for that species (Enger 1981). Examination of the saccular epithelia via scanning electron microscopy (SEM) revealed large patches of hair cells that were missing or almost completely lacking stereocilia. Lower-frequency tones damaged the caudal region of the saccule, while higher-frequency tones damaged the rostral region. Smith et al. (2011) found a similar tonotopic pattern of hair cell damage in goldfish exposed to tones

between 100 and 4000 Hz at 176 dB re 1 μPa RMS for 48 h, suggesting that this saccular organization may be common among fishes.

The first study to examine hair cell loss due to an anthropogenic sound source in the field was McCauley et al. (2003). They found that pink snapper (*Pagrus auratus*) exposed to air gun stimulation exhibited significant hair cell loss and damage 58 days postexposure (no fish were examined sooner so it could not be determined if hair cell loss showed up sooner postexposure). Pile-driving stimulation has also been shown to produce hair cell loss in fishes. Casper et al. (2013) found that 960 pile-driving strikes at 216 dB re 1 $\mu Pa^2 \cdot s$ cumulative SEL produced significant hair cell damage and loss in hybrid striped bass (*Morone chrysops x Morone saxatilis*). Similarly, exposure of caged Pacific mackerel (*Scomber japonicus*) up to 400 m from a single explosion of C4 explosives (4.5 kg) showed damage to sensory cells in the saccule (Smith et al. 2022).

While most work has focused on one end organ, the saccule, a study on the oscar (*Astronotus ocellatus*) found hair cell damage in small regions of the lagena and utricle, and not the saccule, following exposure to a continuous 300 Hz tone at 180 dB re 1 μPa (Hastings et al. 1996). Clearly, more work is needed on each of the inner ear end organs in order to understand potential hearing loss in fishes.

## Correlation Between Hair Cell Damage and TTS

There are only a few studies that have examined both sensory hair cell loss and TTS in fishes (Smith et al. 2006, 2011; Uribe et al. 2013; Breitzler et al. 2020; Lara et al. 2022), and initial analysis shows that there is a linear relationship between percent hair cell loss and the degree of TTS (Smith 2016). This pattern holds during the post-sound exposure period as well, with TTS decreasing, or recovering closer to control thresholds, as hair cell numbers return to control levels (Smith 2016).

At the same time, a possible exception to this relationship between TTS and hair cell loss was reported by Song et al. (2008) who found no hair cell damage using SEM in the same fishes for which air gun-induced TTS was reported (lake chub and northern pike; Popper et al. 2005). Similarly, while exposure to a US Navy Surveillance Towed Array Sensor System (SURTASS) Low Frequency Active sonar with a maximum received RMS SPL of 193 dB re 1 $\mu Pa^2 s$ produced a 20 dB threshold shift in rainbow trout (*Oncorhynchus mykiss*), no sensory hair cell damage was found in the ears of the same fishes (Popper et al. 2007).

The reason that there was TTS but no apparent hair cell damage is likely because these studies were limited in techniques to the examination of the surfaces of the sensory cells using various types of microscopy and not all regions of the ear were examined. In particular, TTS can occur in mammals when there is subtle damage to hair cells that are not easily detected without high-magnification scanning electron microscopy or other techniques. For example, acoustic over-stimulation of hair cells can result in broken tip links between the hair cell stereocilia which prevents mechanotransduction of sound signals or damages the

nerves innervating the hair cells (Lin et al. 2011; Indzhykulian et al. 2013; Liberman 2016).

## Is TTS Useful in Developing Sound Exposure Criteria for Fishes?

The data cited in this chapter demonstrate that anthropogenic sound sources can produce TTS in some fish species (Table 1) and/or damage to sensory hair cells. However, the number of species tested is few, and the experimental approaches used vary substantially, making it very difficult to compare results from different studies.

A fundamental question is whether it is even worth considering TTS when developing criteria to protect fishes from anthropogenic sounds. There are, of course, also questions as to whether a small level of TTS (e.g., 6 dB), if it even occurs, would have any short- or long-term impact on the fitness or survival of fishes (Popper et al. 2014).

While there are few data to directly address whether criteria should be developed to protect fishes from TTS, based on what is known about TTS and fishes, it is reasonable to suggest that TTS should not be an issue with regard to anthropogenic sound. This conclusion is based on several arguments.

First, and foremost, all reported effects on fish ears and hearing have been from exposure to very intense impulsive sources or long durations of moderately intense continuous sounds. While data are very few, it is likely that most species exposed to intense sounds, perhaps with the exception of animals that are "tied" to a site for breeding or other reasons, will likely move away from the source, and not stay in a region of intense sounds for long enough for TTS to occur, as demonstrated in the relatively few studies in the field (Fewtrell and McCauley 2012; Iafrate et al. 2016a, b; Krebs et al. 2016).

Second, considering that sound levels decrease as the distance from a source increases, it is reasonable to argue that most fishes in an area of anthropogenic sound will not be sufficiently near an intense source to be exposed to sounds intense enough to result in TTS. Thus, while some animals close to the source may be exposed to sufficiently intense sounds to result in TTS, these animals are likely to make up a very small part of the population of the species in an area, and even these animals are likely to move away from the source to areas of lower sound level (Iafrate et al. 2016a, b; Krebs et al. 2016; Watwood et al. 2016).

Third, as shown in Table 1, most species studied that have shown TTS to intense sounds were hearing specialists, which have substantially more sensitive hearing than non-specialists. Considering that most species of concern with respect to anthropogenic sound, including species considered threatened or endangered, and/or are of commercial value, are not hearing specialists, they are thus much less likely to develop TTS than specialists at the same level of sound exposure. Or, put another way, most marine species would need to be exposed to sounds far more intense than used in the studies in Table 1 before TTS would be expected.

Thus, the argument made here is that in considering potential criteria for effects of anthropogenic sound on fishes, TTS is not a particularly likely occurrence. At the same time, overall effects of anthropogenic sound on fish hearing, with particular

focus on masking and changes in behavior such as leaving feeding sites, are far more critical issues and need much more study.

Still, the argument made here regarding TTS is based on limited data and conjecture. In order to support the argument, more data on TTS and effects of sound on fish ears are needed. However, a much more structured approach needs to be taken in future studies using species that are likely to be exposed to anthropogenic sounds and using experimental approaches that allow more "natural" behavior of fishes exposed to the sounds (as discussed in Popper et al. 2019, 2022; Hawkins et al. 2020). Finally, far better control is needed for the sound field, and calibration of exposure levels needs to be in terms of particle motion since it is the stimulus that is most directly detected by the ears of all fish species.

**Abstract**

The results of experiments on assessing the reaction of walleye pollock (*Theragra chalcogramma*) to the noise of passing research vessel are presented. A free-drifting buoy with built-in scientific echo sounder (38 kHz) was used. Pollock reactions were accompanied by horizontal and vertical movements from the noise source. The response distances to vessel noise ranged from 140 to 180 m, which is consistent with the model estimates. The total acoustic density curve has a tendency of a small initial rise and then a steady decrease with further approach of the vessel. A stronger decrease in the total density of fish in the upper horizons due to lateral avoidance is typical. The diving of fish when the vessel approaches causes a consistent increase in their density in a deeper layer. In the depth range of 0–100 m, the ratio of pollock density to the background at the closest point of approach was 0.56. At depths of 100–200 m, due to the deepening of fish, the decrease in total density was less significant ($K_{avoid} = 0.86$). The diving speed of pollock in the vessel's noise field is an order of magnitude higher than during daily vertical migrations. Such avoidance behavior can be a source of error in echo integration and trawl fish stock estimations.

## Introduction

Currently, it has been experimentally proven that vessel noise can have a significant impact on fish behavior and, as a result, on fish stock estimates and catch of fishing vessels (e.g., De Robertis and Wilson 2010; De Robertis and Handegard 2013; De Robertis et al. 2010; Kuznetsov 2011; Kuznetsov and Vologdin 2009; Mitson 1995; Ona et al. 2007; Vabø et al. 2002). The frequency ranges of maximum noise energy of the vessel and the best auditory sensitivity of most fish species coincide. Vessel noise levels far exceed fish auditory thresholds. This suggests that fish can perceive the noise of a vessel over long distances (Kuznetsov 2011; Mitson 1995). The main effect of the vessel noise influence is the avoidance reaction of fish (Fig. 1). The avoidance reaction is manifested by the desire of fish to leave the vessel noise field in the direction of its reduction (minimization of the stimulus) and is accompanied by horizontal and vertical movements of fish. These movements cause a change in the natural distribution and density of fish in the path of the vessel and create the possibility of error in the echo integration and trawl estimates of fish stocks.

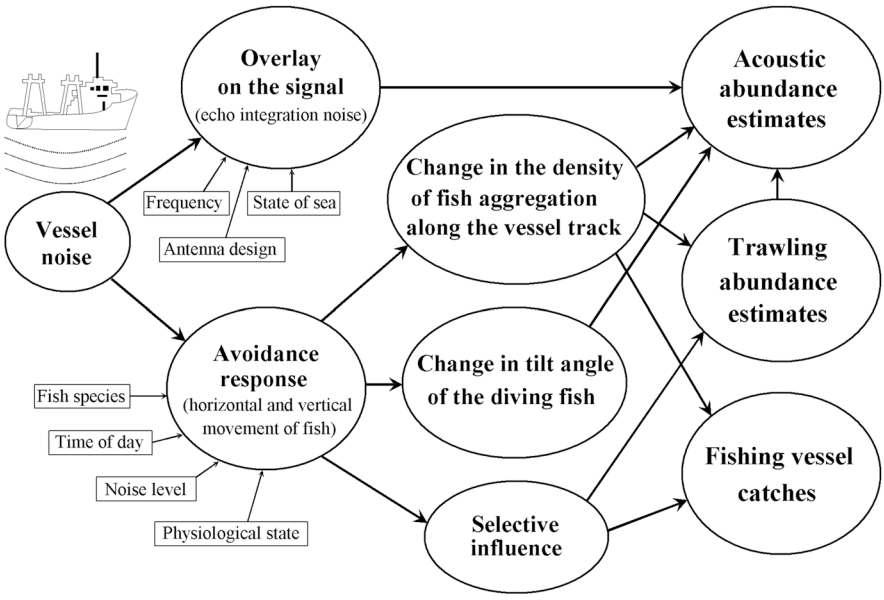

**Fig. 1** Effects of vessel noise influence on acoustic and trawl abundance estimates and fish catches. In the rectangles show the factors that determine the strength or degree of this influence

According to various researchers, the response distance of fish to the noise of the vessel varies significantly from 40 to 500 or more meters (more often from 100 to 200 m), depending on the species (hearing abilities of fish), the physiological state of the fish, the type of vessel (noise level), and environmental conditions (Kuznetsov and Vologdin 2009). The slope of the fish during diving causes a decrease in the values of acoustic reflectivity (backscattering strength), which leads to an underestimation of echo integration assessment of abundance (McQuinn 1999). The vessel noise can be an additional source of echo integration noise in scientific echo sounders (Korneliussen 2000).

The selective influence of the vessel noise field is important. This influence is especially pronounced in mixed aggregations of different species and age classes of fish, which have different energy capabilities (swimming speeds) and behavior (He and Wardle 1988). For example, larger (adult) fish respond more strongly to acoustic stimuli than their juveniles (Engås et al. 1996). The response to an approaching vessel to fish of different ethological groups is largely similar to the defensive response of these fish to the approach of a predator (e.g., Fréon et al. 1993; Skaret et al. 2005; Vabø et al. 2002). The nature of the reaction is determined by the species stereotype of the defensive behavior of fish. The defensive reaction of sedentary bottom fish is characterized to a greater extent by their hiding. Fast near-surface fish respond by more active horizontal avoidance of the vessel noise field. The reaction of vertically migrating fish is accompanied by both horizontal and vertical movements. The strength of the fish's response to the noise of the vessel varies significantly depending on the physiological state of the fish. Fish are usually easily excited in a state of increased locomotor activity (e.g., during migration) and are indifferent to acoustic stimuli during spawning.

This chapter reports on the locomotor reactions of walleye pollock (*Theragra chalcogramma*) to the noise of a passing vessel using an autonomous floating buoy with a built-in scientific sonar. The obtained results were used to simulate the motor behavior of fish in the vessel noise field, which will allow developing a strategy for its accounting and compensation when conducting trawl-acoustic surveys of fish stocks.

## Methods

Horizontal and vertical movements of fish from the noise source, as well as changes in the tilt angle of the diving fish, are accompanied by a decrease in the acoustic density and an increase in the depth of the fish location relative to the initial. This behavior of fish is interpreted as an avoidance response (Olsen et al. 1983).

Observations of the reaction of fish to the noise of the research vessel "Professor Kaganovsky" were carried out during the trawl-acoustic surveys of walleye pollock in the Sea of Okhotsk, Russia, in the spring seasons of 2014–2016. Autonomous hydroacoustic complex (AHC) was used for experiments. AHC is a floating buoy with built-in equipment (Fig. 2): scientific echo sounder Simrad EK60 with 38 kHz transducer, power supply, Wi-Fi module (router), and GPS receiver. The echo

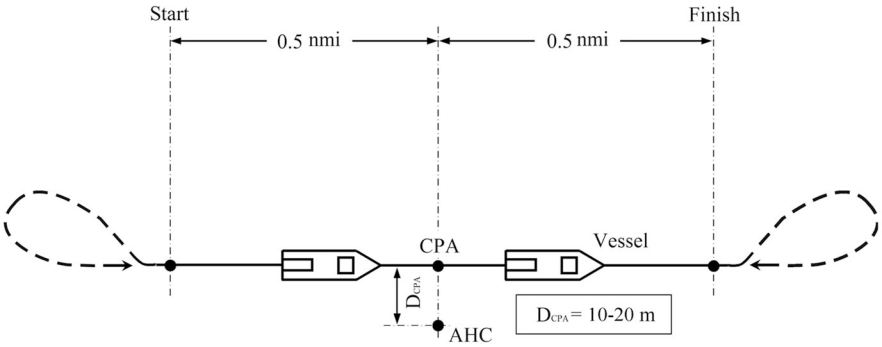

**Fig. 3** The pattern of vessel movement during measurements: *CPA* closest point of approach, *AHC* autonomous hydroacoustic complex, $D_{CPA}$ minimal distance between the passing vessel and the AHC

sounder is launched from the vessel via Wi-Fi and operates autonomously in the vertical location mode at a frequency of 38 kHz, used in the echo integration assessment of fish stocks. Acoustic and navigation data were recorded on the hard disk of a laptop computer in "raw" format using the Simrad ER60 program. All analyses of acoustic data were conducted using "SALTSE" software (Kuznetsov et al. 2021).

Experiments on the measurement of the avoidance reaction were carried out in the presence of uniformly distributed walleye pollock aggregations at a depth of not more than 200 m. Trawl samplings were carried out to identify echograms and determine the size and species composition of the studied aggregation before each series of experiments. The pattern of movement and maneuvering of the vessel during the experiments is shown in Fig. 3. The vessel departs from the buoy at a distance of 1 nautical mile (nmi), makes a circulation, and begins to move in the

direction of the AHC. The vessel passes in a straight line past the AHC, alternately to port and starboard, at a speed of 7–9 knots. The straight-line uniform motion of the vessel between the "Start" and "Finish" points is the transect. The echo sounder at AHC continuously measures the vertical distribution of fish during each transect. The minimal distance between the passing vessel and the AHC in the closest point of approach (CPA) varied from 10 to 20 m. The time interval between passes was at least 40 min in order to restore the background state of the fish aggregation.

The response of fish was assessed by the change in acoustic density (surface backscattering strength) and depth of the fish before and during the passage of the vessel past the AHC. In the mode of post-processing of echograms by the "SALTSE" software complex, nautical area scattering coefficient $s_A$ ($m^2$ $nmi^{-2}$) and weighted average depth of fish $H$ (m) were measured. First, their background values $s_{A(ref)}$ and $H_{(ref)}$ before the measuring transect when the fish were presumably undisturbed by the vessel and then during the transect $s_{A(pass)}$ and $H_{(pass)}$ – the observations at the time of vessel passage during 1- or 2-s echo integration intervals (~5 or 10 m horizontal distance) – were measured. The reference period was defined as 0.5 nmi before and after CPA, and observations during vessel passage were taken as CPA ±1 s (~5–10 m). The change in the density and depth of the fish during the passage of the vessel past the AHC was estimated in relation to the $s_A$ and H on transect to the background value as $K_{avoid}$ avoidance coefficient and $K_{depth}$ diving coefficient:

$$K_{avoid} = \frac{s_{A(pass)}}{s_{A(ref)}},$$

$$K_{depth} = \frac{H_{(pass)}}{H_{(ref)}}.$$

## Results and Discussion

Reducing the density of fish and increasing the weighted average depth (diving) of walleye pollock aggregations during the vessel's approach to the AHC were typical for most experiments (Fig. 4). In a series of experiments, where the proportion of immature fish was high, a stable effect of changing of density aggregations in the near-surface horizons was recorded at a distance from the vessel of 140–150 m. At distances from 30 to 50 m after the passage of the CPA, the avoidance coefficient reached a minimum value, and diving speed decreased to the background. Then the slow rise of pollock began with a wave-like increasing speed to 0.06–0.12 m/s. In aggregations with a predominance of mature pollock, the horizontal avoidance reaction began to appear somewhat earlier: at a distance of 160–180 m in front of the vessel. The decrease in the total density of fish often stopped ($K_{avoid}$ minimal) before the vessel approached to CPA at distances up to 30 m. Then the reverse process of restoring of walleye pollock density began. In aggregations of juvenile pollock, a decrease in the total density at $\leq$90% of the background was recorded at a distance of about 100 m with a tendency for a very slight decrease as the vessel

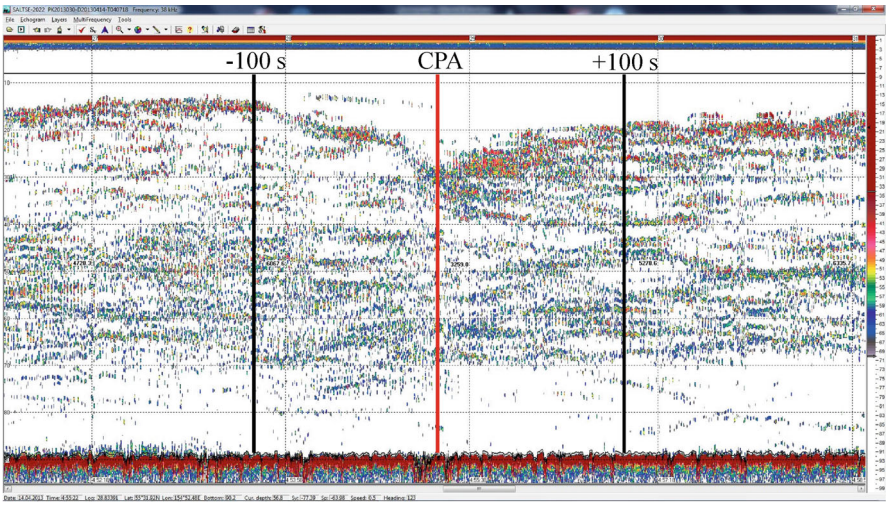

**Fig. 4** Echogram illustrating the walleye pollock's reaction when RV "Professor Kaganovsky" passes by the AHC. See text for explanation

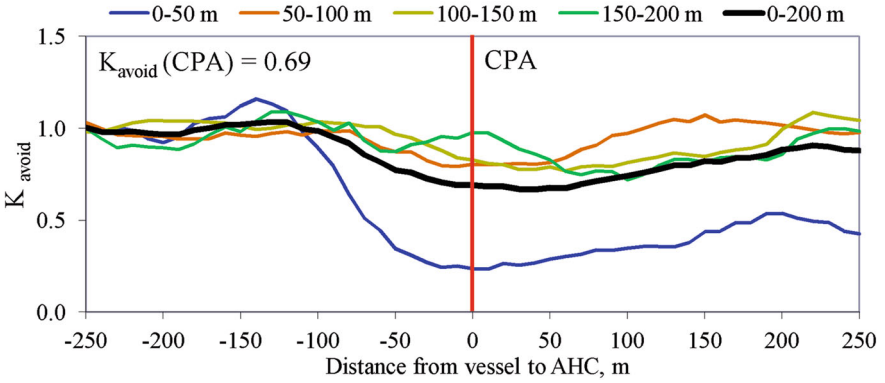

**Fig. 5** Change in density of walleye pollock aggregations in sub-ranges of depths depending on the distance between the vessel and AHC (Sea of Okhotsk, spring 2014–2016). See text for explanation

approached. The diving of fish became noticeable only near the vessel at a distance of about 50 m.

Generalized graphs of the density change (coefficient of avoidance) of walleye pollock aggregations in the vessel's noise field are shown in Fig. 5. At distances to the vessel of 180–140 m, the total density curve tends to have a slight initial rise ($K_{avoid} > 1$) and then a steady decrease with its further approach. Horizontal movements of the fish reacting forward in the course of the vessel and already there, apparently, cause the increase in density, due to which there is an effect of "crowding" of walleye pollock at response distances.

A steady decrease in the total density of walleye pollock aggregations $s_A$ was recorded at a horizontal distance to the vessel of about 120 m. At first, this decrease was mainly due to the intensive scattering of fish in the near-surface horizons of 0–50 m. Then, as the vessel approached, a decrease in density was observed in the deeper layers – 50–100 and 100–150 m (Fig. 5). Since the reaction of fish is accompanied not only by horizontal avoidance but also by their deepening, the density reduction curves in the subsurface layers of depth (50–150 m) summarize these effects and have a more gentle character.

In the depth range of 150–200 m (i.e., at the pollock response distances) near the CPA, the reverse process of increasing the density of aggregations was observed. This is due to the movement of fish from the upper horizons there, similar to the "crowding" of the pollock in front of the vessel.

Thus, part of the fish in the way of the vessel goes to the sides (dissipates). A stronger decrease in the density of fish in the upper horizons due to lateral avoidance is typical. It is also typical to redistribute the density of pollock by depth layers. The diving of fish when the vessel approaches causes a consistent increase in their density in a deeper layer. With a sufficiently wide vertical distribution of aggregations and if horizontal avoidance is small, at certain depths, the noise field of the vessel increases the density of fish relative to the initial (background). These results confirm the data of model calculations (Kuznetsov et al. 2015). In almost all experiments, the decrease in the total density during the vessel passage was due to a decrease in the density of fish in the upper horizons, and its growth – due to an increase in the density of pollock in the lower layers of depth.

The coefficient of avoidance in the CPA at depths less than 100 m according to the generalized data was 0.56 (Fig. 6a). This means that the density of pollock at the minimum distance from the vessel decreased by almost 1.8 times compared to the initial, measured with the natural (undisturbed) state of the fish in front of the vessel. In the depth range from 100 to 200 m (Fig. 6b), the trend of the initial rise and subsequent decrease in the total density of aggregations in CPA due to the deepening of fish was less significant ($K_{avoid} = 0.86$). The underestimation of the number of pollock in the depth range of 100–200 m did not exceed 15% under the vessel and 20% behind the vessel. The ratio of the total density of fish to the background in CPA in the entire depth range of 0–200 m was 0.69 (Fig. 5).

After the passage of the CPA, the density in the layer of 150–200 m decreased as the vessel departed, i.e., the fish left the densification zone, which was formed at response distances under the vessel. Then, at a horizontal distance from the vessel of more than 50 m, the process of reverse restoration of the density of fish in other layers, starting from a deeper one, became noticeable. Restoration of the total density of fish occurred more hollow than its decrease, at a distance of 220–240 m after the passage of the vessel, and only partially: up to 80% of the initial in the depth range 0–100 m and up to 90% of the initial in the depth range 0–200 m. In the depth range 100–200 m, the decrease and restoration of the total density behind the vessel went approximately at the same speed. The fish density was restored completely ($K_{avoid} = 1$) at a distance of 400–500 m from the vessel (after 1.5–2.0 min.). However, the weighted average

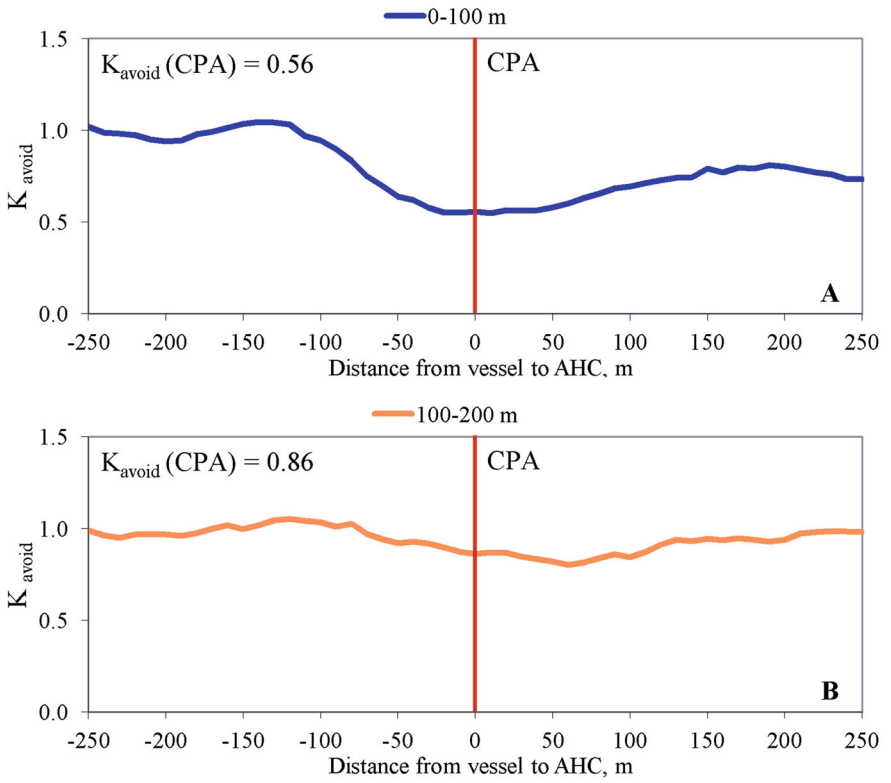

**Fig. 6** The density of walleye pollock aggregations varies depending on the distance between the vessel and AHC in the depth ranges: (**a**) 0–100 m; (**b**) 100–200 m

depth of the fish remained 7–10 m below the background. The initial vertical distribution of fish was restored for more than 20 min.

In a number of experiments, diving of fish was found at a distance of 350–500 m or more from the vessel. At the same time, the density of the aggregations did not change significantly (pollock did not dissipate). This state conforms to the first phase of the reaction, when fish hear sound (the noise level exceeds the auditory threshold), but cannot determine the direction of the arrival of the sound wave (Kuznetsov 2011). The reaction of fast near-surface fish (e.g., sardine, mackerel, salmon) is characterized by more active than background horizontal movements inside of the school (Kuznetsov and Kuznetsov 2007). Less mobile species (which include pollock), as long as the source of noise is not localized, respond mainly with vertical movements of fish (known as "squatting" of pollock). At distances to the vessel at which the increasing sound pressure of the noise exceeds the threshold of the avoidance reaction, the response of fish becomes directed. This reaction is accompanied by both vertical and horizontal movements of the fish from the noise source.

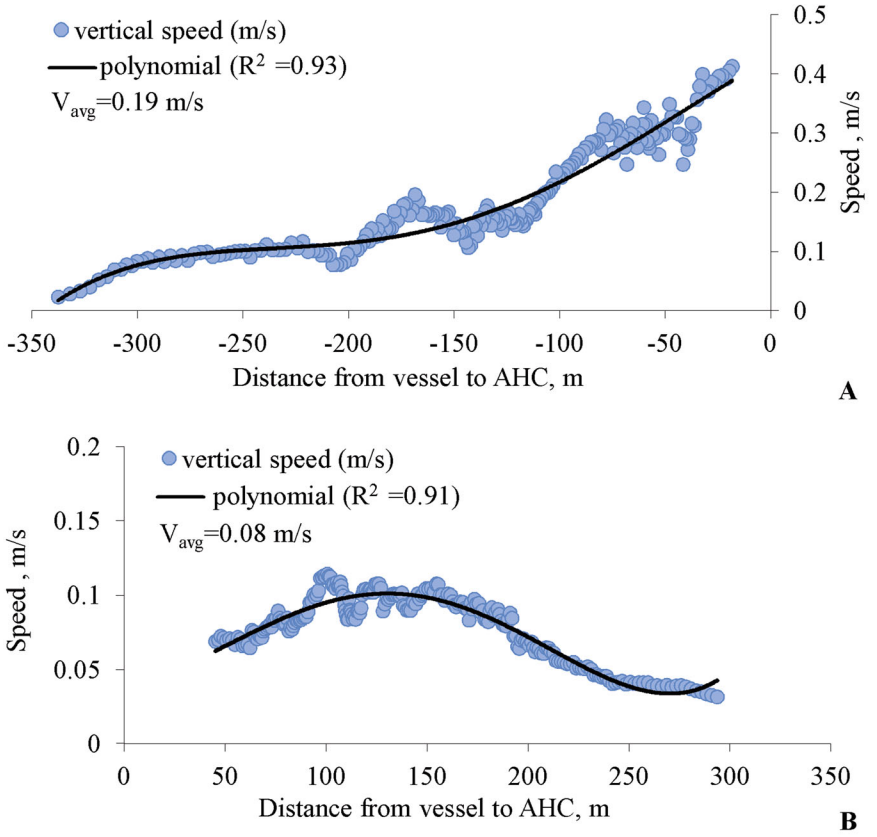

**Fig. 7** Dependences of the speed of diving (**a**) and lifting (**b**) of walleye pollock on the distance between the vessel and the AHC in the depth range up to 100 m. The dots represent a vertical speed (a running mean of 11 s). $V_{avg}$ average velocity

Generalized for all experiments, the dependence of the speed of diving and lifting of pollock on the distance between the vessel and the AHC is shown in Fig. 7. The speed values are well approximated by a fourth-order polynomial. The diving speed gradually increases from 0.04 to 0.15 m/s between 350 m and 150–180 m. At these distances, the behavior of the fish by noise level conforms to the first phase of the reaction (horizontal avoidance is absent). At distances less than 150 m (the noise source is localized), the speed of diving increases sharply and at the minimum distance from the vessel becomes the maximum – up to 0.42 m/s (at distances less than 50 m, the average speed is 0.35 m/s). The obtained results show that the dive rate of walleye pollock in the vessel's noise field is significantly (more than an order of magnitude) higher than those during their natural migrations.

The speed of lifting of pollock after the passage of the vessel is less than the speed of diving, but also significantly higher than during daily migrations. At a distance of

about 100 m from the vessel, the lifting speed becomes maximum – up to 0.12 m/s. The lifting speed of pollock slows down smoothly as the distance from the vessel increases (Fig. 7).

A simple model of the locomotor behavior of fish in the noise field of the vessel has been developed. The model uses experimental estimates of the pollock response distance, data on the change in the acoustic density $s_A$, and the depth and speed of diving and lifting of the pollock during the passage of the measuring transect. The initial distribution of fish in the model is assumed to be uniform in horizon and depth. By specifying the species and size of the fish and the type and speed of the vessel (acoustic field characteristics) in the model, it is possible to predict horizontal and vertical position of the fish relative to the vessel at any time.

Model estimates of the change in the density of walleye pollock aggregations are well consistent with experimental results. In the depth range of 0–100 m, the model curve, like the experimental results, tends to have a slight initial rise due to horizontal avoidance and densification of fish in front along the course of the vessel (Fig. 8). The ratio of the density of the fish aggregation to the background in the depth range

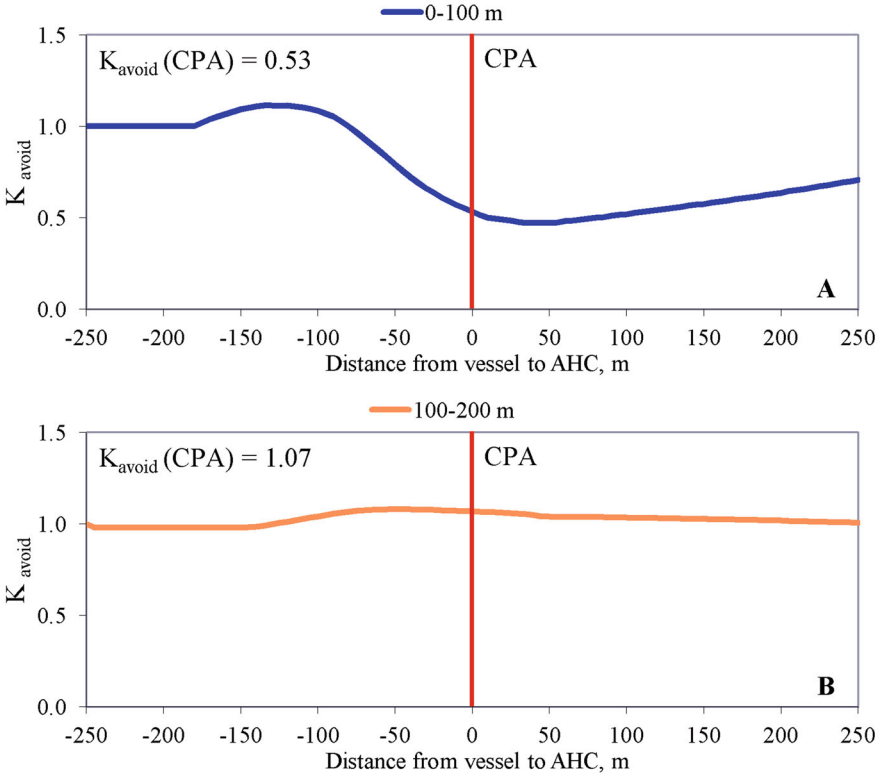

**Fig. 8** The change in the density of walleye pollock aggregations on the distance to the vessel in the depth ranges: (**a**) 0–100 m; (**b**) 100–200 m (model estimates)

of 0–100 m in the CPA according to the model was 0.53, which is close to the experimental estimates (0.56). In the layer of 100–200 m, where part of the fish moves from the upper horizons during the reaction, model and experimental estimates differ somewhat. The uniform initial distribution of fish adopted in the model is rarely observed in experiments. In the depth range of 100–200 m, the effects of horizontal avoidance (scattering) and an increase in density due to the movement of fish there from the upper horizons are simultaneously observed, which, with a uniform initial distribution in the model, mutually compensate for each other. As a result, a layer is formed where, according to model estimates, the pollock density may be higher than the initial one ($K_{avoid} > 1$).

Figure 9 illustrates the horizontal distribution of pollock in the noise field of the vessel depending on the size of fish and depth. The perturbed area, where the avoidance reaction and distortion of the spatial distribution of fish occur, is clearly visible. The square of the perturbed area (fish reaction zone) and the number of deviated fish significantly decrease with depth. Horizontal and vertical displacements of fish, minimizing the impact of noise, decrease as they move away from the vessel. As a result, at the edges of the disturbed area, a zone is formed, where the density of reacting fish becomes higher than the initial one. This zone is formed both on the sides and under the keel of the vessel and looks like a hemisphere, the radius

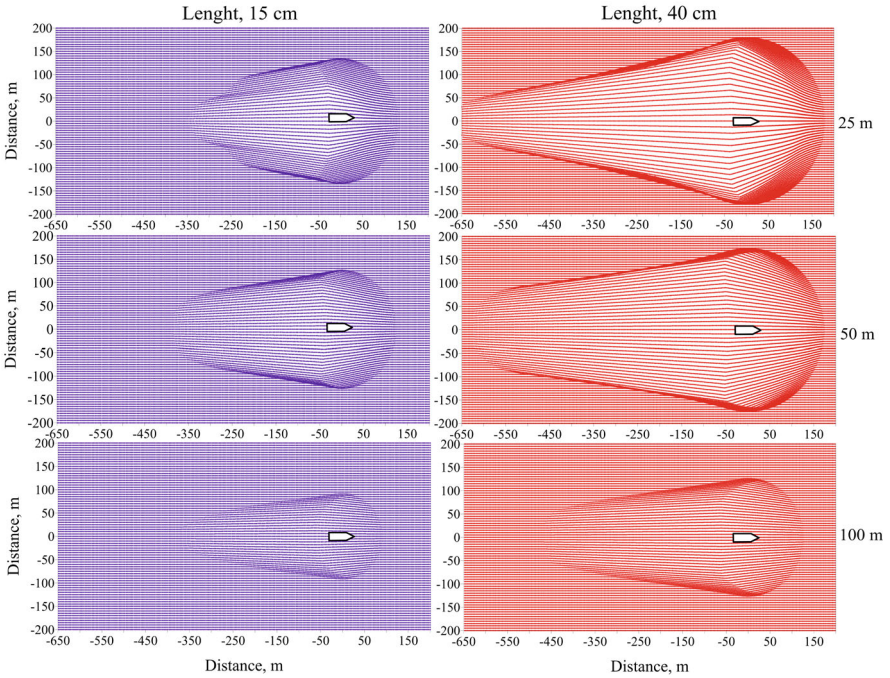

**Fig. 9** Model of walleye pollock behavior in the noise field RV "Professor Kaganovsky." Top view, section at depth 25, 50, and 100 m, speed 9 knots. See text for explanation

of which is the response distance of the fish. The restoration of the spatial distribution and density of fish is completed at a distance of 500–700 m after the passage of the vessel.

The large fish with higher energy and auditory abilities, in the process of reaction, move farther from the vessel and have a larger disturbance area than small objects, which demonstrates one of the manifestations of the selective effect of the noise field. The final location of the fish at various speeds of the vessel is different. The perturbed area where the avoidance reaction occurs, at a lower speed of the vessel significantly more fish manage to leave than at a higher vessel speed. In this case, the square of the perturbed area does not change.

In the transverse plane, a plurality of fish in the vessel's noise field forms a typical tunnel shape. Visually noticeable are the effects of reducing the density of fish aggregation relative to the initial one in the active reaction zone near the surface and densification (concentration) of pollock in a more comfortable zone along the edges of the tunnel.

## Conclusions

The results of experiments showed that the reaction of walleye pollock to the noise of the approaching vessel is manifested by their diving and dispersion. The response distances of pollock to the vessel noise ranged from 140 to 180 m from the vessel and are consistent with the calculated estimates. At such distances, the reaction of the fish becomes directed and is accompanied by their initial densification and subsequent decrease in density as the vessel approaches. The speeds of vertical movements of walleye pollock significantly exceed those of its daily migrations. The results confirm that the noise of the vessel is a strong irritant for fish, stimulating a pronounced defensive reaction. Experimental and model estimates showed a decrease in the acoustic density of pollock near the vessel of more than 40% at depths of up to 100 m. Such avoidant behavior can be a source of error in echo integration and trawl estimates of fish stocks.

**Abstract**

Aquatic noise has increased in the last decades, especially along the routes of freighter and in harbor areas. The increasing sounds are likely augmenting the pressure on aquatic animals' acoustic communication and causing enhanced stress on populations inhabiting such regions. One of such areas, the Tagus estuary (Portugal), holds important maritime harbors and a network of ferryboat routes. It is also used as breeding grounds for several fish species, namely the meagre (*Argyrosomus regius*), which might be impacted by anthropogenic noise since it produces loud breeding choruses. This study assessed the impact of boat noise on this species by inspecting changes in chorus sound levels in the field during boat passages. Results show that the sound level of meagre choruses is often reduced during a boat passage, a behavioral effect that might ultimately impact reproductive success of this species.

## Introduction

Anthropogenic noise is changing underwater soundscapes around the globe (Duarte et al. 2021). Some of the most common sources of underwater noise in shallow waters are boats and vessels. Such sounds are known to affect the behavior and physiology of various fish species (Bruintjes and Radford 2013; Graham and Cooke 2008; Picciulin et al. 2012; Amorim et al. 2022).

Sciaenidae are one of the best-known fish vocal families. They can produce conspicuous chorusing behavior associated with the breeding season (Luczkovich et al. 2008; Montie et al. 2017; Vieira et al. 2022). The choruses produced by these species are so extraordinary that they are described in the famous book "20,000 Leagues Under the Sea" by Jules Verne (1870) as follows: "Some authors more poet than naturalist – believe that these fish sing melodiously, and when they unite in a choir human voices scarcely equal them. I do not dispute this, but the sciaenidae did not serenade our passage, to my regret."

The meagre (*Argyrosomus regius*) is a large (up to 2 m) long-lived (can reach 40 years or more) sciaenid that, as other sciaenids, forms large aggregations during the breeding season (Haffray et al. 2012). An important spawning and nursery area is the busy Tagus estuary (Portugal) that holds important maritime harbors and a network of ferryboat routes that generate significant low frequency noise (Vieira et al. 2021a). Exposure to boat noise might interfere with chorusing behavior and ultimately with reproduction outcome. Vieira et al. (2021b) presented the non-stochastic decrease of the meagre calling activity during a boat passage. Here, this study go further to report changes in calling activity associated to boat passages, taking into account different chorus intensity, which should reflect different number of calling individuals and/or different individual calling rate.

## Methods

Continuous acoustic recordings were obtained in Tagus estuary (Air Force Base 6, Montijo, Portugal; 38°42′N, 8°58′W) at a site known to have meagre choruses and boats passing by regularly (Vieira et al. 2021a). Recordings were made using a High Tech 94 SSQ hydrophone (sensitivity – 165 dB re. 1 V/μPa, flat frequency response up to 6 kHz ± 1 dB) anchored near the bottom and connected to a stand-alone 16 channel datalogger (LGR-5325, Measurement Computing Corp, Norton, MA, USA; 4 kHz sampling rate, 16 bit). The data set consisted of ca. 27-day continuous recordings (from the 1st to the 30th of April 2018, with some interruptions).

To annotate the continuous recordings, two automatic sound recognition systems using hidden Markov model (HMM)-based supervised machine learning were applied to detect and identify both the boat passages (system-1, as described by Vieira et al., 2020) and the presence of meagre choruses (system-2, as described Vieira et al. 2021b). In short, multiple HMMs were trained using sounds of each defined category and then used to classify the recordings according to their maximum likelihood, i.e., the model with the best distribution to represent a given sound type (a vector representing a time series) was selected. Note that in an HMM-based sound recognition, it is assumed that the time series of an observed sound can be represented by a linear Markov model. For detailed information, see Vieira et al. (2021b).

For each boat passage annotated using the automatic recognition system, sound level was measured in third-octave bands (TOL) centered at 500 and 1584 Hz (computed according to Merchant et al. 2015; averages for every 10 s were used) to quantify the variation of the acoustic behavior during each detected boat passage. These bands were selected according to the description of Tagus soundscapes by Vieira et al. (2021a): TOL 500 Hz as proxy of the meagre chorus and TOL 1584 Hz as a proxy of the boat noise. Note, however, that to standardize the analysis to measure the changes on the sound level throughout a boat passage, it was considered 180 s before and 180 s after the TOL 1584 Hz peak at each boat passage. To evaluate changes in meagre calling activity, it was measured the minimum TOL 500 Hz before(−180 to −110 s), during(−10 to 80 s), and after (110–180 s) the TOL 1584 Hz peak. Because TOL 500 Hz levels also receive some contribution from boat noise, we used the minimum values registered in the different periods to evaluate changes in meagre calling activity, as these levels should have a minimum influence from boat noise. Note that, although the ferryboats follow approximately the same route between Lisbon and Montijo, the distance of ferryboats to the hydrophone can vary (usually between 100 and 300 m). The before, during, and after periods were selected based on the results reported by Vieira et al. (2021b), namely the during period was considered from −10 to 80 s to encapsulate the decrease of chorus sound level that usually occurred shortly after the peak of the boat noise sound level. These values were compared using a factorial two-way ANOVA with interactions using the following categories: (1) period relative to the boat passage (before, during, and after) and (2) the meagre chorusing level that was divided in three classes according to the minimum TOL 500 Hz before the boat passage (low, from 90 to 100 dB; medium, from 100 to 110 dB; and high intensity,

above 110 dB). This approach aimed at assessing if any changes in calling behavior due to boat noise could be influenced by chorus intensity, a proxy for meagre aggregation calling activity. Each boat passage was included as a random effect factor. ANOVA was followed by Tukey post hoc test. For all the statistical analyses, standardized values were computed for each meagre chorus class because they have different magnitudes. To respect the ANOVA assumptions, logarithmic transformations and removal of outliers were conducted. Assumptions were evaluated by visual inspection of residual plots (predicted vs. residuals values, normal probability plots).

## Results

On average, there was a decrease in the TOL 500 Hz, a proxy for the intensity of meagre choruses, during ferryboat passages (Fig. 1). This reduction usually had its maximum after the peak of the boat noise. A significant effect of boat passage period was found

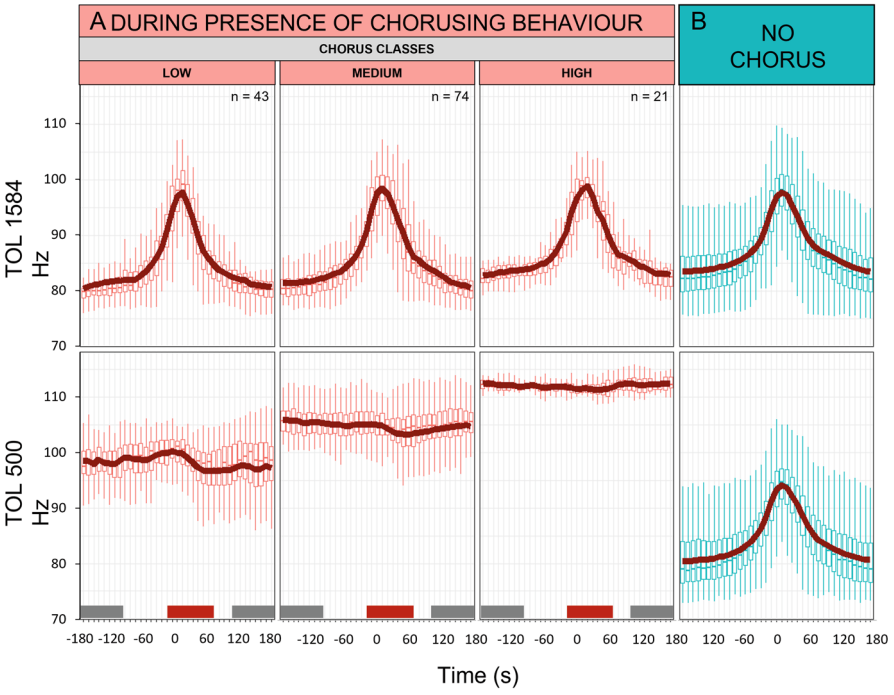

**Fig. 1** Effect of boat passages on the meagre chorus sound level. Red line represents the mean TOL around ferryboats passages in two bands (centered on 500 and on 1584 Hz). (**a**) represents ferryboat passages in the presence of meagre chorus at different classes of intensity, and (**b**) represents sections without meagre choruses. Zero seconds represent the energy peak of the ferryboat passages. Colored bars represent the before (gray), during (red), and after (gray) periods

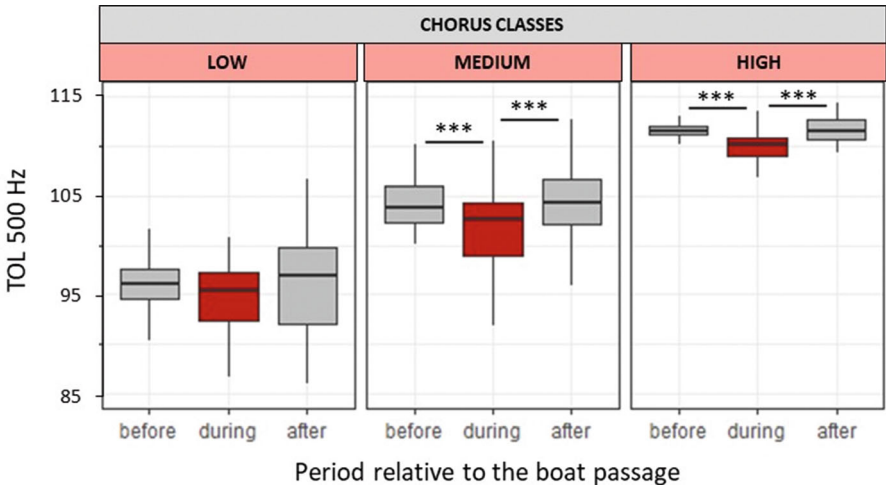

**Fig. 2** Change in TOL 500 Hz before, during, and after the boat passages. ***$p < 0.001$, Tukey test for pairwise comparisons within each chorus class. Note that statistical analysis was performed on standardized values

($F_{(2,254)} = 26.8$, $p < 0.001$) but no significant effect of the intensity of chorus ($F_{(2,135)} = 0.09$, $p = 0.9$). The interaction of these variables was significant ($F_{(4,254)} = 3.9$, $p = 0.004$). In choruses of medium (100–110 dB) and high intensity (above 110 dB), values before and after were significantly higher than during a boat passage (Tukey test, $p \leq 0.001$; Fig. 2), but no significant changes were observed in choruses of low intensity (before-during, $p = 0.26$; during-after, $p = 0.43$). No significant changes were observed between before and after periods ($p = 0.95$, $p = 0.82$ and $p = 0.98$ in chorus of low, medium and high intensity, respectively). A reduction in the chorus (TOL 500 Hz) from before to during a boat passage was observed on 67%, 85%, and 85% of boat passages with choruses of low, medium, and high intensity, respectively. Figure 3 shows two examples of chorus energy reduction associated with a boat passage.

## Discussion

We investigated how meagre choruses can change in the presence of a ferryboat. The sound level of meagre choruses decreased during boat passages, the levels resuming shortly after. Vieira et al. (2021b) showed that these changes are not random, meaning that on average, when boat passages occur, the reductions observed are more pronounced than what would be expected by chance. Furthermore, Vieira et al. (2021b) also presented cases where call activity was interrupted, suggesting that the sound level reduction was due to a reduction in the number of fish calling. This reduction in calling activity is consistent with the findings from other species, such as the reduction in chorusing of silver perch (another sciaenid, *Bairdiella chrysoura*) in response to whistles from predator bottlenose dolphins (Luczkovich et al. 2000) or

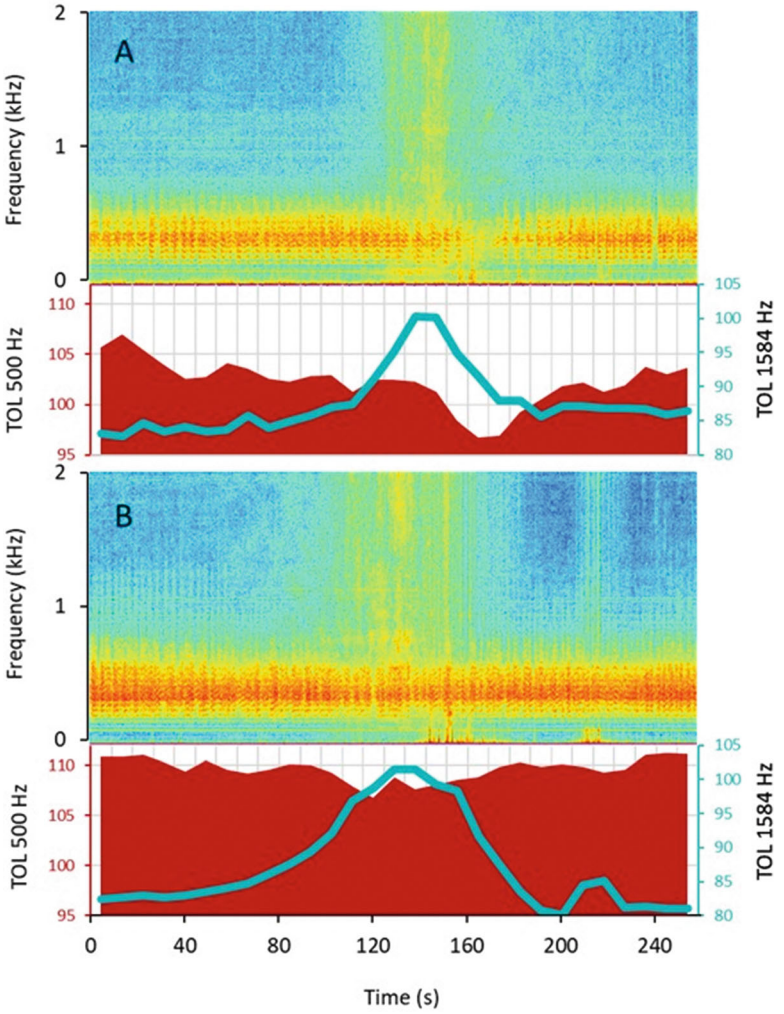

**Fig. 3** Example of the effect of a boat passage in the meagre chorus of (**a**) medium (100–110 dB) and (**b**) high intensity (>110 dB). Note that in (**b**), it is possible to observe a chorus dominated by long grunts with a high rate of overlap, forming a mostly continuous roar

the response of the Lusitanian toadfish that did not produce calls during boat noise playbacks (Alves et al. 2021).

Interestingly, other species have been shown to attempt to compensate for communication loss due to increased noise levels. For example, Picciulin et al. (2012) observed that the brown meagre *Sciaena umbra* increased pulse rate with repeated boat passages. Notice, however, that in cases where real boats were used (including the results presented here), the effect of boat noise could not be disentangled from those of visual and mechanical stimuli associated with the boat passage.

Here, it was further evaluated if the reaction in calling activity was affected by chorus intensity, and significance was found in the interactions between the main effect factors (period relative to the boat passage and chorus intensity classes). It was observed that when the chorus is of medium or high level, the reduction in energy of the chorus occurred more consistently (85% of the boat passages analyzed). In choruses of low intensity, a decrease in the chorus was observed in only 67% of boat passages. However, a higher variability in the response when the chorus had lower intensity was noticeable, i.e., the range in chorus sound level upon boat passages was larger (see boxplots in Fig. 1). Still, in most cases, a decrease in sound level was observed, and in some cases, disruption in the chorusing behavior was observed. Note that at the lowest chorus intensity, the increase in TOL 500 Hz due to the boat noise might be a confounding factor. Also, other confounding effects are associated with the fact that initial chorus intensity may result from the combination of the number of active calling individuals, individual calling activity, and the proximity to the hydrophone.

Whether the observed changes impact the reproductive behavior remains to be investigated. Recently, Amorim et al. (2022) reported a field experiment aiming to determine boat noise effects on Lusitanian toadfish reproduction. This study reported that boat noise elicited a stress response, reduced calling activity, and decreased the likelihood of a male receiving eggs. Although Lusitanian toadfish might be considered particularly vulnerable as they will lose their offspring if they abandon their nesting site, meagre may also be impacted. Sciaenids, as many other groups of species like groupers or cod (Zemeckis et al. 2019; Hughes et al. 2020), form spawning aggregations at predictable times and locations, which might make them particularly vulnerable (Erisman et al. 2017). Although these species are not attached to nesting sites, they are dependent on particular spawning grounds, and their fitness may be affected if they need to escape their spawning grounds to avoid noise or other stressors. Meagre use estuaries for spawning grounds where shipping and boating are often pervasive. If individuals continuously react to boat presence throughout the breeding season, this might have a significant impact on the mating rituals of this species. The permanence of aggregations in particular sites with chronic boat noise calls for further studies addressing possible fitness impacts (for further discussion, see de Jong et al. 2020).

**Abstract**

Anthropogenic noise is now recognized as a global pollutant and a major threat to marine biodiversity. It affects the behavior, physiology, communication, and reproductive success of many marine organisms. However, there are several remaining gaps in its effects on certain taxa, such as reef fish. This chapter provides an overview of studies regarding the impact of noise on reef fish. Important steps to guide future research are also discussed.

## Introduction

Biodiversity is a critical functional link to key ecological processes in reef systems and the consequent quality and provision of ecosystem services (Moberg and Folke 1999). Impacts such as overexploitation, eutrophication, and climate change are some of the major drivers acting synergistically and contributing to eroding reef resilience worldwide (Hughes et al. 2017). Noise pollution, despite having been exponentially growing in the last decades (Bittencourt et al. 2020; Duarte et al. 2021), is still neglected as a major threat to biodiversity with no proper management actions.

The underwater soundscape is formed by three main sound sources: biotic, abiotic, and anthropogenic, and it is an important proxy for understanding many ecological processes (Pijanowski et al. 2011). The understanding of how anthropogenic noise affects marine ecosystems has exponentially increased in the last few years (Duarte et al. 2021). Many studies have shown the increasing contribution of different anthropogenic noise sources in marine systems (Duarte et al. 2021). However, there are still many gaps in the effects of noise on species and ecological processes. Anthropogenic noise can affect behavior (Leduc et al. 2021; Nedelec et al. 2022; Velasquez-Jimenez et al. 2020), physiology (Fakan and McCormick 2019; Mills et al. 2020; Staaterman et al. 2020), and survival (McCormick et al. 2018) of different reef fish species, and doing so can exert direct and indirect ecological effects in the dynamics of reef systems.

Sound plays a crucial role in the dynamics of different species and consequently marine environments, including reefs. Due to the efficient propagation of sound waves, hearing is a primary sense in aquatic environments (Mooney et al. 2012; Putland et al. 2019). The acoustic signature of a reef, for example, is used by larvae for guidance during settlement and habitat use (Lillis et al. 2014). These acoustic cues can also be used in intra and interspecific interactions, including reproduction, territory and nest defense, foraging, predator-prey interactions, and many others (Popper and Hawkins 2019). Low-frequency noise (below 1000 Hz) from small vessels is the most frequent source of noise impact in shallow water areas (Bittencourt et al. 2014, 2020), and can overlap the same frequency range of hearing and sound production in many reef fish species (Lobel et al. 2010; Putland et al. 2019). A detailed understanding of the effects of different anthropogenic noise frequencies on reef species is critical to elaborate management rules to minimize impacts on species and critical functional processes.

Reef fishes are a diverse and abundant group in reef systems (Parravicini et al. 2013), being a classical ecological model for understanding the effects of different anthropogenic pressures (e.g., anthropogenic noise). Reef fish, as well as all vertebrates, can hear, but the aspects of their hearing capabilities are less known. There is

still a large gap in which species are vocal, and the types of vocalizations that are used (Ladich 2014). Many reef fish species use acoustic cues throughout their lifecycle, from settlement to habitat use (Gordon et al. 2018; Radford et al. 2011; Simpson et al. 2005). Damselfishes, for instance, are a great model for acoustic ecology studies, as territorial behavior makes them comparatively easy for experiments both in the lab and in the field. Also, vocalization in Damselfishes has been widely studied for territory and nest defense to reproductive interactions (Frederich and Parmentier 2016).

This chapter summarizes the main results found in the last few years regarding the effects of anthropogenic noise on reef fishes. The main topics for future research are also discussed.

## Effects of Anthropogenic Noise on Reef Fish

### Behavior

Anthropogenic noise affects different reef fish behavior across their life cycle, with behavioral changes usually being the first response of organisms to different environmental drivers (e.g., temperature, salinity). Looking at early life stages, Holles et al. (2013) showed primary evidence of how boat noise can negatively affect the selection of habitat by reef fish species. Later, a similar study indicated a disruptive effect of anthropogenic noise on the natural rate of settlement in reef fish larvae (Simpson et al. 2016a). The effects of noise on larvae settlement have been detected not only for tropical species but also for temperate ones (Jung and Swearer 2011). Those significant effects at early life-history stages could have detrimental effects on both populations and community levels. Survival rates are other important metrics used to evaluate the effects of anthropogenic noise on reef fishes. Recently, Nedelec et al. (2022) used both field and lab experiments to demonstrate how limited boat activity leads to greater survival rates of offspring. In "limiting-boat" conditions, the offspring of the spiny chromis *(Acanthochromis polyacanthus)* were more likely to survive, when compared to "busy-boating" conditions. The same pattern was seen for the ambon damselfish *(Pomacentrus amboinensis)* where less than one-third of recruits survived in boat noise treatments (Simpson et al. 2016b). Though, this is not always the pattern, as the survival rates of two other damselfishes did not alter after noise exposure in the laboratory (Fakan and McCormick 2019). Thus, these data suggest that more studies are needed to determine the differential effects of anthropogenic noise at earlier life stages of reef fishes.

Foraging is a crucial behavior not only for the performance of individuals but also for maintaining population dynamics since habitat use and food selection by consumers have been widely recognized to affect lower and higher trophic levels (Stephens et al. 2008). Some studies using damselfishes showed that individuals submitted to noisy conditions had lower foraging rates. For instance, a planktivorous damselfish, *Chromis chromis,* reduced its bite rates in the presence of heavy nautical traffic (Bracciali et al. 2012). The same pattern was observed for land-based

(Leduc et al. 2021) and underwater noise pollution (Lessa et al., *in prep)* on the *Stegastes fuscus* foraging behavior. Leduc et al. (2021) also experimented with flight-initiation responses to predators under elevated noise conditions, and found significantly reduced fleeing distance in these same conditions. Foraging in rays was also affected by noise pollution, since boat noise induced escape behavior (Berthe and Lecchini 2016; Mickle et al. 2022).

Increased refuge behavior is a common response of some species to a threat (Cooper and Blumstein 2015). For instance, territorial species are unable to move away in the presence of a stressor, due to their limited home range and swimming abilities. In a study with the red-mouth goby *(Gobius cruentatus)* noise playback significantly increased its refuge time for short-time exposures (Sebastianutto et al. 2011). A similar pattern was detected for the domino damselfish *(Dascyllus trimaculatus)* under noisy conditions (Nedelec et al. 2016).

Acute stress caused by noise may also increase aggression levels and, therefore agonistic interactions in reef fishes. Some studies found increasing aggressiveness in the presence of noise. Mills et al. (2020) highlighted that orange-fin anemonefish *(Amphiprion chrysopterus)* increased agonistic interactions toward heterospecifics when exposed to boat noise playback in two different exposure experiments. The same pattern was observed for the spiny chromis *(Acanthochromis polyacanthus)* males guarding nests exposed to boat noise playback (Nedelec et al. 2017). Increased territoriality in the presence of noise can affect other important aspects of reef fish life cycle. If they spend more time being territorial, they have less time to spend on other crucial daily activities, including parental care and mating, which may directly affect energy budget and individuals' fitness. However, Lessa et al. (*in prep*) found that noise does not necessarily increase agonistic interactions of the dusky damselfish *S. fuscus.* Therefore, the trade-off between territorialism and other crucial behaviors (e.g., parental care and mating) during noise exposure should be investigated.

## Physiology

Physiological responses, mostly associated with stress, are a central topic of discussion on the effects of noise on marine life. Noise can lead to primary (e.g., hormone release) and secondary responses (e.g., ventilation and heartbeat changes). For the first response, Armstrong-Smith (2016) observed elevated levels of corticosteroids in two reef fish species: starved green chromis *(Chromis viridis)* and spiny chromis *(Acanthochromis polyacanthus),* while Staaterman et al., (Staaterman et al. 2020) showed heightened whole-body cortisol levels of *Halichoeres bivittatus* to boat noise. Another physiological marker recognized as a stress response to boat noise was testosterone. Orange-fin anemonefish *(Amphiprion chrysopterus)* had elevated testosterone levels in short- and long-term experiments of noise exposure (Mills et al. 2020).

Noise can also have secondary physiological responses in reef fishes. An experimental study with embryos of the staghorn damselfish *(Amblyglyphidodon*

*curacao)* showed that heart rates significantly increased after exposure to 2-stroke and 4-stroke boat noises (Jain-Schlaepfer et al. 2018). Interestingly, the 4-stroke had a lesser effect on heart rates than the 2-stroke engines, where the latter had more than twice the effect. Possibly because the spectral content in terms of sound pressure levels, sound exposure levels and particle acceleration of the 2-stroke powered-boats was greater, when compared to the 4-stroke engines. Similarly, Fakan and McCormick et al. (Fakan and McCormick 2019) tested whether boat noise affected the early life history traits of the cinnamon clownfish *(Amphiprion melanopus)* and the spiny chromis *(Acanthochromis polyacanthus)*. The results showed that both species had elevated heart rates with the playback of boat noise compared to ambient noise. However, when looking at morphological traits the results diverged between species.

## What's Next?

### Starting from Scratch

Acoustic signals are used throughout a fish life cycle for orientation and settlement, and for different social interactions, including intra- and interspecific ones (Amorim 2006; Amorim et al. 2013; Gordon et al. 2018; Lobel et al. 2010; Radford et al. 2011). However, many species do not have their hearing range or the vocal repertoire fully described. This huge gap in acoustic ecology is keeping us distant from an integrative evaluation of the impacts of noise on wildlife. Therefore, future studies must focus on basic information about reef fish bioacoustics (e.g., hearing sensitivity, acoustic signatures), rather than just using applied science to evaluate the effects of noise.

### Integrative Approaches

Most studies focused on behavioral responses, nonetheless only a small number of studies explore the physiological responses of reef fishes to noise or even the interaction of both (see Mills et al. 2020). In addition to behavioral responses, physiological indicators of stress can also be used as proxies for the deleterious effects of noise. Physiology plays a vital role in understanding the mechanisms behind the effects of what we can see, such as changes in behavioral patterns. Thus, an important question may arise: how can physiological and behavioral responses be combined to address conservation efforts? Having longer experiments using combined response approaches (e.g., behavioral and physiological) is crucial to better understanding the effects of noise on wildlife. Also, it is important to evaluate the responses of key species, with different functional roles, to have a representative set of the ecological effects of noise, at both community and ecosystem levels.

## Multiple Contexts

From a conservation perspective, the effects of noise under multiple stressors (e.g., overexploitation, climate change, habitat loss) are still a topic we know little about. The responses of organisms to multiple stressors can be synergistic when the effect is greater, or antagonistic when the effect is minor (Côté et al. 2016). In natural systems, where the multiple-stressor-scenario is usual, isolating the effect of a single threat is a major challenge, and that is why most studies use a single-stressor approach in the field or prefer to run lab experiments, with controlled conditions. However, these results are not always realistic, as individuals and species may vary their responses depending on different contexts (Purser et al. 2016; Radford et al. 2016). Thus, experimental designs for multi-stressor studies should be explored and conducted to have a more naturalistic risk assessment of noise and, therefore, assist in conservation efforts.

## Across Scales

It is clear that there are still remaining gaps in reef fish responses to noise (Fig. 1) at different ecological and time scales. Such responses can vary with the type (e.g., low or high frequency sounds), duration, and time of exposure as well (chronic or acute, daily fluctuations) (Holles et al. 2013; McCormick et al. 2018). Although anthropogenic noise can be transient, there is an increasing number of noisy sources in the marine environment, such as ships, boats, wind farms, coastal constructions, seismic surveys, and many others (Duarte et al. 2021; Popper and Hawkins 2019). The continuous exposure to these sources may lead to habituation in some fish species, sometimes with recovering and even compensating for those stimuli (Nedelec et al. 2016; Picciulin et al. 2012). Therefore, extrapolation of short-term responses ranging from individual to population levels must be treated with caution, as some species may habituate and have different responses over time (*Pomacentrus amboinensis*: Holmes et al., 2017; *Dascyllus trimaculatus*: Nedelec et al. 2016; *Halichoeres bivittatus:* Staaterman et al. 2020).

Habituation itself is a controversial theme, as it may be associated with other unexplored topics, such as temporary and/or permanent noise-induced threshold

**Fig. 1** Conceptual diagram of the main topics for future research

shifts. Furthermore, defining response patterns and applying them from one species to another is a very simplistic approach, as some responses may be species-specific. For instance, Fakan and McCormick (2019) showed different responses in the morphological development of two damselfish species to the same noise. In addition, intrapopulation variation should also be investigated in more detail. Individuals of the same population cannot be treated as a homogeneous unit, as they can respond differently to anthropogenic stressors, due to intrinsic and extrinsic factors (Harding et al. 2018). Further research is needed to better understand: (1) how fish responses may change over time, and (2) how those responses change inside a population and through different taxa. Moreover, (3) how those individual responses have ecological significance and are indeed affecting population dynamics.

## Conclusions

Anthropogenic noise is a major concern for marine systems since noise has been recognized as a global pollutant. Despite recent efforts, the extent of knowledge on how it affects certain groups, like reef fish species, is limited. Some species can be affected by noise; however, a wide range of this impact on reef systems has not yet been determined and much work remains to be done. For instance, information about which species are more or less vulnerable to noise is crucial for management and decision-making in the future. There is also a lack of important basic bioacoustics information on reef fishes that would considerably enhance our understanding. Future research may explore the topics highlighted here for a better understanding of the range of effects of noise in reef systems.

**Abstract**

As noise pollution in coastal environments continues to grow, it is imperative to understand how it may be negatively impacting marine life. The study in this chapter tested whether noise from a real motorboat would alter the vocalizations of nesting plainfin midshipman fish (*Porichthys notatus*), a soniferous toadfish

that breeds in the intertidal zone and uses its vocalizations for courtship and defense. The results show evidence that wild plainfin midshipman guarder males may decrease their agonistic vocalizations in periods where they are exposed to large amounts of boat noise. There was an overall decrease in agonistic vocalizations on the nights when boat noise trials were run compared to control nights. While there was not a statistical difference in the number of agonistic vocalizations exhibited in sequential 10-minute periods with and without boat noise in the same night, there was a trend of fewer vocalizations during boat noise periods. This study helps elucidate how boat noise affects midshipman vocalizations in their natural habitat at the level of the individual, which has never been tested in plainfin midshipman fish and has scarcely been studied in other species.

## Introduction

Many marine animals rely on sound to communicate, perceive environmental cues, and detect prey and predators (Myrberg 1997). Anthropogenic noise in the ocean has risen drastically over recent decades, causing widespread changes to underwater soundscapes (Duarte et al. 2021). Contributing to these changes are activities such as construction, seismic exploration, and commercial shipping. In coastal environments, one of the primary contributors to noise pollution is recreational boating (Hermannsen et al. 2019). Accordingly, understanding the impacts of noise pollution on underwater soundscapes has become a major focus of current conservation research (Slabbekoorn et al. 2010; Duarte et al. 2021).

Many fishes use sound to communicate, and even nonvocalizing fish species rely on low-frequency sound for environmental perception, prey and predator detection, and navigation (Popper 2003; Slabbekoorn et al. 2010; Simpson et al. 2016). Noise pollution can have many negative effects on fish, including increased mortality by predation (Simpson et al. 2016), temporary hearing loss or altered auditory thresholds (Smith et al. 2004; Vasconcelos et al. 2007), physical damage to hearing structures (McCauley et al. 2003), distribution shifts away from noisy environments (Paxton et al. 2017), physiological stress responses (Wysocki et al. 2006; Nichols et al. 2015; Mills et al. 2020), numerous behavioral changes (Sarà et al. 2007; Sebastianutto et al. 2011; Nedelec et al. 2017; Mills et al. 2020), and masking of vocalizations (Vasconcelos et al. 2007). In addition to masking, noise can cause individuals to alter the amplitude, frequency, or duration of their vocalizations or to reduce how often they vocalize in the presence of noise (Holt and Johnston 2014; Brown et al. 2021).

In this study, a model soniferous toadfish species, the plainfin midshipman (*Porichthys notatus*), was used to investigate how boat noise affects fish vocalizations. Plainfin midshipman fish rely on acoustic communication for mate attraction

and defense (Zeddies et al. 2010). By rapidly contracting specialized sonic muscles attached to the gas-filled swim bladder, they produce three vocalizations: hums (tonal and lasting several minutes to over an hour), grunts (~0.5 s and either produced alone or in a series called a grunt train), and growls (frequency modulated and lasting up to several seconds; Brantley and Bass 1994; McIver et al. 2014). As the plainfin midshipman is nocturnal (Brantley and Bass 1994; McIver et al. 2014), they vocalize most often at night – hums in particular are often solely produced at night (McIver et al. 2014), with the chorus of hums peaking around midnight to 1 a.m. (Halliday et al. 2018; WDH and MBW, pers. obs.).

Every year in the late spring, plainfin midshipman fish migrate from deep waters to the shallow intertidal zone to breed. Nesting males endure a long (>60 days) and energetically costly parental care period in the intertidal zone (Bose et al. 2016), a habitat exposed to frequent noise from nearshore boat traffic (Halliday et al. 2018), during which they attract females using a mate advertisement hum, and care for their multiple clutches of eggs while continuing to attract new females (Brantley and Bass 1994). For spawning to occur, females must be able to hear and locate a male within his nest (Zeddies et al. 2010). Additionally, plainfin midshipman males use agonistic grunts and growls to defend themselves, their nests, and their young from rival males and predators (Brantley and Bass 1994; Woods et al. 2022). Consequently, masking of these vocalizations could have severe reproductive consequences and interfere with their ability to protect themselves and their territory.

The low-frequency noise generated by boats (e.g., recreational motorboats, commercial shipping vessels) can be particularly deleterious to species whose hearing is most sensitive to low-frequency sounds, and to those species that produce low-frequency vocalizations necessary for con- or heterospecific communication (e.g., defense) or for mate attraction. Like many fishes, the plainfin midshipman is most sensitive to low-frequency sound (Ladich 2014). The hum produced by nest-guarding, or "guarder" males, has a fundamental frequency of ~100 Hz, with dominant harmonics between 200 Hz and 400 Hz (Sisneros 2012; Halliday et al. 2018), while grunts and growls have a fundamental frequency of ~60–120 Hz (McIver et al. 2014). Therefore, plainfin midshipman vocalizations fully overlap the frequency range of boat noise (Halliday et al. 2018), resulting in the potential for masking of their crucially important mating hums, in addition to their agonistic low-frequency grunts and growls used for defense.

Animals sometimes alter the spectral (e.g., frequency, amplitude) or temporal characteristics of their vocalizations to overcome masking – a phenomenon known as the Lombard effect (Brumm and Zollinger 2011). Animals may also reduce their overall rate of vocalizations in the presence of noise in some cases (Miksis-Olds and Tyack 2009). This could be detrimental when the vocalizations are necessary to convey important signals, such as attracting a mate or deterring intruders. Recent work has shown that plainfin midshipman males can exhibit the Lombard effect when exposed to an artificial noise stimulus producing a tone of ~118 Hz along with several weaker harmonics (Brown et al. 2021). In that study, the males increased the amplitude of their hums, lowered the frequency of their vocalizations, and produced fewer of all three vocalizations (hums, grunts, and growls) in the presence of

artificial noise. However, that study used a relatively low-amplitude artificial noise stimulus that was both overpowered by and greatly resembled plainfin midshipman hums (Brown et al. 2021). How boat noise affects plainfin midshipman vocalizations in the wild has never been investigated.

This study expands the investigation of the Lombard effect by using a true anthropogenic noise stimulus (a motorboat driven near the nests) to explore whether plainfin midshipman alter their vocalizations as a strategy to overcome masking by anthropogenic noise pollution. It was predicted that boat noise would reduce the number of vocalizations produced, resulting in fewer vocalizations during boat noise periods compared to ambient control periods within the same night. In the future, the data will be further analyzed to quantify additional parameters of the vocalizations, including any changes to frequency and amplitude in response to boat noise.

## Methods

### Study Location and Nest Construction

Experiments were performed in June 2022 at a private beach in the Hood Canal region of Washington, USA. Four artificial nests were constructed from 929 $cm^2$ concrete tiles placed on small rocks to partially prop them up off the substrate on one side to encourage fish to enter and take them up as a nest. An area of the beach with the fewest natural nests was selected, and the artificial nests were placed at least 5 m away from each other and from all suspected natural nests (i.e., medium to large rocks that looked like they would make a good midshipman nest and/or rocks that had indications of being a nest, such as having a dug-out entrance or a shell midden outside a potential entrance).

The first three nests were placed in a horizontal row, parallel to the shoreline. As there was not room for a fourth nest in line with the first three due to the presence of many suspected natural nests, the fourth was placed 6 m behind (away from the shoreline) the third nest (Fig. 1).

The artificial nests were checked for occupancy every few days at low tide or by snorkelers when the nests were underwater. Once a male was discovered in one of the nests guarding a brood of eggs, the nest was covered with plastic mesh (1 $cm^2$ openings) weighed down by rocks along the edges to ensure that the same focal male remained for the duration of the experiment, as well as to exclude rival males, predators, or additional mates (Brown et al. 2021; Woods et al. 2022).

### Noise Stimulus

A 4-m aluminum hull boat with a four-stroke 9.9 horsepower engine was used as a noise stimulus. During the boat noise periods on each of the three trial nights, the boat was driven at full throttle continuously for 10-minute intervals, in loops with the closest point approximately 20 m from the nests (Fig. 1a). This distance was chosen

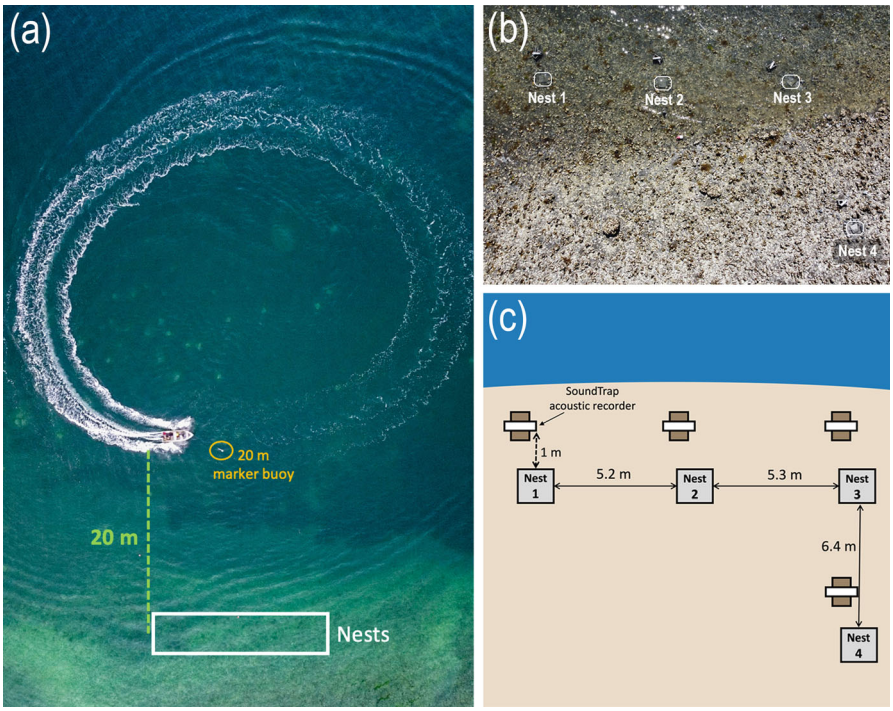

**Fig. 1** Nest layout and experimental setup: (**a**) An aerial photograph of the motorboat stimulus being driven in continuous loops during a boat noise period on a trial day. The four experimental nests are underwater in the area outlined in white. The closest point of the boat loop was 20 m away from the nests (shown in green) and was marked with a 20 m marker buoy (shown in yellow) to guide the boat loops; (**b**) aerial photograph of the artificial nests and acoustic recorders at low tide; and (**c**) schematic diagram of the layout of artificial nests and SoundTrap acoustic recorders on the beach. The distances between each of the four experimental nests and the acoustic recorders are noted. Recorders were placed 1 m in front of each nest. The waterline shown is at low tide; the nests were underwater during all experimental trials, as seen in (**a**)

because the nests were in shallow water, and therefore the boat noise they would naturally experience would rarely come from boats driven directly over the nests. The boat was always driven by the same individual (MBW) for consistency. SoundTrap acoustic recorders (Ocean Instruments New Zealand) placed 1 m away from each nest (Fig. 1c) were used to record the vocalizations of the focal fish as well as the received sound levels in both the boat noise and ambient control periods (Fig. 2).

## Experimental Trials

Because plainfin midshipman fish are nocturnal, this experiment was conducted at dusk. Trials were conducted between 20:10 and 21:30 for 5 consecutive days

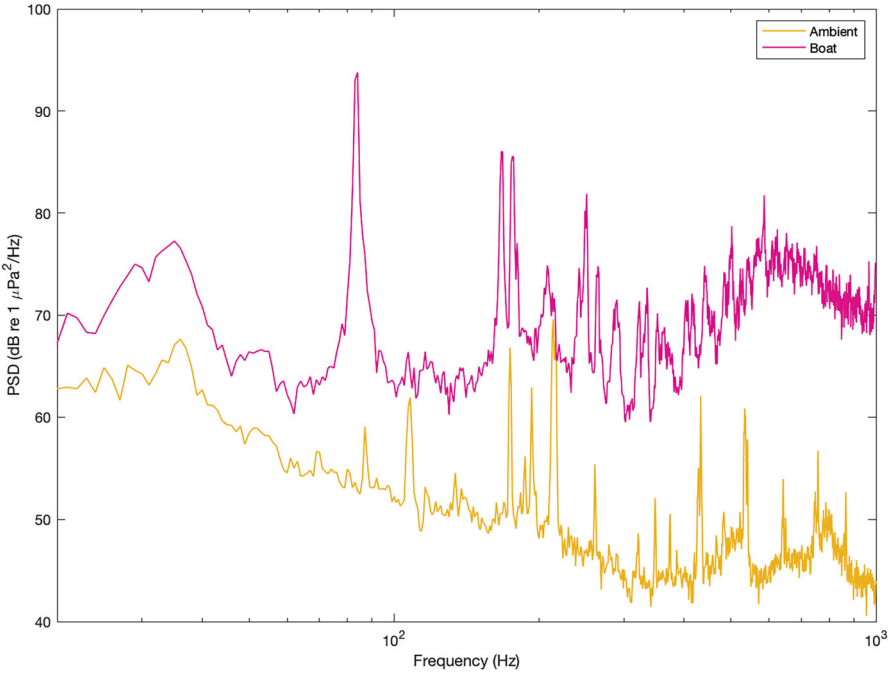

**Fig. 2** Power spectral density (PSD) of the sound levels in the ambient trial periods (gold), with no motorboat or introduced noise, and the boat noise trial periods (pink), during which a motorboat with a 9.9 hp engine was driven in continuous loops at full throttle

between June 23 and 27, 2022. The 5-day sequence consisted of two control nights (with no boat noise) and three trial nights (with boat noise) in the following order: Pre-Trial Control Night, Trial Night 1, Trial Night 2, Trial Night 3, and Post-Trial Control Night (Fig. 3). On the first day, acoustic recorders were deployed, and that night (the "Pre-Trial Night") the fish were left undisturbed, and their vocalizations were recorded. The second night (Trial Night 1), boat noise trials began. Immediately before trials, the boat was quietly rowed until it was in deep water far away (>150 m) from the nests, where the engine was then started and allowed to warm up before exposing the fish to the boat noise. Starting approximately 45 min before sunset, the first boat treatment began.

Each boat noise treatment was 10 min long and consisted of the boat being driven in loops continuously (Fig. 1a). After 10 min, the boat engine was turned off and the first 10-minute ambient control period began. This was repeated until there had been three boat noise periods. There was then a 10-minute follow-up period once the boat engine was shut off for the final time (Fig. 3). Before each boat noise period, the boat was started far away (>150 m) from the nests (after a full 10 minute of engine-off ambient), and the 10-minute noise period only commenced when the boat started the full-throttle loops. The interval between the boat engine being started and the beginning of each boat noise period were not analyzed for vocalizations.

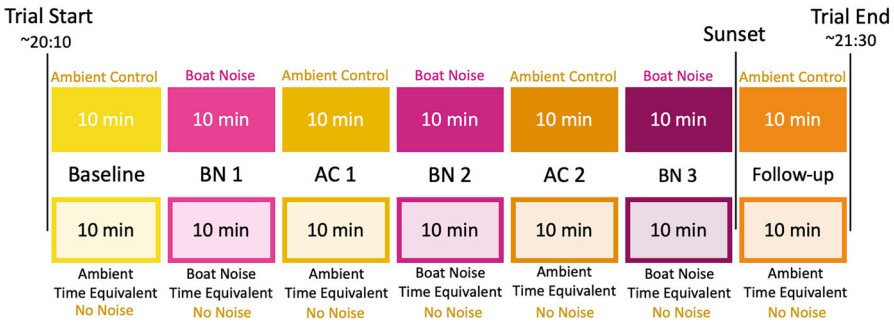

**Fig. 3** Nightly timeline showing the order of trial periods during which vocalizations were analyzed. Trial nights (top) had alternating ambient and boat noise periods, and control nights (bottom) had no boat present and no noise introduced. The colors correspond to the colors of each trial period in the results figures, with variations of yellow/gold/orange as ambient control periods and variations of pink/purple as boat noise periods. (Note: The darkening colors correspond only to time of night and not stimulus intensity)

This sequence was repeated on each of the next two nights (Trial Night 2 and Trial Night 3). On the fifth and final day (Post-Trial Night), the boat was not present and no noise was introduced, but the recordings were analyzed for vocalizations. The two control nights (Pre- and Post-Trial Nights) were used to control for any patterns or variation in vocalizations relating to time of night.

## Acoustic Analysis

All acoustic recordings were analyzed using Raven Pro acoustic software. Spectrograms were built in Raven Pro with 7000 samples, a Hanning window with 50% overlap, and time and frequency axes set to 10 s and 1000 Hz, respectively. The 10 minutes before the boat was initially turned on was scored as a baseline period, and each of the 10-minute boat noise and ambient control periods were scored. All vocalizations from the focal male of each nest were annotated in Raven Pro, where the peak frequency and duration of each vocalization were measured, and number of vocalizations per 10-minute period were counted. Vocalizations were assigned to the focal male based on the higher relative amplitude of the vocalizations suspected to be from the focal male compared to fainter vocalizations within the same file.

## Statistical Analysis

All statistical analyses were conducted in RStudio (v.2022.07.2; R Core Team 2021). Agonistic vocalizations were defined as the sum of grunts and growls for each fish within each trial period, over each of the 5 days.

A negative binomial generalized linear mixed effects model (GLMM) (*glmmTMB* package; Brooks et al. 2017) was fit to these counts of agonistic vocalizations over the 3 trial days (i.e., days that included the boat noise treatment) to examine whether there was a difference in the number of agonistic vocalizations during boat noise periods versus ambient control periods. Nest ID was included as a random intercept to account for the within-subjects study design, and acoustic treatment (ambient control or boat noise) was the fixed effect. Likelihood ratio tests were used to assess the statistical significance of the acoustic treatment effect.

A second negative binomial GLMM was then used to assess whether there was a difference in overall vocalization count during control nights (Pre-Trial and Post-Trial Nights; no boat noise) or experimental trial nights (Trial Nights 1–3; boat noise present). Again, the nest ID was included as a random effect and the fixed effect for this model was night type (trial or control). Likelihood ratio tests were used to assess the statistical significance of the night type effect.

Statistical analyses were not performed for mating hum vocalizations because there were too few hums present in the experimental recordings.

## Ethical Note

All procedures in this study complied with guidelines set by the ASAB/ABS (2012) and the Canadian Council on Animal Care (Olfert et al. 1993) and were approved by the University of Victoria Animal Care Committee (AUP: Juanes-2021-012). All procedures implemented were noninvasive. Following experimentation, the mesh was removed from the nests, all equipment was removed, and fish were allowed to continue guarding their brood in their artificial nests at the study site for the remainder of the breeding season.

## Results

There was no significant difference in the number of vocalizations during the ambient control periods (including the baseline period) and the boat noise periods on the three trial nights ($\chi^2 = 1.08$, $df = 1$, $p = 0.30$; Fig. 4). However, the figures show that there may have been slightly more vocalizations in the ambient periods compared to the boat noise periods, particularly on the first and second trial nights, during which no fish vocalized in any of the boat noise periods (Fig. 5); however, this pattern was not statistically significant. As expected, there was also no difference in the number of agonistic vocalizations during the ambient and boat noise time-equivalent periods on the control nights ($\chi^2 = 0.27$, $df = 1$, $p = 0.61$; Fig. 5). However, there were overall more vocalizations during the control nights compared to the trial nights ($\chi^2 = 6.95$, $df = 1$, $p = 0.0084$; Fig. 6).

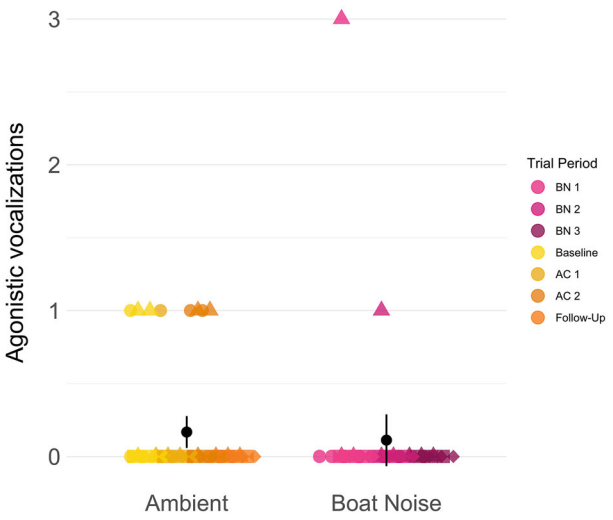

**Fig. 4** The number of agonistic vocalizations (grunts and growls), exhibited by each of four nesting plainfin midshipman guarder males during each 10-minute trial period, comprised of alternating ambient control periods and boat noise periods, pooled across the three trial nights. ## Discussion

There was evidence that nesting plainfin midshipman guarder males may decrease their agonistic vocalizations (grunts and growls) in periods when they are exposed to large amounts of boat noise. While there was not a statistical difference in the number of agonistic vocalizations exhibited in sequential 10-minute periods with and without boat noise, there was a pattern of slightly fewer vocalizations during boat noise periods. Furthermore, there was a significant overall decrease in agonistic vocalizations on nights when boat noise trials were conducted, compared to control nights.

Our findings are consistent with Brown et al. (2021) which found that plainfin midshipman guarder males elicited fewer vocalizations (grunts, growls, and hums) in the presence of introduced artificial noise. However, the present study is the first to test whether plainfin midshipman fish alter their vocalizations in response to boat noise. Brown et al. (2021) also found that the plainfin midshipman males increased the amplitude of their hums and lowered the frequency of their vocalizations (i.e., exhibited the Lombard effect) in response to the artificial noise stimulus, which had a fundamental frequency of ~118 Hz with several weaker harmonics, and which strongly resembled a midshipman mating hum. The results presented in this chapter are preliminary and represent only a small part of a larger study, which will also examine whether the males at the study site exhibited the Lombard effect in response to motorboat noise by altering the amplitude or frequency of their vocalizations. The

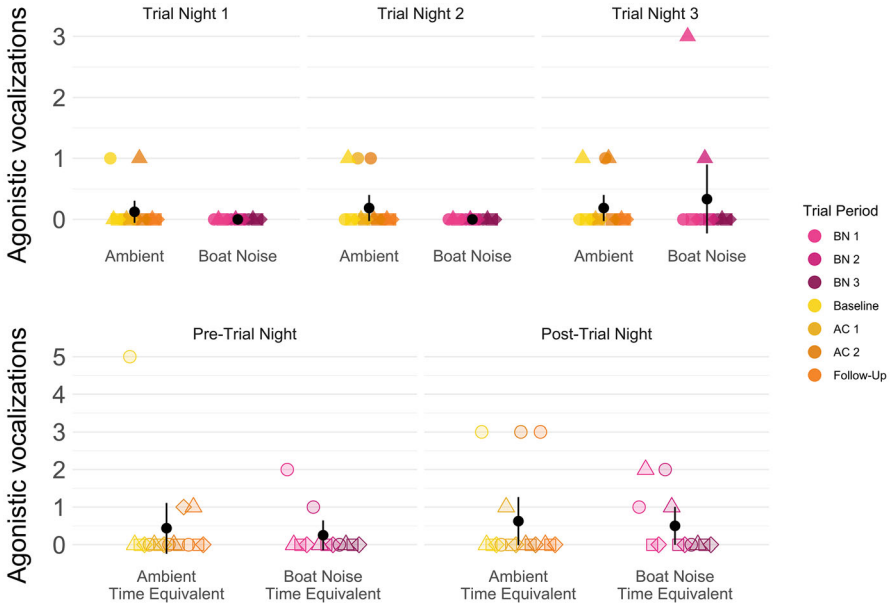

**Fig. 5** The number of agonistic vocalizations (grunts and growls), exhibited by each of four nesting plainfin midshipman guarder males during each 10-minute trial period, comprised of four ambient control periods and three boat noise periods, on each night in the five-night trial sequence. Top: the three trial nights; in these trials, the boat periods consisted of a motorboat being driven continuously at full throttle. Bottom: control nights before and after the three trial nights; there was no motorboat or introduced noise present during any part of the control trials, as the control nights were analyzed to compare the vocalizations in each corresponding period to the trial nights. The shapes correspond to the four individual fish tested. The means and 95% confidence intervals are shown in black

results of this study will help us understand whether the previous results reported in Brown et al. (2021) were due to the males trying to overcome masking by low-frequency anthropogenic noise or if they were trying to outcompete what resembled the hum of an additional rival guarder male.

Several studies have found decreases in fish calling rates in the presence of noise (Ladich 2019), consistent with the results of both the present study and those of Brown et al. (2021). For example, de Jong et al. (2018) tested two species of goby in the lab and found a reduction in acoustic courtship during noise playbacks in both species. This reduction in courtship vocalizations may have contributed to the lower spawning success of painted gobies in the noise treatment group. In the field, Mackiewicz et al. (2021) observed a 32% decrease in male oyster toadfish vocalizations post-exposure to an idling boat engine compared to pre-exposure calling rates. In contrast, increases in calling rate in the presence of noise are commonly observed in birds and mammals to increase signal redundancy – an additional tactic that can be used to overcome masking (Shannon et al. 2016). This increase in calling rate has also been found in fish in a few studies (e.g., Picciulin et al. 2012), but it

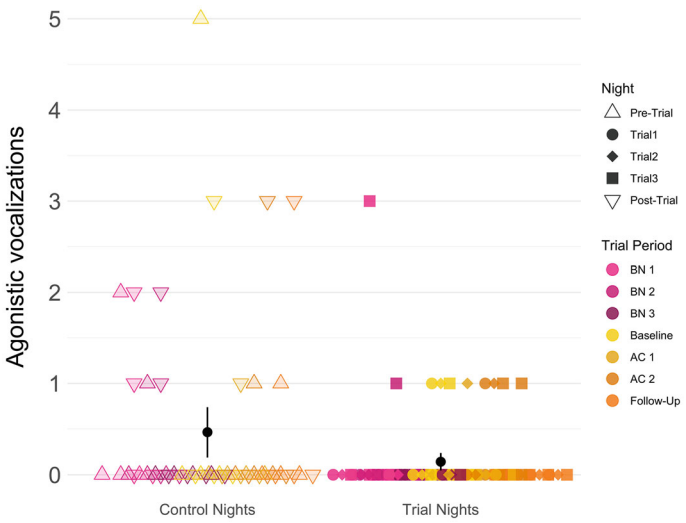

**Fig. 6** The number of agonistic vocalizations (grunts and growls), exhibited by each of four nesting plainfin midshipman guarder males during each 10-minute trial period, comprised of four ambient control periods and three boat noise periods, pooled across the two control nights and the three trial nights to compare the overall number of vocalizations present on nights when boat noise was (trial nights) and was not (control nights) present. In the control night "boat noise" periods (BN 1–3; pink data points), no boat or introduced noise was present, as the control nights were used to compare equivalent time periods of the evening to the trial nights when boat noise was present. During the boat noise periods (BN 1–3; pink data points) on trial nights, a motorboat was driven in continuous loops at full throttle. During ambient control periods (Baseline, AC 1–2, and Follow-Up; gold points), the boat engine was shut off and the boat was far from the nests. The means and 95% confidence intervals are shown in black

appears that it may be a less commonly used tactic among fishes given the number of studies reporting the opposite pattern of decreased calling rates during noisy periods.

The primary limiting factor of the current study was the small sample size. This may be why there was only a slight trend of fewer vocalizations during boat noise versus ambient trial periods but not a significant difference. However, the individual-level data of the four fish discussed in the current chapter are only one component of a larger overarching study; additional fish were tested at the group level. The group-level data contain far more vocalizations and will enable us to better assess the effect of the experimental boat noise on all three types of vocalizations – agonistic grunts and growls and the mating hum. The preliminary group-level data are pointing toward a decrease in the number of agonistic vocalizations during boat noise periods, as well as a potential decrease in humming. Further analysis of the data collected in both the group- and individual-level experiments will contribute to our growing understanding of the ways in which anthropogenic noise alters fish vocalizations.

## Conclusion

It was evidenced that plainfin midshipman males may reduce their calling rate in the presence of motorboat noise, but those results were not conclusive, and additional data would be required to draw firm conclusions. The overall decrease in vocalizations on trial nights compared to control nights indicates that boat noise did decrease the rate of agonistic vocalizations. However, when comparing sequential boat noise and ambient control periods on trial nights, the data visualization suggests that there might be fewer vocalizations during boat noise periods, but that did not turn out to be a significant pattern. The results were likely impacted by the small sample size; however, a complementary experiment was conducted on groups of nesting plainfin midshipman males and the addition of those data (once analyzed) will allow stronger conclusions to be drawn. Future analysis, both on the individual-level data presented here and the group-level data still being analyzed, will include assessing whether frequency or amplitude of midshipman agonistic vocalizations or mating hums are altered by boat noise.

**Abstract**

Red drum (*Sciaenops ocellatus*), a vocal fish species found in waters along North America's East Coast and northern Gulf of Mexico, forms large, vocal spawning aggregations in near-shore waters. These in-shore regions also experience frequent vessel traffic, both commercial and recreational, and resulting noise pollution is predicted to negatively impact sound-producing fishes. Noise pollution can increase hearing thresholds, damage sensory epithelia, and alter behavior. The aim of this research was to determine how often red drum calls are masked and how they respond via sound production. During 2021–2022, vessel noise and fish sounds were obtained via passive acoustic recorders in Saint Andrews Bay, Panama City Beach, Florida. Presented here are preliminary analyses of October 2021. Red drum sounds occurred frequently at this site during spawning season (June–November). Red Drum calling peaks immediately after sunset and significant overlap was found between chorusing and vessel noise during this calling period. The contribution of call pulse number, vessel noise, and sound pressure was tested. Preliminary results indicate red drum decreases call rate when intense boat noise occurs, and calls are masked. This suspected behavior modification and subsequent call masking could decrease spawning success and impact fitness.

## Introduction

In recent decades, anthropogenic noise has steadily increased in marine coastal habitats, such as bays and estuaries. Vessel noise associated with commercial and recreational boat traffic is a major component of this noise pollution, in addition to construction of renewable energy infrastructure and seismic exploration (Duarte et al. 2021; Hildebrand 2009). Coastal regions experience disproportionate anthropogenic impacts as human activity is coastally concentrated (Crossett et al. 2013). Coastal habitats are important to marine animals, biologically productive, and used by many species at different life stages for foraging, shelter, migration, spawning, and nursery habitat (Seitz et al. 2014).

In addition, sound travels farther in water than in air, making the region of impact of noise pollution much larger, particularly from sources of low-frequency sound (Rogers and Cox 1988). Vessel noise is often low frequency and overlaps with the call spectra and bandwidth of hearing of many fish species (Duarte et al. 2021; Ramcharitar et al. 2006). This makes it ever more critical to assess implications of vessel noise in coastal waters as its effects may be widespread and varied.

Noise pollution has been shown to cause organ and tissue damage, produce shifts in hearing sensitivity in fishes, and alter animal behavior (Duarte et al. 2021). Shifts in behavior can include conspecific interactions (de Jong et al. 2018), habitat use, and changes in acoustic behaviors (La Manna et al. 2016; Picciulin et al. 2012; Vieira et al. 2021). With so many impacts already documented, it is critical to continue to study effects of noise pollution on fish and their sound production. Thankfully, fish sound production can be readily studied via passive acoustic monitoring (PAM) in coastal waters.

## Study

The goal of this study was to observe red drum (*Sciaenops ocellatus*) spawning aggregation vocal behavior in the presence of anthropogenic noise. Red drum is a member of the family Sciaenidae, which includes several economically and ecologically important species (National Marine Fisheries Service 2022). This species ranges throughout the Gulf of Mexico and along the East Coast of North America as far north as Massachusetts. Individuals in the Gulf can reach ~110 cm total length (Bennetts et al. 2019; Hightower et al. 2022). In the summer and autumn, fish form

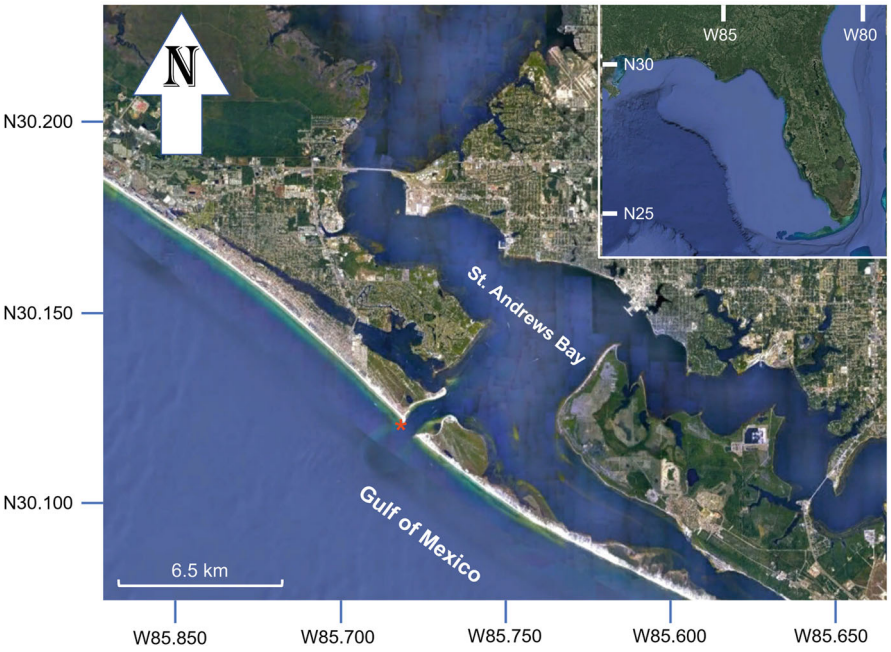

**Fig. 1** Site of recorder (*), St Andrews Bay, Florida, USA

large, high density spawning aggregations in coastal waters (Monczak et al. 2022). These aggregations are associated with intense choruses made by male fish that peak August through October. Peak chorus activity is also associated with seasonal abundance of young of year fish in the months after (Monczak et al. 2022). These sounds consist of multiple repeated pulses in rapid succession and are produced via activation of the sonic muscles near the swim bladder (Tower 1908).

Coastal waters in the northern Gulf of Mexico experience both recreational and commercial boat traffic that co-occur with fish sound production behavior. In 2021–2022, Saint Andrews Bay Pass, which runs through Saint Andrews State Park, Florida (Fig. 1), was monitored with a semiautonomous recorder (SNAP recorder, Loggerhead Instruments) during the red drum spawning season (June–November). The recorder was set to record 45-second files on a 15% duty cycle. For preliminary analysis, every file from a 2-h crepuscular period (30 min prior to sunset, 90 min post sunset) was screened for each day in October 2021. This time was chosen as it is when red drum spawning activity is most prevalent (Holt et al. 1985; Lowerre-Barbieri et al. 2008; Monczak et al. 2022). Files 12 h prior to this period were screened for vessel activity with the focus being on files with high-intensity SPL (>120 dB re 1 μPa) in the 0–1000 Hz band, which encompasses the dominant bandwidth of red drum calls (Fish and Mowbray 1970). Through this, fish and vessel interactions and how fish responded to anthropogenic sound were observed via PAM.

## Hypotheses and Predictions

Sound-producing fish may respond to vessel noise in several different ways. One hypothesis (disturbance hypothesis) is that fish may be disturbed by noise which would cause fish to reduce vocal activity. An alternative hypothesis is that fish may compensate (compensation hypothesis) to increase or alter calls to compete with higher background noise. Finally, fish may ignore vessel noise and not modify vocal behavior (nonresponse hypothesis).

A prediction of the disturbance hypothesis (prediction 1) is that fish might be disturbed and lessen or completely cease calling immediately when exposed to noise pollution which was termed masking avoidance. Vessel noise could also disrupt fish calling immediately after vessel noise (immediate disruption). Fish could also show a decrease in calling outside of vessel noise periods events as the level of exposure to vessel noise throughout the day is increased (daily disturbance) or as the amount of boating during the crepuscular period is increased (evening disturbance). If fish reduce calling at any point due to vessel noise, this will reduce the time spent calling to conspecifics and potentially reproductive success.

A prediction of the compensation hypothesis prediction (prediction 2) is that fish may compensate for background noise via an increase in their call rate during vessel noise (masking compensation) Fish could also increase pulse rate immediately after vessel noise exposure (immediate compensation), increase call rate when prior noise exposure during diurnal hours occurs at a higher rate of occurrence (daily compensation), or increase overall pulse rate throughout the entire crepuscular period, even during intervening quiet times, when vessel noise occurrence increases during these periods (evening compensation). Another means of compensation for increased background noise is the Lombard Effect. This is displayed when an animal modifies its call frequency or intensity to be heard while exposed to competing sounds (Lombard 1911; Zollinger and Brumm 2011). A compensation response during boating events would be wasted effort of the part of the calling fishes expending energy if conspecifics are unable to perceive the acoustic signal.

The nonresponse hypothesis (prediction 3) predicts that fish will not change their call rate, amplitude, or frequency during or immediately after vessel noise, or based on exposure to vessels over a given period (daily or evening exposure). This also represents wasted efforts for reproductive fishes if calls are being masked during these events to the degree that signals are not received, and fish might have greater reproductive successful if waiting to call outside of vessel noise.

## Analysis

A positive correlation between fish pulse rate and the SPL of the 0–600 Hz band was observed. This allowed for use of SPL in this band as proxy for fish calling outside of masking events. During vessel noise, fish calls are only discernible below an SPL where boats fully mask fish calling. This study is also limited in its ability to address whether single vessel noise events impact fish calling rate or amplitude immediately after a vessel passed (immediate disturbance) because the duty cycle and brief file

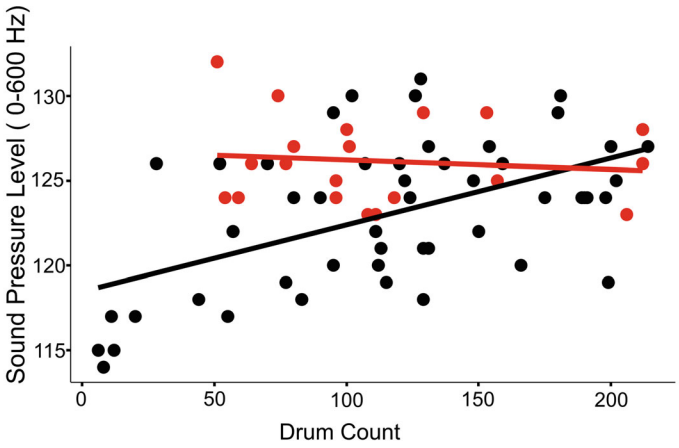

**Fig. 2** Relationship between band (0–600 Hz) sound pressure level (SPL) and red drum call pulse number in the presence and absence of vessel noise ($R^2 = 0.30$). SPL has a positive relationship with drumming in the absence of vessel noise. During vessel noise, however, lower pulse rates are associated with higher SPL, which is consistent with the prediction that high vessel noise (which increases overall SPL) reduces calling

duration limits the opportunity for vessel noise detection, vessel noise cessation, and potential vocal response by fish to occur within 45 s. Analysis of continuous recordings made at the study site in 2022 is in progress. However, preliminary data show that during vessel noise occurrence, the greater sound amplitudes were associated with lower pulse rates, which is consistent with predictions of masking avoidance**,** not masking compensation (Fig. 2). Continued analysis for both 2021 and 2022 full spawning seasons is ongoing.

This decrease in pulse rate could be because fish alter their acoustic behavior or vacate habitat when noise pollution is present. Previous studies have shown similar responses in other species. In another sciaenid (meagre, *Argyrosomus regius*), chorusing was diminished and at times fully disrupted by the passage of vessels in Portugal's Tagus estuary (Vieira et al. 2021). Also, two goby species (*Pomatoschistus pictus* and *Gobiusculus flavescens*) both showed decreases in sound production as part of their courtship when exposed to noise in the lab (de Jong et al. 2018).

This research also looked at how fish responded to vessel noise exposure outside of periods when vessel noise was present. To test for disturbance/compensation as a response to daily levels of exposure, call rate of periods without vessel noise during the crepuscular period were measured and compared to the rate of intense vessel noise (>120 dB, 0–1000 Hz band) 12 h prior to sunset for each day in October 2021.

There was no correlation between prior diurnal vessel noise and subsequent red drum pulse rate during crepuscular periods when vessel noise was absent (Fig. 3a) and thus no evidence for daily disturbance or daily compensation of red drum vocal behavior. Similarly, in October 2021 there was no correlation between vessel noise occurrence during the crepuscular period and red drum pulse rate during quiet intervening times during the same crepuscular period (Fig. 3b). This observation is

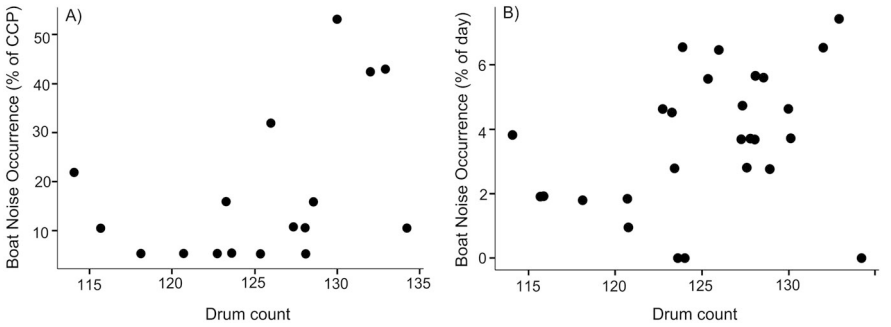

**Fig. 3** Percent of CCP (crepuscular calling period) calculated experiencing vessel noise (>120 dB, 0–1000 Hz) as compared to SPL of files without vessel noise (**a**). Percent of 12 h prior to evening calculated experiencing vessel noise (>120 dB, 0–1000 Hz) as compared to SPL of evening files without vessel noise (**b**). Neither show a significant relationship (**a**) $R^2 = 0.12$, (**b**) $R^2 = 0.18$

not consistent with predictions of evening disturbance or evening compensation. These preliminary findings indicate fish may be undisturbed by vessel noise immediately following vessel noise events. However, these data are still preliminary and limited to October 2021. Analysis of data over the two spawning seasons continues to better understand how vocalizing red drum respond to vessel noise.

These early findings indicate that red drum sound production may be disturbed during vessel noise, but it is not known if or how long sound production is disrupted following noise exposure. Sound production disruption during and following vessel noise exposure was observed in meagre, a related sciaenid species (Vieira et al. 2021). In contrast, in another sciaenid species (Brown meagre, *Sciaena umbra*), fish displayed increased vocalization rates after repeated boat exposure (Picciulin et al. 2012). Though the authors note, boat noise was too great to assess fish sounds during masking. However, in Sarasota, Florida, the presence of ferry boat traffic was found not to impact the vocalizations of Atlantic croaker (*Micropogonias undulatus*) (Luczkovich et al. 2012). Additionally, brown meagre in Venice, Italy did not show any avoidance of louder waterways in a study that used sound production as a measure for fish presence (Picciulin et al. 2022). It was hypothesized that other attributes, such as bathymetry, made noisy habitat desirable even over quieter waters (Picciulin et al. 2022).

Methods continue to be assessed and adjusted to better understand impacts on fish at the study site. Measuring vessel noise exposure 12 h prior to crepuscular calling period may not reveal the full extent of behavioral modification if it is occurring. The impacts of vessel noise in such a highly trafficked area may be compounded over days or even weeks of exposure. The current aim to address this question with further analysis over the two seasons of data collected and measuring vessel noise over greater periods of time.

It is possible that red drum exhibits the Lombard effect to adjust their call features to compensate for increased background noise when vessels are present. Both plainfin midshipman (*Porichthys notatus*) and oyster toadfish (*Opsanus tau*) were recorded with increased amplitude (Lombard effect) during noise exposure to compete with background sound (Brown et al. 2021; Luczkovich et al. 2017).

Interestingly, plainfin midshipman also lowered the frequency of their calls, in addition to increasing amplitude, when noise exposed (Brown et al. 2021). Red drum presents a challenge to measure the Lombard Effect as fish aggregations do not allow for responses in individual fish to be observed. With choruses, an increase in amplitude could indicate individuals in the group increased call amplitude or more fish in the aggregation vocalized. Methods continue to be explored which might better answer how choruses might change based on noise exposure and if the Lombard Effect is occurring with this species.

Another methodological challenge faced is vessel noise is highly variable, both in terms of vessel types producing sound and the source distances from the recorder. Noise source distance impacts the relative contribution of sound pressure and particle motion, which the HTI hydrophone does not measure. Particle motion is the primary way fish perceive sound and so should be considered in noise pollution studies (Higgs and Radford 2012). Additionally, with noncontinuous recordings, there exists a lack precision when addressing impacts of individual instances of boat noise during the time when fish are calling.

Call masking by background noise, either partially or wholly, presents a major issue in communication. Masking has been documented in terrestrial and aquatic environments (Halfwerk et al. 2011; Templeton et al. 2016) and is of major concern because it can obscure biologically important signals. In the May River, South Carolina, it was shown that spaces where fish were communicating via sound also contained vessel noise and this noise overlapped in the sound spectrum with fish calls. The researchers also saw overlap in the time when fish chorused and vessel traffic occurred. This interaction was observed with several sciaenid species during their spawning period (Smott et al. 2018). This study also confirmed multiple soniferous species co-occurring with vessel sound in Saint Andrews Bay Pass. However, the auditory system of red drum will need to be further investigated to fully understand what extent vessel noise is masking calls for this species.

Boat noise in Saint Andrews Bay Pass was highly prevalent and led to substantial levels of masking. Crepuscular calling periods on two nights were over 90% masked. This could lead to whole evenings during the spawning season representing wasted effort if fish are unable successfully communicate or reproduce in these conditions, potentially impacting population fitness. Further analysis of field recordings will be required to assess if this is a common trend throughout the spawning season and in other times of the year. However, the full extent of masking can be difficult to assess as background noise grows more intense. There is a finite window in which masking is observable via PAM (Figs. 4 and 5), and it is still important to know when fish sounds are complete masked. Future work in lab will better address if fish alter calling when exposed to such high-intensity noise.

## Impact

Passive acoustic monitoring Saint Andrews Bay showed that red drum is impacted by masking from vessel noise. During vessel noise, call rate was reduced as SPL of noise increased. This along with the extensive levels of vessel noise and masking

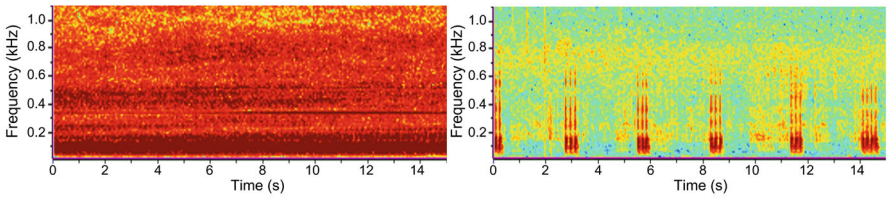

**Fig. 4** Spectrograms showing 15-second intervals of field recordings (0–1.1 kHz). Left – high-intensity vessel noise. Right – six instances of red drum calling with minimal background noise

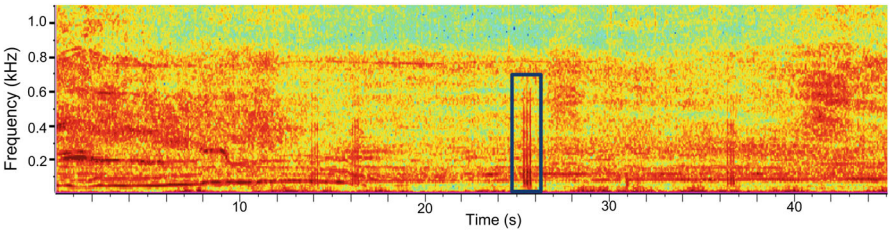

**Fig. 5** A 45-second spectrogram showing red drum calls (highlighted) coinciding with low-frequency (0–1.1 kHz) vessel noise resulting in observable masking

observed means that time spent with reduced calling is likely significant. This large amount of exposure to vessel noise could also be impacting animals in other ways not measurable through PAM, such as hearing threshold changes, tissue damage, or predator–prey interactions. Additionally, there were vocalizations from several other species observed on recordings that may also be impacted by this high rate of vessel noise.

Continuous PAM recording will also allow further insights to animal and vessel noise interactions that can be missed on duty cycle deployments. Immediate impacts post noise exposure may not always be seen on shorter recordings and the full scope of anthropogenic sound may not be fully represented. There is research currently working toward this goal currently with continuous recordings being made in the same location during the 2022 red drum spawning season. These recordings along with continued in lab experiments will allow for greater understanding of about red drum response to vessel noise in the northern Gulf of Mexico. Additionally, future analysis of both 2021 and the 2022 spawning seasons will allow for test of predictions (disturbance, compensation and nonresponse) of these alternative hypotheses of how vocalizing red drum respond to vessel noise.

**Abstract**

Most marine soundscapes have changed due to the massive presence of anthropogenic noise. Lusitanian toadfish (*Halobatrachus didactylus*) is a vocal fish species that has been recurrently used as a model in both behavioral and physiological studies, making it an excellent species also to understand the effects of aquatic noise. This chapter aims to review what is known about the effects of boat noise on this species and its possible implications. Vocal behavior, hearing, reproduction, and early stages development of the Lusitanian toadfish are summarized, including several studies that observed effects of boat noise on this species in these different topics. Boat noise can disrupt and decrease calling activity, mask environmental and conspecific signals, reduce reproduction success, induce stress, affect parental care, and even affect larvae development. These results warn of the possible severe effects of noise pollution on fish and warrant the need of further studies addressing the consequences of noise at the population level.

## Introduction

There are over 30,000 species of fish that have adapted to numerous aquatic environments showing a remarkable diversity in behavior, anatomy, physiology, and ecological adaptations (Helfman et al. 2009). However, human activities are affecting marine ecosystems at unprecedent rates (Villéger et al. 2017). Aquatic noise pollution is one important form of pollution. Indeed, it is so chronic and widespread that its effects have changed underwater soundscapes all around the globe (Duarte et al. 2021). The major sources of anthropogenic noise include commercial shipping, recreational boating, pile-driving, seismic surveys, and power stations, but in shallow waters one of the most prevalent sources of underwater noise are boats (Hildebrand 2009; Popper and Hawkins 2019; Vieira et al. 2021a).

Sounds can be a rapid, directional way to convey critical information through short and even long-distance to marine animals (Hawkins and Popper 2018). However, anthropogenic noise can mask sounds of interest, affect behavior, increase stress levels and trigger other physiological effects, or even cause physical injuries or death in fishes (Duarte et al. 2021; Pine et al. 2021). In this context, here is reviewed what is known from the highly vocal Lusitanian toadfish (*Halobatrachus didactylus*) as a model to understand the impact of this anthropogenic stressor on fishes.

## Vocal Behavior

The family Batrachoididae is known to include several highly vocal fish species that rely on acoustic communication for reproduction (Bass and McKibben 2003), such as the Lusitanian toadfish (Vasconcelos et al. 2012). This species has a remarkably large repertoire that includes calls like the boatwhistles (BW), croaks, double croaks, long grunt trains, and several combinations of these sound types (see Amorim et al. 2008, for details of the vocalizations). Males calling activity peaks from May to July, corresponding also to the peak of time nest occupation (Carriço et al. 2014). At that time of the year, they produce choruses that are some of the most dominant sounds on the Tagus estuary soundscape (Amorim et al. 2006; Vieira et al. 2021a). Although some other toadfish species are known to produce calls only at night, Lusitanian toadfish usually produce sounds throughout the day (Vieira et al. 2021a). Nevertheless, diel patterns of vocal activity can be affected by tide level, tide velocity, and time of day (Vieira et al. 2021b). It is still unknown if diel patterns of vocalizations change under anthropogenic noise, but a controlled experiment using boat noise playbacks has shown that Lusitanian toadfish exposed to this noise reduced the overall calling activity (Amorim et al. 2022). Control males produced on average 35 BW per hour while males exposed to boat noise reduced calling activity to only 13 BW per hour. It was also noted that the onset of vocal activity usually occurred earlier in nests exposed to control conditions. The detrimental effect found in the Lusitanian toadfish is consistent to what has been reported to other batrachoidids, namely, the oyster toadfish (Luczkovich et al. 2016), which showed depressed calling rates in a site with high boat traffic relative to a site with low boat traffic.

The BW, the most frequent sound of this species, is a highly stereotyped low-frequency signal that is mostly used as an advertisement call but can also be used in agonistic situations (Amorim and Vasconcelos 2008; Vasconcelos et al. 2010). This sound type presents significant differences between males that allow to distinguish different singing males based on the features of their sounds. If fish can use this information to recognize different neighbors, it could mediate interactions among territorial males (Amorim and Vasconcelos 2008; Vieira et al. 2015). Looking into vocal interactions of fish occupying nearby nests, it was observed that males can adjust the rate of BWs depending on whether they are calling alone or in a chorus (Amorim et al. 2011) and may also adapt calling activity to match a neighbor's calling rate (Jordão et al. 2012). Recently, Vieira et al. (2021b) showed that male-male interactions can be even more complex than previously thought. In a chorus, each male appears to be aware of its neighbors' calling activity, adjusting not only the calling rate but also the timing of each vocalization. Interactions like alternation or synchrony of the calls were observed, possibly dependent on advertisement or agonistic context, respectively. If anthropogenic noise disrupts acoustic communication, the complexity of the calling behavior in this species points to important implications for possible interference of boat noise on fish calling behavior. Indeed, the investigation of fine-scale temporal changes in the presence of boat noise playbacks revealed that fish avoided singing during each boat passage and vocal interactions between males were disrupted (Alves et al. 2021). The Lusitanian

toadfish's avoidance response to noise is consistent with a similar effect observed in the oyster toadfish (Krahforst et al. 2016) and the plainfin midshipman (Brown et al. 2021), i.e., these species also decrease the calling rate during the exposure to boat noise playbacks. However, although some fine-scale interactions are described in vocal patterns of other fishes (Mensinger 2014), further studies are needed to characterize in detail the fine-scale male–male vocal interactions and its possible disruption in the presence of noise.

## Hearing

Hearing sensitivity in the Lusitanian toadfish is best at low frequencies (<200 Hz), with best hearing sensitivity coinciding with the range of frequencies contained within conspecific calls, and decreases at higher frequencies (Vasconcelos et al. 2007). Nevertheless, recordings of auditory evoked potentials (AEP) revealed that Lusitanian toadfishes are capable of resolving temporal patterns, amplitude fluctuations, and frequency content of conspecific calls (Vasconcelos et al. 2011). This suggests that the auditory system of the Lusitanian toadfish is suited to discriminate conspecific vocalizations, which is likely important for communication and orientation during territorial defense and mate attraction. However, fish can also resolve the temporal patterns of boat noise, as this noise spectral components overlap with the Lusitanian toadfish hearing frequency range (Alves et al. 2021). The effects of boat noise on the hearing abilities of this species were evaluated in laboratory conditions. Vasconcelos et al. (2007) measured hearing sensitivities under quiet lab conditions and in the presence of ambient noise and ferryboat noise at levels encountered in the field. Using the AEP recording technique, these authors observed that, under ambient noise conditions, hearing was only slightly masked at lower frequencies. However, in the presence of boat noise the auditory thresholds increased 3–36 dB, with higher shifts occurring at the lower frequencies. More recently, Alves et al. (2021) tested how boat noise impacted the communication range of BWs. Using BWs recorded at different distances from the source in the intertidal zone, this study measured the signal detection threshold under ambient noise and boat noise conditions based on AEPs. As expected, boat noise impacted communication range. Small motorboat and ferryboat noise reduced the communication range from ca. 6 and 10 m to 2 m and 6 m, respectively. These experiments also showed that the masking effect depended on noise spectral content of both the BW and the boat noise. Both studies evidenced that hearing and acoustic communication are constrained during exposure to boat noise.

## Reproduction

During the breeding season in Portugal, Lusitanian toadfish can be found in estuarine or coastal shallow waters, where breeding males occupy nests under rocks or other hard substrates in the intertidal/subtidal areas (Amorim et al. 2010). As with other batrachoidids, males produce advertisement calls to attract reproductive females

(Amorim and Vasconcelos 2008). This vocal behavior is very important as females appear to choose the nest based on the acoustic information sent by breeding males. Indeed, calling rate and effort (percentage of time spent calling) reflect male quality (Amorim et al. 2010) and influence reproductive success (Vasconcelos et al. 2012). Amorim et al. (2016) confirmed the importance of the calling behavior in a field experiment that compared the reproduction success between muted and vocal males. These experiments demonstrated that if a male does not produce calls it will not be able to successfully mate. In addition, the number of eggs in the nests was positively associated with the male's maximum calling rate, supporting earlier studies by Vasconcelos et al. (2012). Note, however, that other factors may also influence mate choice, such as the easiness of directly sampling different males, i.e., accessing the male's nests (Amorim et al. 2016).

Since noise can interfere with vocal activity and communication range, one would expect that it should negatively affect reproduction. Recently, Amorim et al. (2022) reported another field experiment that examined the effects of boat noise on Lusitanian toadfish reproduction. This study used two sets of artificial nests deployed in the natural habitat, exposed to either ambient sound or boat noise playbacks. Nests were left undisturbed during a fortnight, and male toadfish spontaneously occupied both these sets of nests for breeding. Amorim et al. (2022) observed that boat noise did not affect nest occupation by Lusitanian toadfish males but decreased the likelihood of receiving eggs. This decrease is consistent with the study by Krahforst (2017) that showed oyster toadfish nesting in areas with boat traffic had lower reproductive success than in quiet areas. This, however, contrasts with the results reported by Brown et al. (2021) that did not find an effect of tonal noise exposure on plainfin midshipman reproductive success. In Amorim et al. (2022), concurrent with the decreased likelihood of receiving eggs, males exposed to boat noise also showed depressed vocal activity and slightly higher cortisol levels. In this study, oxidative stress and energy metabolism-related indicators revealed no increase in oxidative damage but pointed toward a decrease in the activity levels of energy metabolism-related biomarkers. These results suggest that boat noise depressed males metabolism and overall activity (including vocal behaviors) to cope with an acoustic stressor, thus decreasing the ability to attract mates. Although toadfishes might be especially vulnerable to the impact of boat noise due to the reliance on acoustic communication for mating and being attached to a nesting site, noise exposure effects can still be extrapolated to other fish species that may suffer similar or other fitness impacts (for further discussion, see de Jong et al. 2020). Detrimental noise effects should, however, be higher in fish species that reproduce in nests and provide parental care or in other species associated with restricted spawning or feeding grounds, i.e., that have higher costs to leave particular sites (de Jong et al. 2020).

## Eggs Survival and Development

Female Lusitanian toadfish lay large benthic adhesive eggs (>5 mm) in the nest and leave the eggs for male toadfish to provide parental care until the fry are free-swimming (Costa 2004). Note that Lusitanian toadfish larvae stay attached until

nearly all the yolk sac has been absorbed (Collette 2005). This means that larvae cannot escape from noise exposure for up to 2–3 months, depending on temperature (Felix et al. 2016; MCP Amorim, personal observation). Recently, Amorim et al. (2022) and Faria et al. (2022) have revealed some insights on the impact of boat noise in eggs' survival and early life stages development. These authors reported a field experiment where females laid the eggs on artificial nests during sound exposure to either ambient sound or boat noise playbacks. Eggs from each nest were divided in a split-brood design and exposed to both treatments in nests without a male to provide parental care. The first noticeable effect was an increase in the number of dead eggs in nests exposed to boat noise. Also, boat noise exposure affected larval development resulting in smaller larvae. Oxidative stress and energy metabolism-related indicators were also measured (Faria et al. 2022); consistent with the growth deficit, noise-exposed larvae showed larger overall stress responses, with increased levels of superoxide dismutase (SOD), DNA damage (oxidative stress-related responses), and electron transport system activity (ETS; energy-related metabolism). Note that this is a pivotal study providing evidence of effects of boat noise exposure in field conditions. It is thus urgent to conduct more studies to improve our understanding on the effects of anthropogenic noise on the early stages of fish development.

## Conclusion

Anthropogenic noise can affect the Lusitanian toadfish and other fish species at multiple levels and in different stages of development. However, we still lack insight into how these noise-induced effects translate into population-level consequences in this taxonomic group (Slabbekoorn 2019). Further studies addressing the consequences of noise at population and community levels are crucial to provide recommendations to reduce the impacts of anthropogenic noise. Nevertheless, the knowledge obtained until now demand for measures to limit boat noise at least in protected areas and sensitive coastal habitats such as major breeding areas.

**Abstract**

Vessel noise is expected to occur at sites with human activity, such as areas near boat channels, harbors and marinas, and petroleum exploration platforms. How noise varies among sites and how such variation may impact associated fish communities are not well-known. Passive acoustic monitoring (PAM) was used to examine spatial, diel, and longer temporal variation in vessel noise occurrence among five coastal sites in the northern Gulf of Mexico. Dramatically higher vessel noise occurrence was observed at some sites. Noise-related impacts on fishes are likely influenced by differences in species composition among sites, times of peak sound production among species, and bathymetry at sites that impacts propagation of lower-frequency vessel noise.

## Introduction

Globally, aquatic vessel noise has increased over time and presents a pervasive global pollutant in marine waters (Duarte et al. 2021; Slabbekoorn et al. 2010). Vessel noise pollution, however, is expected to vary spatially because of established navigation channels, locations of marinas and ports, and proximity to coastal areas (Neenan et al. 2016). Further, human activity and industry around areas of petroleum exploration and extraction may be expected to have noise associated with construction and maintenance of drilling platforms and other infrastructure. Additionally, noise from some vessel activity may vary seasonally (Neenan et al. 2016). Noise associated with recreational fishing and pleasure boat activity may be predicted to increase in the summer, on weekends and holidays, and during calmer weather (Boyle et al. 2022a). On finer temporal scales, diel patterns of noise are influenced by patterns of human activity (Kaplan et al. 2016), such as ferry schedules and daylight patterns that are likely to influence when boating, fishing (Boyle et al. 2022a), and vessel traffic is more likely to occur. Together, these influences on vessel activity contribute to variation in vessel noise occurrence that complicates measurement of impacts on fishes and other marine life.

## Spatial and Temporal Variation in Vessel Noise Among Coastal Northern Gulf of Mexico Sites

Vessel noise is expected to vary among sites and over short term (diel) and longer temporal (seasonal scales). This variation has important ramifications for predicting impacts on fishes and other fauna. Passive acoustic monitoring was used to measure variation in noise among sites and across time over largely overlapping time periods at five sites along the northern Gulf of Mexico (Fig. 1). These sites include recordings made at two offshore oil rigs off of coastal Louisiana (Rig 1, Rig 2), ~18 m sea depth, with recorders placed at 12 m depth. These oil rigs lack permanent personnel but are serviced periodically by crew boats. The third site, Grand Isle, is along the southern edge of a vessel channel in Bayou Rigaud, Grand Isle, Louisiana, with a recorder placed at ~2 m depth. The fourth site, Big Lagoon, in western Florida, is along the Gulf Intracoastal Waterway, in a no-wake zone, where vessel speed is regulated and the recorder was at approximately 3 m depth. The last site, furthest east, was in St. Andrews Bay Inlet, in Panama City Beach, Florida. This site was a navigation channel into St. Andrews Bay, with the recorder placed at approximately 9 m depth. Intense vessel noise was defined as a sound file with a 1–3000 Hz band sound pressure level ($SPL_{1–3000Hz}$) $\geq$ 135 dB re: 1μPa. This 135 dB amplitude was chosen because it exceeds amplitudes shown to cause temporary threshold shifts in fish after 24 hours of exposure (Breitzler et al. 2020), and the number of sound files with amplitudes $\geq$135 dB provided a manageable dataset for confirmation of vessel noise as the source. This frequency band was examined because it encompasses the range of hearing of most fishes, including species with adaptations for detecting higher frequencies (Ladich and Schulz-Mirbach 2016; Popper et al. 2003). Average

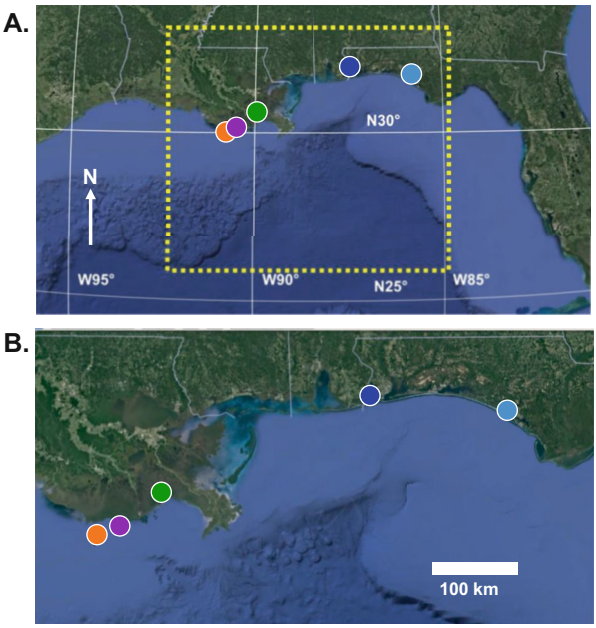

**Fig. 1** (**a**) Location of study sites in the northern Gulf of Mexico. Yellow-dashed line shows region of close-up view in (**b**). Sites from east to west: Rig 1 (orange), Rig 2 (purple); Grand Isle (green); Big Lagoon (dark blue); St. Andrews Inlet (light blue)

$SPL_{1–3000Hz}$ was calculated from PAM sound files collected at each site that ranged from 30- to 60-s duration depending on deployment and site (duty cycles ranged from 6.7 to 25%). For files in which the average was $\geq$135 dB, occurrences of vessel noise were verified aurally and visually from spectrograms.

## Fish Composition Among Sites That Vary in Noise Exposure

In the northern Gulf of Mexico, it is important to consider spatial variation in noise occurrence because fish species composition differs among habitats and location. Coastal marine fish species composition and abundance are influenced by habitat features such as proximity to freshwater input, bottom type (mud, sand, oyster reef, rocky, and artificial hard substrate), and depth (Gain et al. 2016; Garner et al. 2019; Nelson et al. 2021; O'Connell et al. 2019; Plumlee et al. 2020). Fish species that are more likely to occur in habitats modified by human activity may be more likely to experience high levels of noise exposure. Certain habitat modifications associated with human use, such as deepening of navigation channels by dredging, addition of hard bottom, vertical relief, and fouling community substrate in the development of wharfs, piers, jetties, and petroleum platforms, are likely to attract species that associate with these habitat features (Clynick et al. 2008; Putt et al. 1986; Wakefield et al. 2013). Thus, fish typically associated with artificial structures along ports and drilling platforms may be prone to exposure of vessel sound associated with these

developments. In addition, fishes that utilize deeper channels may be prone to vessel noise exposure in navigation channels.

Along the northern Gulf of Mexico, sites within bays and estuary passes include large aggregations of sciaenid fishes that produce sounds during spawning aggregations (Lowerre-Barbieri et al. 2008; Luczkovich et al. 2008). Spawning aggregations along bay entrances and navigation channels can result in exposure to vessel noise (Picciulin et al. 2022).

Fish composition varies among the five sites in the present study, and fish species present at these sites may be impacted by noise in different ways. The offshore Rig 1 and Rig 2 sites include many reef-associated species, such as red snapper *Lutjanus campechanus*, gray snapper, sheepshead *Archosargus probatocephalus*, and Atlantic spadefish *Chaetodipterus faber*. The inshore estuarine sites Grand Isle and Big Lagoon include several well-known soniferous species that were detected on recordings: gulf toadfish *Opsanus beta*, silver perch *Bairdiella chrysoura*, and spotted sea trout *Cynoscion nebulosus*. In addition, black drum *Pogonias cromis* vocalizations were detected at Big Lagoon. St. Andrews Bay Inlet includes vocal estuarine species like silver perch, red drum *Sciaenops ocellatus*, black drum, and gulf toadfish. In addition, St. Andrews Inlet has a rock jetty that provides an artificial reef habitat, and reef-associated species like gag *Mycteroperca microlepis* and cocoa damselfish *Stegastes variabilis* are present.

## Spatial and Temporal Variation of Vessel Noise Among Northern Gulf of Mexico Sites

Wide variation was observed in the frequency of occurrence of intense vessel noise among sites and months (Fig. 2). In September 2021, intense vessel noise was present for 15% of the month at Rig 1 (Fig. 2). This period occurred following Hurricane Ida, which passed very close to this site and may have resulted from service vessel presence at the platform. Noise levels at rig sites in other months were much lower. Among coastal sites, St. Andrews pass exhibited higher incidences of vessel noise occurrence in most months than other nearshore sites examined (Fig. 2). Broad variation among months indicates that long-term monitoring is necessary to assess noise occurrence among sites in the northern Gulf of Mexico. Further, because noise varies among months, the potential for negative impacts on fishes depends on seasonal variation of fish abundance at sites (e.g., within estuaries vs. further offshore) and seasonal activities of fishes (e.g., spawning aggregations and sonic activity).

## Impacts on Fish Vary by Taxa

Vessel noise impacts on fishes are expected to vary among species. In addition, noise impacts directly related to hearing may vary with auditory sensitivity and the behavior of affected species. Species that use hearing to detect sounds of predators

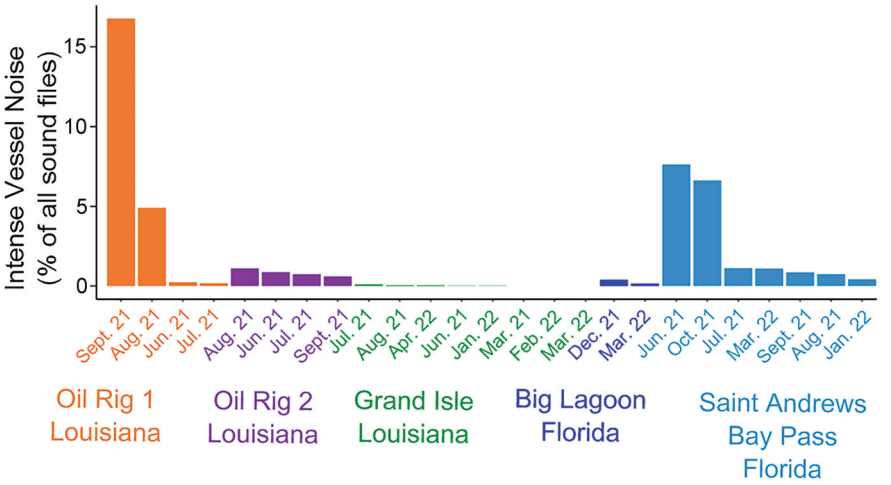

**Fig. 2** Spatial and monthly variation of intense vessel noise occurrence at five northern Gulf of Mexico sites in 2021 and 2022. Highest occurrence of vessel noise was observed at Rig 1 in September 2021; 15% of all files had $SPL_{0–3000} \geq 135$ dB re: 1μPa. Intense vessel noise also occurred more than 5% of the month during June and October 2021 at St. Andrews Inlet

and prey may be predicted to have less opportunity when such sounds are masked by vessel noise and would be expected to have reduced capacity to detect such cues when repeated noise exposure causes hearing loss. Soniferous fishes are predicted to be particularly susceptible to impacts from noise because exposure may not only damage hearing but can also mask calls from conspecifics (Codarin et al. 2009; Vasconcelos et al. 2007; Vieira et al. 2021). Co-occurrence of vessel noise and fish calls was observed at study sites in the Gulf of Mexico (Fig. 3). These events could potentially mask acoustic communication for these fishes.

Diel activity patterns of fishes, especially soniferous species, are likely to contribute to impact of vessel noise because boat traffic is often diurnally biased. Diurnally active soniferous species in noisy areas are likely to have more masking interactions with vessel noise. The timing of impacts on hearing and reception following vessel noise exposure is relevant because vessel noise is more prevalent during diurnal hours (Fig. 4). Impacts that quickly follow noise exposure, such as temporary threshold shifts in hearing (Scholik and Yan 2002), elevated stress (Celi et al. 2016), and altered behavior (Cox et al. 2018), are likely to disrupt responses by fish to calling conspecifics that may have roles in spawning behavior for species with mating calls or school and shoal cohesion for species with contact calls. At some of the study sites in the northern Gulf of Mexico, damselfish species (*Stegastes* spp.) produce diurnal calls associated with territory defense, mate attraction, and nest defense (Boyle et al. 2022b). When vessel noise is most prevalent in diurnal hours (Fig. 4), these fishes are more likely to have calls masked, and immediate effects of noise exposure on the auditory system may reduce efficacy of their calls.

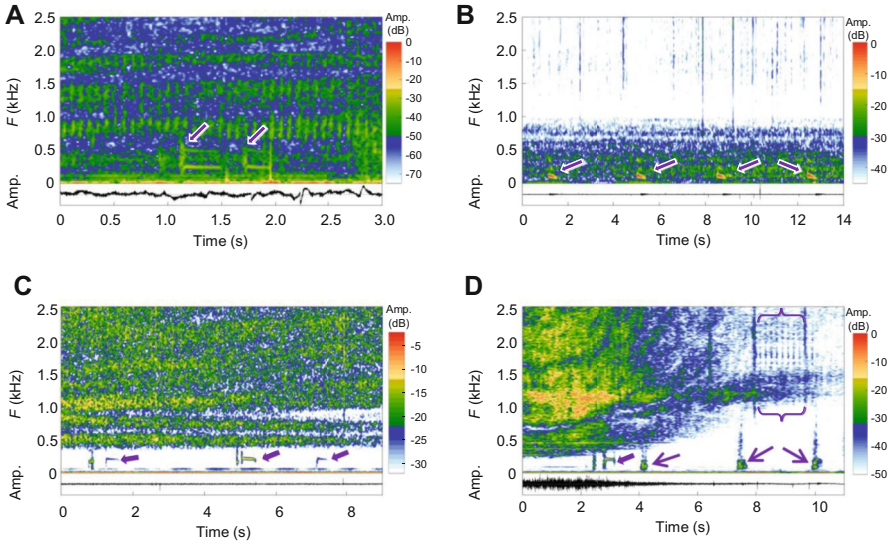

**Fig. 3** Vessel noise co-occurrence in the same frequency range as fish sounds in the northern Gulf of Mexico. (**a**, **b**) A shallow navigation channel in Bayou Rigaud, Grand Isle, Louisiana, results in a high-pass transmission of vessel noise because the shallow water prevents propagation of longer sound wavelengths. This low-frequency cutoff results in a quiet communication window below ~400 Hz for gulf toadfish boatwhistle (block arrows) and grunt sounds (open arrows) but overlaps higher-frequency sounds, like silver perch sounds (brackets in **b**), which are only audible when vessel noise is less intense. (**c**) Deeper channel along the Gulf Intracoastal Waterway in Big Lagoon, Florida, does not filter lower-frequency vessel noise. Thus, low-frequency fish calls, like gulf toadfish boatwhistles (block arrows), partially overlap frequencies even during weak vessel noise. (**d**) A channel >10 m deep at St. Andrews pass, Panama City Beach, FL, allows low-frequency vessel noise transmission that partially overlaps black drum calls (block arrows)

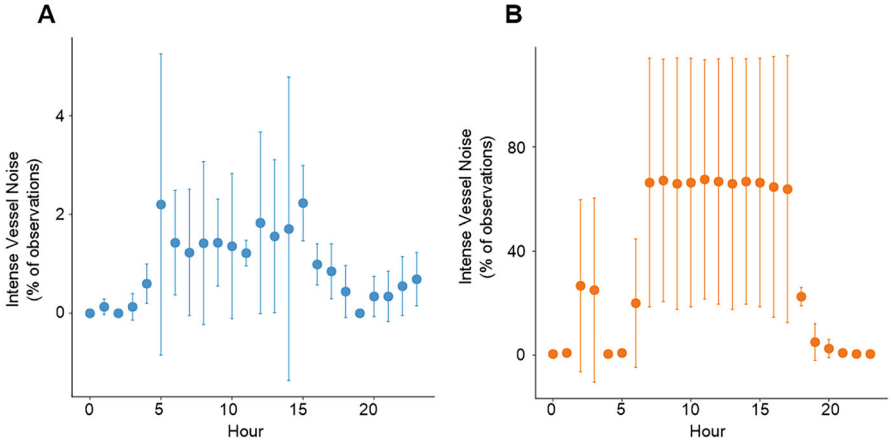

**Fig. 4** Diel patterns of vessel noise at (**a**) Rig 1 from September to October 2021 and (**b**) St. Andrews Inlet from December 2021 to March 2022. Mean + SD

Several sciaenid fish species present along the northern Gulf of Mexico spawn in the evening (Holt et al. 1985; Montie et al. 2016, 2017). At the study sites, vessel noise is less prominent in the evening than the day, though still occurs with some regularity. Thus, the amount of masking of calls associated with spawning is mitigated in part by the time of peak spawning for sciaenids. Another concern, however, is the potential impact of diurnal vessel noise exposure on calling and sound reception in the evening. If fish are present at a spawning ground prior to periods of calling, exposure to intense noise may disturb calling fish or increase stress before evenings when calling would normally occur. A sciaenid species in Portugal (meagre, *Argyrosomus regius*) was observed to reduce calling during and following ferryboat noise (Vieira et al. 2021). However, in another sciaenid species (brown meagre, *Sciaena umbra*), nocturnal sound emission rates were observed to increase following vessel noise exposure (Picciulin et al. 2012), while in another study conducted during diurnal hours, the same species did not change sound emission rates when boat noise was present, though fish increased hiding and flight reactions (La Manna et al. 2016). These differences in observed outcome may result from variation in behavioral responses of species, differences in the motivation associated with calls made during the day vs. calls made during evening spawning aggregations, or differences in the type of noise produced from vessels in each study. Daytime noise exposure may also temporarily decrease hearing sensitivity of fish, which would reduce the detection space available to fish listening to evening calls. Large schools of red drum were observed at the St. Andrews study site during the daytime during late summer and early fall when fishes produce spawning calls in the evenings.

Duration of exposure may vary depending on the degree of residency of fish at specific habitats. It is not known how long mobile species, like many sciaenids, remain in noisy locations within bays and estuaries. Spawning site location may involve many factors, and individual fish that selects noisy habitats may be predicted to remain at such locations multiple days if spawning continues to occur at the site (Picciulin et al. 2022). For intermittent vessel noise, it may not be possible for fish to avoid or easily discriminate between sites with vessel noise because noise builds gradually and travels over great distances. Studies have observed fish avoidance behaviors when vessels pass, which include diving to greater depth (De Robertis and Handegard 2013). At shallow sites, however, it is not possible for fish to flee to avoid intense noise while it is occurring. Over longer periods, fish may be predicted to leave a noisy habitat if they are able to assess longer-term noise patterns and if such information influences habitat preferences. Alternatively, fish that increases swimming activity in the presence of a noise stressor may be more likely to move and encounter quieter areas by chance.

Life history strategies of some fish species, such as species that nest or defend territories, also may influence the likelihood of a fish remaining in a noisy habitat. Gulf toadfish were observed aurally at Grand Isle, Big Lagoon, and St. Andrews (Fig. 3a, c), and at the latter site, a fish was visually observed next to the recorder during a PAM recorder recovery scuba dive. Male toadfish use calls to advertise for mates and defend nests (Gray and Winn 1961). Site attachment over the period of

nest preparation, advertisement, and defense extends the duration of potential noise exposure in sites with high vessel traffic. In the closely related oyster toadfish (*Opsanus tau*), males were observed to guard eggs and free-swimming young for a period between 23 and 49 days (Gray and Winn 1961). Vessel noise incidence was shown to cause a reduction in boatwhistle calls in oyster toadfish (Mackiewicz et al. 2021). At sites further offshore, like the oil rig sites monitored in this study, reef-associated species may be site attached in part because of distance to suitable habitat: artificial and natural reefs. Reef-associated species were observed on Rigs 1 and 2, such as Atlantic spadefish, gray snapper, and red snapper. Red snapper in the Gulf of Mexico exhibits site fidelity (Schroepfer and Szedlmayer 2006; Topping and Szedlmayer 2011) and thus may experience high levels of noise when vessel operations are busiest at rigs.

## Bathymetry of Sites and Noise Exposure

Sites with shallower vessel channels may mitigate potential impacts of vessel noise because of the low-frequency cutoff imposed by depth that prevents propagation of longer wavelength sounds. Shallower channels reduce the total amplitude of vessel noise by preventing lower-frequency components from extending as far from the source (Rogers and Cox 1988). Further, lower-frequency fish sounds will not be masked because of the quiet window below the cutoff frequency. A quiet window below 500 Hz was observed at Bayou Rigaud in Grand Isle, which is a shallow vessel channel with commercial (shrimp trawler and petroleum vessels) and recreational vessels. This quiet window prevents vessel noise from masking gulf toadfish boatwhistle sounds that are likely within a wavelength to the recorder (Fig. 3c, d). Fish species that produce higher-frequency calls like silver perch, however, are masked by higher-frequency vessel noise spectral components (Fig. 3e). At sites along deeper vessel channels, low-frequency fish sounds from gulf toadfish and black drum are masked by vessel noise.

## Particle Motion Versus Sound Pressure

Sound particle motion is the default pathway for fish hearing, though some fish lineages have evolved secondary mechanisms to additionally detect sound pressure (Ladich and Schulz-Mirbach 2016). Thus, for fish without accessory structures to detect sound pressure, sound particle motion is predicted to be the source of noise-induced damage to hair cells of the sensory epithelium (Popper and Hawkins 2018). Sound particle motion attenuation occurs more rapidly than sound pressure and is frequency dependent. Thus, the duration of intense particle motion noise exposure of a passing vessel will be lower than that for sound pressure. The assumption that particle motion is the main source of damage to most fish ears, however, needs more study. Further, it is challenging to address the contribution of these two aspects of noise exposure on fish ears because studies that expose fish to noise in the lab occur

in the acoustic nearfield where particle motion predominates (Popper and Hawkins 2018). Estimating particle motion noise levels in the field is more challenging than sound pressure measurement (Nedelec et al. 2016; Popper and Hawkins 2018). Passive acoustic monitoring of vessel noise in fish habitats is most often conducted using hydrophones that measure sound pressure. Further, sound particle motion estimates can require knowledge of source distance and water depth (Nedelec et al. 2016), which is complicated with a moving vessel. Lastly, more research is needed to determine the relative impacts of particle motion and sound pressure of vessel noise pollution on fishes to determine the limitations of PAM with sound pressure.

## Conclusions

Our limited observations from coastal northern Gulf of Mexico sites with moderate human activity indicate broad variation in vessel noise occurrence among sites. Notably, within sites, vessel noise differs over longer temporal scales (weeks-months), which underscores the importance of long-term monitoring for assessing vessel noise pollution in fish habitats. Future research needs to assess the residency time of individual fish at locations with high vessel noise to adequately determine potential impacts. This is especially important for mobile species that form spawning aggregations, which include many sciaenid fishes.

**Abstract**

This chapter reviews studies on the effect of aquaculture sounds from pumps, generators, and other equipment on the development, physiology, and behavior of fishes. The chapter also examines select studies using boat playback sounds, as these studies can still inform understanding of noise impacts on commercially important aquaculture species. Anthropogenic sound can have a direct effect on the target species being reared in aquaculture facilities, including negative impacts on embryonic development, sensory function, and stress. Hatchery sounds can also impact critical behaviors such as predator avoidance or parental

Aquaculture · Hatchery · Anthropogenic noise · Fish · Stress · Development · Inner ear · Lateral line

## Introduction

A significant byproduct of industrialization is the increasing negative effect on the environment. Habitat fragmentation, overharvesting, and climate change have altered ecosystems around the globe (Brander 2010; Haddad et al. 2015). Aquatic environments have not been spared from this impact, and conservationists have been toiling to preserve species in a rapidly changing landscape. Marine and freshwater fish species are exposed to shifting water chemistry and temperatures, causing changes in their development and behavior (Domenici et al. 2019; Huang et al. 2021). Governments worldwide have initiated aquaculture systems to propagate aquatic species of economic, ecological, and cultural importance to mitigate these anthropogenic threats.

Many aquaculture facilities were established to provide protection for developing juveniles of fish populations of interest. These complexes offer a habitat that is largely isolated from predation and where food is in ample supply. Whether the objective is to propagate fish for recreational or commercial use or to preserve a threatened population, a common goal of aquaculture facilities is to reduce the high mortality rate in early developmental stages, thereby increasing the number of fish that survive to reproduction or market. While these facilities do accomplish the goal of eliminating natural predation, they have the unfortunate side effect of altering the development and behavior of captive-reared fish (Olla et al. 1998; Marchetti and Nevitt 2003). Aquaculture facilities are industrial complexes where juveniles are raised in manufactured enclosures that are a poor reproduction of the complex habitat these fishes would naturally inhabit.

Typically, fitness assessments in aquaculture operations have focused on the presence of parasites and diseases and fish weight upon release (Piper 1986; Barber 2007). These factors are undoubtedly important in the long-term survival of captive-reared animals but do not fully capture proper development or physiological function. The ability to interact with the surrounding environment is crucial for survival to adulthood, and metrics to measure this ability should be incorporated into aquaculture practices. A substantial body of research has shown that fish raised in industrial aquaculture environments are morphologically and behaviorally different from their wild conspecifics (reviewed in Anderson et al. 2020). Exposure to artificial lighting, processed diets, and excessive sound have marked effects on the development of these fish (*e.g.,* Ridha and Cruz 2000; Fakan and McCormick 2019).

This brief chapter explores the impact of anthropogenic sound on the development, physiology, and behavior of aquaculture fish populations (see Popper and Hawkins 2019 for further review on this topic). We highlight contemporary literature to give the reader a broad understanding of conservationists and aquaculturists' challenges in their attempt to rear viable populations.

## Effects of Aquaculture Noise on Development

Anthropogenic sound exposure is generally not acutely lethal to fish larvae (Wysocki et al. 2007; Bruintjes and Radford 2014; Lara and Vasconcelos 2021; Faria et al. 2022). However, sound exposure can alter embryonic and larval development and these changes may impact subsequent life stages (Jain-Schlaepfer et al. 2018; Fakan and McCormick 2019). The effects of this exposure are species-specific and also depend on the time and intensity of exposure. For example, a lab study of two species of reef fish, cinnamon clownfish (*Amphiprion melanopus)* and spiny chromis (*Acanthochromis polyacanthus*), exposed embryos to a continuous ~120 dB (re 1 μPa) recording of a two-stroke engine (Fakan and McCormick 2019). Sound-exposed embryos of either species had a faster heart rate, suggesting increased stress. Further, mean yolk volume decreased in *Ac. polycanthus* exposed to boat noise. Yolk sac reserves in early development help to nourish young fish before they can feed, so early absorption can lead to reduced survival. Interestingly, sound-exposed *Ac. polycanthus* had an increase in body length and eye diameter (Fakan and McCormick 2019). By contrast, a field experiment showed that boat noise playback reduced larval growth in Lusitanian toadfish (*Halobatrachus didactylus*) (Faria et al. 2022), demonstrating a complex relationship between anthropogenic sound and fish growth that likely depends on species, noise stimulus, and other parameters.

The type and regularity of anthropogenic sound also impacts fish development. While boat engine noise increases heart rate in some reef fishes, as described above, exposure to sound from a 2-stroke engine increased heart rate significantly more than similar exposure to a four-stroke engine (Jain-Schlaepfer et al. 2018). Along similar lines, a study in larval Atlantic cod (*Gadus morhua*) demonstrated that while exposure to either random or consistent noise reduced larval body size (compared to fish reared in ambient sound levels), larvae exposed to consistent noise depleted their yolk sac faster and had a lower body width-length ratio, suggesting lower energy reserves. Width-length ratio was positively correlated with predator avoidance behavior in a simulated predation experiment, indicating that constant sound exposure may attenuate predator avoidance behavior (Nedelec et al. 2015). Interestingly, a study in the daffodil cichlid *Neolamprologus pulcher* found no significant effect of intermittent boat noise exposure on larval growth (Bruintjes and Radford 2014). The authors concluded that moderate sound levels (127 dB re 1 μPa RMS) did not impact larvae (Bruintjes and Radford 2014). However, subsequent studies described above suggest that a continuous sound stimulus may have produced a different result.

### Effect of Noise on Gene Expression

Sound exposure can also alter gene expression in fishes, with potential impacts for both adult animals and their offspring. RNA-seq analysis of brain tissue from the African cichlid species *Astatotilapia burtoni* found that females exposed to 3 h periods of anthropogenic sound (~140 dB) expressed transcripts associated with feeding and brooding behavior differently than those not exposed to sound (Butler and Maruska 2021). Specifically, sound exposure increased expression of appetite-stimulating neuropeptides and downregulated leptin receptors, molecules that collectively regulate food intake. Sound exposure also reduced expression of prolactin and vasotocin, which are peptides linked to maternal care behavior (Butler and Maruska 2021). *A. burtoni* is a mouthbrooding species, and many noise-exposed females cannibalized or prematurely ejected their young, reducing brood success by 55%. Boat noise exposure also had a negative effect on parental care behavior in male spiny chromis, a nest-brooding damselfish, leading to a reduction in larval survival (Nedelec et al. 2017). These studies demonstrate that sound exposure may have a greater impact on larval mortality in species that require parental care versus those without such care, owing to noise-induced effects on parental behavior. Furthermore, offspring of noise-exposed *A. burtoni* females had upregulated isotocin levels in the brain (Butler and Maruska 2021). Isotocin is the fish homolog of oxytocin and helps regulate social behavior, including parental care in cichlids (Reddon et al. 2014). Therefore, maternal sound exposure could affect breeding success in subsequent generations.

While many of these studies used boat noise exposure in cichlids and damselfish, rather than aquaculture noise exposure in common hatchery species with greater commercial importance, they collectively highlight the detrimental impact of sound exposure on reproductive success and larval development.

## Effects of Hatchery Noise on Sensory Systems

Given that intense noise can cause hearing loss, it is unsurprising that several studies have examined the effect of anthropogenic noise – including sounds from aquaculture operations – on fish ear structure and function (Wysocki et al. 2007; Halvorsen et al. 2012; Casper et al. 2013; Popper and Hawkins 2019; Sapozhnikova et al. 2020). This section briefly discusses a few studies (of many) as part of our broader survey of the impacts of aquaculture noise on fishes.

The fish inner ear contains three otolithic end organs, the saccule, utricle, and lagena (Popper and Fay 1993, 2011). Each end organ is comprised of a sensory epithelium that contains a population of sensory hair cells associated with a calcareous otolith, where motion of the otolith relative to the epithelium initiates the signal transduction cascade in hair cells, ultimately resulting in perception (Popper and Fay 1993, 2011). In most fishes, the saccule is the primary auditory end organ, although the lagena and utricle may play roles in both hearing and balance (Mann et al. 2001; Meyer et al. 2012; Vetter et al. 2019; Rogers and Sisneros 2020). Broadband sound

exposure for 1–2 days causes saccular hair cell damage and hearing loss in model fish species such as goldfish (*Carassius auratus*) and zebrafish (*Danio rerio*), two otophysan species with relatively sensitive hearing thresholds over a broad range of frequencies (up to 4 kHz) (Smith et al. 2006; Breitzler et al. 2020).

However, sound-induced damage is much more variable in typical hatchery species and is likely correlated with both stimulus paradigm and relative hearing sensitivity of that species. For example, 18 days of exposure to a 300 Hz pure tone (corresponding to the peak frequency of a recirculating aquaculture system) at ~180 dB (re 1 μPa) caused damage to saccular hair cells and associated sagittal otoliths in peled (*Coregonus peled*), an important aquaculture species in parts of Russia (Sapozhnikova et al. 2020). By contrast, rainbow trout (*Oncorhynchus mykiss*) exposed to 150 dB (re 1 μPa) broadband noise showed no hearing loss, even after 8 months of continuous exposure (Wysocki et al. 2007). This lack of hearing loss in rainbow trout may reflect the lower intensity sound used in this study. However, hatchery rearing can reduce auditory sensitivity in Chinook salmon (*Oncorhynchus tshawytscha*), a fish with similar hearing sensitivity to rainbow trout, by altering the composition of the sagittal otolith (Oxman et al. 2007). It is unknown if changes in otolith composition are caused by hatchery sounds or other features of the artificial rearing environment.

## Effect of Noise on the Lateral Line

In addition to the inner ear, most fish also possess an external lateral line system used to detect nearfield water movement to mediate crucial behaviors such as schooling, predator avoidance, prey detection, and orientation to water flow (Coombs et al. 2014). Similar to the inner ear, each lateral line sensory organ (neuromast) contains a population of sensory hair cells. These hair cells are sensitive to low frequency stimuli (Weeg and Bass 2002; Higgs and Radford 2016), making them potentially susceptible to damage from vibration and low-frequency sound generated by hatchery equipment. A few hours of broadband sound exposure is sufficient to damage lateral line hair cells in larval zebrafish, with potential consequences for orientation behavior (Suli et al. 2012; Uribe et al. 2018). Hatchery rearing can also negatively impact lateral line morphology in steelhead (*O. mykiss)*, with fewer superficial neuromasts observed in fish reared in conventional concrete raceways than in wild-spawned conspecifics (Brown et al. 2013). Interestingly, fish reared in net pens in the center of an isolated freshwater lake (a relatively quiet environment) had an intermediate number of superficial neuromasts as compared to the other rearing conditions. However, it is unknown if lateral line development is specifically impacted by hatchery sound levels.

## Effect of Noise on Hatchery-Reared Chinook Salmon

To address this question, we exposed hatchery-reared Chinook salmon (unpublished observation) to one of three different noise treatments from yolk sac absorption to

release 4 months later: a quiet treatment in which sound attenuation techniques were implemented; an ambient treatment in which no changes were made to experimental tanks; and a white noise treatment where developing fish were treated with 150 dB (re 1 μPa RMS) broadband white noise. Juveniles exposed to white noise had a significantly lower number of trunk neuromasts than juveniles in the "quiet" treatment (unpublished observation), suggesting that hatchery noise is sufficient to affect lateral line development, with potential behavioral consequences. Future studies will examine the impact of hatchery noise on stress responses in Chinook salmon, as such responses can influence postrelease survival.

## Effects of Aquaculture Sound on Stress and Immune Responses

Excessive sound exposure can reduce disease resistance in fish and potentially impact survival (Wysocki et al. 2007; Quinn 2018; Masud et al. 2020). This threat is exacerbated by the high stocking densities observed in many aquaculture facilities, facilitating the spread of pathogens (Iguchi et al. 2003; Crosbie et al. 2010). In some fish, excessive sound can lead to changes in tissue and blood chemistry that diminish the immune system's ability to combat disease. For example, exposing largemouth bass (*Micropterus salmoides*) to 60 days of recirculating aquaculture system noise (115 dB SPL re 1 μPa) significantly increased catalase (CAT) activity and decreased malondialdehyde (MDA) activity in liver tissue (Hang et al. 2021). CAT scavenges free radicals and is produced in response to oxidative stress to protect cells, while MDA increases due to oxidative stress, suggesting that noise exposure increased oxidative load in this species. Similarly, exposure to ambient offshore aquaculture noise increased oxidative and cellular stress markers in juvenile gilthead sea bream (*Sparus aurata*), a marine aquaculture fish (Filiciotto et al. 2017). Oxidative stress is regulated by several intracellular processes, with mitochondria playing a key role. Unlike mammalian red blood cells, mitochondria are present in mature red blood cells in nonmammalian vertebrates, including fishes (Phillips et al. 2000; Pica et al. 2001). Noise exposure in peled (see above) decreased mitochondrial activity in red blood cells, accompanied by a decrease in red blood cell area (Sapozhnikova et al. 2020). Collectively, these results suggest that sound exposure in fish can increase oxidative stress via multiple mechanisms.

The stress hormone cortisol is a particularly important health metric, as elevated levels of cortisol decrease immune response, growth, and food conversion (Gamperl et al. 1994; Wendelaar Bonga 1997; Harris and Bird 2000). Broadband sound exposure caused a transient, intensity-dependent increase in plasma cortisol level in juvenile and adult Atlantic cod populations (Sierra-Flores et al. 2015). Atlantic cod broodstock exposed to this noise paradigm also had reduced egg fertilization rates, reduced egg viability, and increased egg cortisol levels, suggesting that maternal cortisol levels may impact egg cortisol to decrease embryo viability (Sierra-Flores et al. 2015). Sound exposure also increased cortisol levels in two freshwater aquaculture fishes, the common carp (*Cyprinus carpio*) and the European perch (*Perca fluviatilis*) (Wysocki et al. 2006). Interestingly, these cortisol increases

were only seen with ship playback noise but not continuous Gaussian noise (Wysocki et al. 2006). Radford et al. (2016) noted a similar finding in European seabass (*Dicentrarchus labrax*), where stress responses (ventilation rate, in this case) increased in response to impulse noise from pile driving or seismic survey, but not continuous boat noise. Long-term stress can lead to chronic conditions and make fishes more susceptible to diseases. Monitoring fish health is a crucial aspect of any aquaculture program, and excessive anthropogenic noise may increase the effort and cost to keep pathogens at bay. Further, sound exposure and the resulting chronic stress can negatively impact fish behavior.

## Effects of Aquaculture Noise on Behavior

Environmental conditions and stocking densities can alter social, exploratory, food-searching, and avoidance behaviors (Jørgensen et al. 1993; Papoutsoglou et al. 1998). Anthropogenic sounds have a particularly pronounced effect on what behaviors fish express and to what degree. Aquatic animals exposed to noise pollution often exhibit increased aggression, flight reaction, and hiding behavior, likely due to stress (Kunc et al. 2016). Hasan et al. (2018) found that exposure to boat noise playback attenuated the response to a conspecific chemical alarm cue in fathead minnows (*Pimephales promelas*), greatly reducing refuge-seeking behavior. This muted predator response puts affected minnows at a greater chance of predation. Brief anthropogenic sound exposure also altered behavior in European eels (*Anguilla anguilla*) in a lab experiment (Simpson et al. 2015). Juvenile eels were exposed to recorded ship noise (148 dB re 1 μPa) while experiencing a visual stimulus to simulate a predator attack. Eels exposed to ship noise were less likely to startle in response to the perceived presence of an ambush predator, and fish that did respond had slower startle responses. Boat noise exposure also reduced anti-predator behavior in a field experiment with juvenile ambon damselfish (*Pomacentrus amboinensis*), ultimately reducing survival (Simpson et al. 2016). Much more research is needed to analyze how sound-induced behavioral changes affect hatchery-reared fish that are subsequently released into the wild.

In addition to the direct individual antipredator response, aquaculture sound is likely to alter group swimming behavior. Schooling is a vital swimming behavior that serves social and defensive purposes, used to confuse predators or, in certain instances, to increase feeding efficiency (Partridge 1982). Largemouth bass exposed to sound from recirculating aquaculture systems showed a more irregular schooling pattern than fish exposed to ambient sound levels (Hang et al. 2021). Sound-induced erratic schooling behavior was also observed in an important marine aquaculture species, bluefin tuna (*Thunnus thynnus*). Bluefin in a very large sea pen exposed to boat noise swam in looser schools and with more vertical movement than fish exposed to ambient sound (Sarà et al. 2007). Just like many other responses to anthropogenic noise, changes in swimming behavior are species-specific, with some fish showing more pronounced reactions. Boat noise exposure elicited an obvious escape response in spottail shiner (*Notropis hudsonius*), a species with

specializations that increase hearing sensitivity, while bluegill sunfish (*Lepomis macrochirus*), a species considered a hearing generalist, showed no discernable escape behavior (Stasso et al. 2023). Both species in this study showed a decrease in overall swim behavior, and the kinds of behavior they exhibited tended to be more erratic than in a quiet environment. Given that food can be sparse in natural environments, energy conservation becomes key to survival. The erratic behavior observed in fish exposed to noise serves no function as an antipredator or food-seeking behavior. Superfluous movements deplete critical energy by increasing respiration, pulse rate, and utilizing muscles.

## Conclusion

This chapter demonstrates that aquaculture and related anthropogenic sounds can impact fish at many levels, from development to behavior to reproductive success. The better the consequences of noise are understood, the better is the ability to design solutions to counteract these effects. To form reasonable solutions, much more research is needed to determine if and to what degree long-term survival is affected in aquaculture species. In many cases, fishes raised in aquaculture facilities are either released into the wild or harvested for food, making obtaining reliable survivor measures difficult. The chapter summarized in this review adds to the pool of knowledge that conservationists can use to form a viable way forward.

**Abstract**

Anthropogenic low-frequency continuous noise is on the rise in aquatic environments due to increased shipping, resource exploration, and infrastructure development. Tank-based studies using low-frequency continuous noise caused temporary hearing loss and behavioral alterations or masked relevant acoustic signals in some species. Various examples of acoustic communication in fishes reflect the importance of the reception of acoustic signals. Recent results have proven that noise also affects free-ranging fish, but regulating measures and mitigation approaches have not yet been taken. The European Union Marine Strategy Framework Directive is currently working on the assessment and monitoring of continuous noise, with focus on vessel noise. A necessary new energy resource such as wind farms, although expanding, is not specifically included. Prevention and mitigation measures, e.g. speed restrictions and technical improvement in vessels, have been discussed but have not been made mandatory to reduce underwater source levels. Current expertise demonstrates that source-level reduction is also reducing impact area and mitigation could be implemented regardless of knowledge gaps.

Fish · Low-frequency noise · Continuous noise · Temporary threshold shift · Noise mitigation · Offshore wind farms

## Introduction

The increase of anthropogenic noise in the ocean, due to globalization, population growth, and expanding transportation sectors, is contributing to an ongoing rise of low-frequency noise of up to 3 dB per decade (Andrew et al. 2011; Chapman and Price 2011). Fishes are capable of detecting, discriminating, and localizing sounds. Sounds are used for orientation and habitat selection, predator and prey detection, and intra- and interspecific behaviors such as aggression, territory protection, defense, and reproduction (Popper and Hawkins 2019). This makes them vulnerable to a wide range of effects of acoustic pollution.

Assessing the effects of underwater noise is complex due to sound source and environment-dependent variability in things such as amplitude, spectral, and temporal properties. Further, noise can derive from single or from multiple sound sources simultaneously. These factors determine the acoustic characteristics of noise in a certain area and are mainly described in terms of intensity, frequency, and wavelength. The acoustic characteristics used in describing noise evidently determine the degree of behavioral and physical impact of noise on fishes (Popper and Hawkins 2019). Studies on the effects of high-intensity impulsive noise have found behavioral changes in fishes, such as higher state of vigilance (Spiga et al. 2017), affected shoaling behavior (Herbert-Read et al. 2017), and potential displacement (Iafrate et al. 2016). Besides behavioral effects, particularly high noise levels can also induce physical injuries. Impulsive noise, from pile driving or air guns used in seismic surveys, damages sensory hair cells (Casper et al. 2013) or swim bladders (Halvorsen et al. 2012a, b), both important elements in hearing. Temporary effects on hearing thresholds can also derive from the exposure to impulsive noise in fishes (Smith and Monroe 2016). Fish species with better hearing abilities were found to be the most vulnerable for effects on hearing (Popper et al. 2005).

Up to now, most efforts focused on mitigating the effects from high-intensity impulsive sounds on aquatic animals, since immediate physiological injury to tissues and behavioral reactions have been clearly demonstrated (Halvorsen et al. 2012b; Neo et al. 2014, 2015; Southall et al. 2019). However, continuous noise from shipping, construction work, rotating wind, and tidal turbines occurs temporally and all around the oceans and potentially affects fishes over wide geographic areas (Popper and Hawkins 2019). Growing transportation sectors are increasing the global vessel fleet each year and raise the anthropogenic low-frequency noise levels (Andrew et al. 2011; Chapman and Price 2011). Offshore wind farms are expanding as a renewable energy solution in recent years, especially in European waters. This rapid expansion of offshore wind energy will inevitably increase low-frequency noise levels, which should be considered for marine spatial planning and

environmental impact assessments (Tougaard et al. 2020). These anthropogenic sources produce long-term continuous sounds that increase the overall sound level in the aquatic environment, interfering with critical aspects of fish behavior and potentially hearing.

This chapter reviews current knowledge of the impacts of low-frequency continuous noise, its ecological consequences for wild fishes, current assessments, and noise mitigation measures.

## Behavioral Effects of Continuous Noise Exposure

Continuous noise can affect the behavior of fishes in various ways, but data is restricted to few species showing considerable variability. Most data is from tank experiments with playbacks often not resembling actual sound sources (Akamatsu et al. 2002), and behavioral responses to stimuli may differ from wild fish (Leplage et al. 2000; Calisi and Bentley 2009; Benhaïm et al. 2012).

Vessel noise exposure can reduce the foraging rate (Purser and Radford 2011; Magnhagen et al. 2017; Pieniazek et al. 2020) and lead to increased stress levels (Wysocki et al. 2006). Fish are less successful in repelling intruders (Sebastianutto et al. 2011) and are compromised in their antipredator behavior during playbacks of vessel noise compared to "silent" controls (Velasquez Jimenez et al. 2020). Increased aggregation in fish was found immediately upon white noise exposure with a return to control condition after 2 h (Mauro et al. 2020). Continuous noise can delay reproduction (Blom et al. 2019) and lead to decreasing exploratory activities and to alterations in home ranges (Ivanova et al. 2020; Kok et al. 2021).

In addition to behavioral effects, continuous underwater noise can also affect auditory detection of biologically relevant signals in fishes. Continuous noise has a high potential for masking if it overlaps in time and frequency with fitness-relevant sounds (Popper and Hawkins 2019). Detection thresholds are found to increase in the presence of background noise in goldfish and catfish (Wysocki and Ladich 2005). Continuous noise that is 34 dB re 1 μPa higher than ambient sound delayed female spawning decisions due to a reduced ability to assess male acoustic signals (Blom et al. 2019). Such reduced effective vocalization radii are a well-described problem for fishes (Radford et al. 2014; Stanley et al. 2017). Masking may be overcome by adjustments of amplitude or frequency of signals, also known as the Lombard effect (Codarin et al. 2009; Luczkovich et al. 2016; Brown et al. 2021). However, biological constraints exist in the ability to compensate for masking effects.

## Temporary Threshold Shifts Induced by Continuous Noise

Exposure to intense sounds or sounds of long duration can lead to sensory hair cell damage of the inner ear and is possibly correlated to temporary threshold shift (TTS) in hearing (Smith et al. 2006). Hearing may recover after exposure, which can be

enhanced by simultaneous repair or replacement of sensory cells in some species (Smith et al. 2011; Smith and Monroe 2016).

Continuous noise with much lower received sound levels than pile driving can also cause TTS in fishes. Likewise, hearing thresholds can be elevated by 5 dB after a 10-min exposure to white noise with 160–170 dB re 1 μPa and around 28 dB after 24 h (Smith 2004). The fish had similar threshold shifts after more than 24 h of exposure, indicating that an asymptotic threshold shift (ATS) was reached (Smith 2004). An ATS was also reached after 2 h of white noise exposure of 142 dB re 1 μPa (Scholik and Yan 2001). Even lower levels of 130 dB re 1 μPa could induce a TTS after 24 h exposure (Amoser and Ladich 2003; Breitzler et al. 2020).

Susceptibility to hearing loss in fishes differs between individuals and different species. The presence or absence of a swim bladder as well as other specializations that can contribute to enhanced hearing sensitivity in different species may alter the occurrence of hearing impairment (Popper and Hawkins 2019). Furthermore, impact variability can also be affected by hearing abilities of the exposed fish; a more intense sound will be required to produce TTS in fishes with low hearing abilities (Smith et al. 2004).

## Continuous Noise Exposures in Wild Fishes

It is debatable whether TTS-onset thresholds are regularly exceeded in real-life scenarios and if this is a problem occurring in harbors, wind farms, and shipping lanes. The source levels of large moving vessels can exceed 190 dB re 1 μPa (MacGillivray and de Jong 2021), while source levels from static vessels, when in dynamic positioning mode, can be 10 dB higher (Rutenko and Ushchipovskii 2015). If animals do not move away from static vessels or if a shipping lane is close to a structure with stationary animals, received levels may be exceeded, capable of inducing a TTS. In high traffic areas, cumulative sound exposure levels exceed reported TTS onsets (e.g., 24 h × 130 dB re 1 μPa = 180 dB re 1 $\mu Pa^2s$) (Merchant et al. 2014). However, so far, no hearing tests have been conducted after in situ vessel exposures with wild animals. In addition to vessel noise, dredging is also able to reach levels (SPLs up to 190 dB re 1μPa at 1 m) that are able to induce a TTS, but no direct effects have been investigated yet (Scholik and Yan 2002; Heinis et al. 2013; Liu et al. 2013; Wenger et al. 2017). Operational noise from wind turbines has sound levels reaching up to ~137 dB re 1 μPa at a distance of 40 m, depending on wind and rotational speed, pitch angle of the turbine's blades, the type of foundation, and possibly the age of the turbine (Tougaard et al. 2020). This combination of continuous noise emissions and artificial reef structures, which may attract fish, must not necessarily be a TTS threat, but cumulative contribution from multiple turbines should not be disregarded (Tougaard et al. 2020).

Noise exposure has proven to cause TTS in fishes, but there is no evidence for permanent hearing loss (PTS) (Smith et al. 2006; Smith and Monroe 2016). This raises the question about ecological relevance of temporary hearing effects. While having impaired hearing, animals may have lower survival and reproduction rates in

terms of poorer communication, inability to detect predators or prey, and difficulty in assessing their environment. To our best knowledge, no studies have been done on free-ranging fish to investigate whether a small change in hearing threshold has any real impact on fitness. Although hearing of fishes is more likely affected by impulsive noise, continuous noise still has the potential for inducing TTS as well, which must not be neglected.

In recent years more studies have been done in the wild with free-ranging fish that have the potential to escape from areas with disturbing factors. Field experiments showed decreased presence of wild fish and fewer foraging attempts made during boat noise exposure (160 dB re 1 μPa) (Pieniazek et al. 2020). However, variation in hearing abilities may determine the extent to which their behavior changes and the resulting degree of negative consequences (Pieniazek et al. 2020). A decreased magnitude in antipredator response was found in free-ranging sand gobies (*Pomatoschistus minutus*) during the exposure to boat noise with comparably low levels of 98–101 dB re 1 μPa (Kok et al. 2021). Prey species altered their antipredator behavior in ways that can potentially lead to higher mortality for individuals and ultimately have implications for the food web. Fish also increased hiding and their time spent inside the shelter during boat noise exposure (Picciulin et al. 2010; Nedelec et al. 2016). Tagged common roaches (*Rutilus rutilus)* showed increased swimming speed and increased their use of the central part of the lake (Jacobsen et al. 2014). Vessel noise and vessel presence can be perceived as a threat by Arctic cod (*Boreogadus saida*), which react by moving away and decreasing exploratory activities. These changes in behavior may represent an interruption in a critically needed exploitation of important and seasonally abundant food resources (Ivanova et al. 2020). Male plainfin midshipman fish (*Porichthys notatus*) exposed to noise produced fewer vocalizations, reduced the frequency of vocalizations, and increased the amplitude of their mating hum (Lombard effect). However, it did not significantly affect spawning success, suggesting that the Lombard effect allowed males to sustain signal efficiency (Brown et al. 2021). Likewise, the duration and intensity of chorusing fish were increased by noise from operating wind turbines (Siddagangaiah 2021). Nonetheless, possible limitations for further vocalization adjustments are unknown. Fine-scale telemetry data suggests that dredging does not create a barrier for adult Atlantic sturgeon (*Acipenser oxyrinchus oxyrinchus*) migrating to their spawning habitat (Balazik et al. 2020), while reductions in fish diversity were recorded during dredging most likely due to behavioral avoidance of the sediment plume (Pledger et al. 2021). However, the cause of avoidance cannot be clearly determined, as effects from dredging noise, increased turbidity, reduced light, contaminants, or gill damage cannot be distinguished in the wild (Wenger et al. 2017).

There have also been controversial results with instant effects in wild fish and a return to baseline behavior after an initial reaction during vessel sound exposure (Holmes et al. 2017; Staaterman et al. 2020). Additionally, Nedelec et al. (2016) found that fish increased hiding behavior and elevated ventilation rates during playback boat noise exposure but habituated within 1–2 weeks of exposure. There is evidence that population impacts due to noise disturbance exist, deriving from

subtle effects on fish behavior and physiology that, in turn, may reduce population growth rates (Soudijn et al. 2020). Future studies are needed to determine limits of adjustment possibilities, the potential of habituation, and fitness costs of altered behaviors. These information are critically required to estimate effects on spawning and reproductive success and therefore effects on population levels.

## Future Direction of Noise Mitigation

In 2008, aquatic noise pollution was included in the European Union Marine Strategy Framework Directive (MSFD; European Union 2008) working toward levels of underwater noise that do not negatively affect ecosystems and would ensure "Good Environmental Status" (GES). In recent years, research has proven severe impacts from noise on a broad spectrum of taxa in aquatic life (Duarte et al. 2021). Mitigation measures for high-intensity noise are already in use, mainly bubble curtains and acoustic deterrent devices during pile driving (Juretzek et al. 2021). Quieter alternatives to seismic air gun surveys have been developed and tested successfully but are not commercially used due to a lack of regulatory incentive (Merchant et al. 2022). While high-intensity impulsive noise had a lot of attention due to its capability of inflicting severe damage (Dekeling et al. 2020), progress on monitoring, assessing, and mitigating continuous noise pollution has been comparatively slow, yet regional maps have been produced for the Baltic, North Sea, and wider NE Atlantic (Merchant et al. 2022). Effects for impulsive noise are thought "of lesser relevance for continuous noise sources where received noise levels are insufficient to inflict damage for short exposures, and continuous exposures to high levels are less likely, due to the sources (e.g., ships) and receivers (animals) often move relative to each other, limiting the time with exposure to high levels of noise," states the assessment framework for continuous noise of the MSFD (Sigray et al. 2022).

Nevertheless, low-frequency continuous noise has also been recognized as a threat to the GES in the MSFD. Since shipping makes up the majority of underwater noise pollution, continuous noise is defined in annual trends in one-third octave frequency bands centered at 63 and 125 Hz (Sigray et al. 2022). Although the increasing occupation of wind farms of larger coastal areas contributes considerable cumulative energy to the soundscape, the monitoring programs are mainly considering vessel noise from AIS (automatic identification system) and VMS (vessel monitoring system) data in their continuous noise assessment and do not specifically address wind farms in their impact evaluation on aquatic life. The life cycle of offshore wind farms, includes a range of activities, generating underwater noise of varying intensity, duration, and spectra (Mooney et al. 2020). The effect of continuous noise has to be carefully considered to ensure that wind farms do not represent ecological traps for fishes (Reubens et al. 2014). For example, wind farms could be seen as good habitats with high food availability for fishes (van Hal et al. 2017),

where fishing is forbidden and building reef structures provide shelter and possibly hard substrate for spawning. However, they may compromise animals acoustically, masking necessary mating signals (Blom et al. 2019; Tougaard et al. 2020). Although wind turbines' new substrate habitats generally seem to attract fish, they potentially alter the fish composition with no knowledge about future habitat and population impacts (Bergström et al. 2013). Biodiversity loss and climate change are linked and should be approached simultaneously. Wind farms are essential as a solution as new energy source, but impacts on habitats should not be neglected.

The MSFD states that there is currently no sufficient data to include noise-induced hearing loss in continuous noise assessments. Since fewer fishes are possibly affected by noise-induced hearing loss from continuous sound than those affected by masking, the MFSD is addressing masking in determination of habitat status for continuous noise (Sigray et al. 2022).

The MSFD is ensuring that underwater noise "is at levels that do not adversely affect the marine environment," but the focus is on assessment and monitoring rather than prevention and mitigation (Merchant et al. 2022). To date, effects of continuous noise are often regarded as negligible, although evidence for an impact on hearing and behavior exists. A first step toward considering effects of continuous noise on hearing could be the monitoring of vessel noise on a temporal scale and a review of existing data about TTS in fishes that allows to estimate areas and times which exceeded TTS onsets. For mitigation of continuous noise, mainly shipping, only nonmandatory guidelines exist. Quieting technologies have long been applied to military and fishery vessels (Southall 2005) but are not used for larger commercial ships in general. Vessel noise mitigation can include technical adaptations to decrease underwater noise, while contributing to resource efficiency (Merchant et al. 2022). SATURN, a research project funded by the European Union under Horizon 2020, is currently working to identify the most promising options for measuring and reducing the negative effects of ship noise that can be applied to current and future ships. Operational measures, such as vessel speed restrictions, have proven to reduce noise levels from the majority of commercial vessels (MacGillivray et al. 2019). As the offshore wind industry expands fast globally, research priorities for sound and vibration effects on fishes and aquatic invertebrates have been suggested to fill in knowledge gaps and inform cumulative impact models, to understand effects on populations and ecosystems (Popper et al. 2022). It is often argued that additional in situ studies with actual sound sources and free-ranging fish are needed, since tank experiments do not resemble ideal soundscapes and captive fish do not show normal behavioral reactions. Reducing source levels of a sound reduces the affected habitat size and thus reduces impacts, both known and unknown, in many taxa, from individual to ecosystem level, and could be implemented with current knowledge (Risch et al. 2021). Even moderate-intensity continuous noise is able to elevate hearing thresholds and compromise important behaviors; therefore mitigation measures to decrease ambient noise levels are not unreasonable.

## Conclusion

The ability to perceive and react to acoustic signals is highly fitness relevant for many fish species. Rising low-intensity noise sources alter behaviors that evidently have high impact, such as foraging decrease and spawning reduction, which could affect population growth. Disturbance in perception, no matter if derived from stress, masking, or hearing impairment, must be avoided. Therefore, noise levels have to be monitored and effects on fishes in the wild have to be determined. This should be considered in marine spatial planning for wind farms and marine traffic. Wind farms are a needed energy resource, but biodiversity loss and climate change are interconnected issues that must be approached together. Current knowledge already makes it clear that source-level reduction is also reducing impact area. Therefore, regulatory and mitigation approaches could be implemented regardless of knowledge gaps.

**Acknowledgments** This work was funded as part of the SATURN project, which has received funding from the European Union's Horizon 2020 research and innovation program under grant agreement number 101006443.

**Abstract**

Marine fish inhabit an acoustic world and are often exposed to anthropogenic noise. Natural sounds play an important role in spawning aggregations, finding prey, escaping predators and guiding spatial behavior. Noise pollution at sea includes the prominent presence of sounds from vessels, but also pile driving, seismic surveys, and explosions, which can cause extreme overexposure. Such extreme events can cause physical damage and even mortality for nearby fish. Acoustic Deterrent Devices, using sounds at moderate levels, may be used to scare fish away from dangerous sites. Investigation of acoustic responsiveness to deterrent sound stimuli is challenging at sea due to low-visibility and limitations of tagging studies, while captive studies yield high resolution data that can be used to compare sound treatments. In this study, eight pulse train variants were tested on captive Atlantic herring (*Clupea harengus*) and methodological steps

for measuring 3D behavior automatically for groups of four fish are reported. Potential decay in responsiveness was tested at two levels: within the repetitive exposure of ten pulse trains during a treatment, and across eight treatments over 2 days. Upon sound onset, herring showed an immediate increase in turning behavior and swam deeper in the basin. There was no decay or change in any behavioral response at either level. The discussion explores the importance of response persistence within the context of responsiveness tests in captivity.

## Introduction

Human activities at sea can be noisy and thereby affect marine fauna (Slabbekoorn et al. 2010; Kunc et al. 2016; Duarte et al. 2021). Such anthropogenic noise can lead to issues for marine animals through deterrence, disturbance, distraction, and/or masking of relevant sounds. High amplitude, impulsive sounds, such as from seismic surveys, pile driving, or explosions, may cause physical injury, which can even be fatal. The behavioral and physiological effects of anthropogenic noise may affect many individuals and species spread over a large area (Slabbekoorn et al. 2010; Cox et al. 2018). The physical and mortal effects are typically restricted to smaller areas, affecting fewer individuals and species (Ladich 2008; Popper and Hastings 2009; Halvorsen et al. 2012). The relatively short range at which impulsive sounds pose a direct danger opens up opportunities to exploit moderate acoustic stimuli to herd animals away from danger, for their own safety.

Moderate-level sounds can be used in Acoustic Deterrent Devices (ADDs) to protect aquatic animals from severe overexposure to loud sounds (Putland and Mensinger 2019). Minke whales (*Balaenoptera acutorostrata*), for example, moved away immediately after sound onset during an experimental test of an ADD, typically increasing horizontal speed, and directionality, away from the source, while extending dive duration (Boisseau et al. 2021). The so-called "Seal-scarer" and "FaunaGuard" were developed with the intention of guiding marine mammals away from dangerous acoustic events at construction sites, and there are reports of successful application for harbor porpoise (*Phocoena phocoena*) (Brandt et al. 2013; van der Meij et al. 2015; Geelhoed et al. 2017; Voss et al. 2023). ADDs are also often used to scare marine mammals away to prevent predation of the harvest at fish farms and marine mammal by-catch during fishing at sea, although the success of deterrence may be variable and fade over time (Carretta and Barlow 2011; Götz and Janik 2013).

Not only marine mammals, but also fish, may be spatially affected and redirected by sound, as is clear from several examples from studies in rivers. At short distance from the source, migrating individuals of European eel (*Anguilla Anguilla*) were

shown to avoid the river side from which infrasound was played, to guide them to a safe passage (Sand et al. 2000). Maes et al. (2004) reported large reductions in trapped Atlantic herring (*Clupea harengus*) and sprat (*Sprattus sprattus*) using an ADD at a cooling water inlet of a nuclear power plant. Combinations of sound, strobe lights, and bubble screens proved to be successful in guiding juvenile Chinook salmon (*Oncorhynchus tshawytscha*) away from a low-survival migration route (Perry et al. 2014), and in curbing the upstream migration of invasive silver carp (*Hypophthalmichthys molitrix*) and bighead carp (*H. nobilis*) (Ruebush et al. 2012). A recent review (Putland and Mensinger 2019) showed that most of the published deterrence studies showed positive results (>50% deterrence); however, these results varied among taxonomic groups (Popper and Carlson 1988) and publications may be biased to positive results. Examples of acoustic herding or redirecting of fish at sea are reported with respect to both deterrence and attraction in the context of fishing (Wahlberg 1999). However, detailed insights into general acoustic responsiveness patterns for marine fish at sea are lacking (Hawkins et al. 2014; Slabbekoorn et al. 2019), and very little is known about whether responsiveness persists or fades over time with repeated exposure (Wahlberg 1999; Bejder et al. 2009; Rankin et al. 2009).

Habituation is an important phenomenon, not only to understand the detrimental impact of anthropogenic noise, but also to understand the persistent efficiency of ADDs. Habituation concerns a decrease in behavioral response to repeated stimuli, when this decrease cannot be attributed to sensory adaptation or motor fatigue (Bejder et al. 2009; Rankin et al. 2009). Sensory adaptation refers to a decrease in response of the sensory system and motor fatigue to exhaustion of the muscles. Several marine animals, including fish (Johansson et al. 2016; Radford et al. 2016; Neo et al. 2018), cephalopods (Samson et al. 2014; Mooney et al. 2016), and bivalves (Hubert et al. 2022), have been shown to decrease their behavioral or physiological stress response over repeated sound exposures. Persistent potential to trigger a response at moderate sound levels, after repeated exposure, or long-term impact on swimming behavior and spatial avoidance, seem to be the most critical features for efficient stimuli for ADD applications.

However, data on pelagic fish are particularly limited, as they are difficult to gather not only due to the obvious exposure and observation challenges at sea, but also due to the challenges of testing them in captivity. Sound propagation in basins and tanks differ substantially from propagation at sea (Rogers et al. 2016; Campbell et al. 2019), and lack of escape possibilities are an inherent restriction, and thus determine the specific research questions that can be targeted. Nevertheless, studies in captivity are an important tool to study behavioral responses to acoustic stimuli in fish, complementary to observational and exposure studies in the field (Slabbekoorn 2013). Advantages of indoor studies include better visibility, known subject condition and exposure history, easier replication of comparable exposure events, and appropriate controls. Insights from indoor studies typically require outdoor follow-ups to confirm and test findings in real-world applications.

Variation in responsiveness in wild-caught Atlantic herring (*Clupea harengus*) to pulse train stimulus variants was tested with the intention of potentially improving

sounds for ADDs (Demuynck et al. unpublished). A pulse train was repeatedly played back in an indoor basin study: ten times within an exposure treatment of one sound stimulus, and eight different sound stimuli, in eight sequential treatments over 2 days. Persistence of immediate response patterns over repetition of ten of the same pulse trains of a treatment, and persistence of a response in a longer-term change, over the complete trial of eight different treatments per group of four fish, was explored. Changes over time, or lack thereof, at these two different time scales, may provide fundamental insights into auditory perception and anxiety-related responsiveness of pelagic fish, reveal validity of our experimental design, and suggest applied potential for ADDs.

## Methods

### Study Species and Housing

Atlantic herring are a common species of the North Sea, including the Belgian and Dutch parts, where they stay for the first one or two years of their life. Herring have a pelagic lifestyle and typically swim in large schools. In the early life stages, they live in relatively shallow coastal waters (up to 30 m depth in the southern part of the North Sea). They are among the better hearing fish species and hear frequencies up to 4 kHz or more (Enger 1967; Popper and Fay 2011). Young Atlantic herring were caught in the Westerschelde (sea inlet in Zeeland, the Netherlands), on July 16, 2021 (Demuynck et al. unpublished), with a large net by professional fishermen and then transported in two 500 L, well-aerated water tanks. The fish were kept in two stock basins (3 m diameter, 1 m height) until the exposure experiments at the marine fish facilities of Stichting Zeeschelp (Kamperland, the Netherlands). Fish were fed daily with crushed amphipods (*Gammarus spp*). The herring had an average length of 8.4 cm and average weight of 3.7 g when they were transferred for the experiment to a third basin, identical in size and shape to the stock basins. All basins had a continuous flow-through of filtered sea water from the adjacent Oosterschelde sea inlet (Zeeland, the Netherlands).

### Experimental Exposure Conditions

The herring were transferred in groups of four to the experimental basin to acclimatize for at least one night. In total, ten groups were exposed to eight different sound treatments over two subsequent days (see Demuynck et al. unpublished). Each sound treatment consisted of a different pulse train variant, which was repeated for a total of ten times. The pulse trains were 10 s long and made in Audacity® version 3.0.2 (Audacity Team 2021) with 35 white noise pulses of 0.02 s each, with a high-pass (150 Hz) and low-pass (4 kHz) filter applied. The eight different pulse trains varied in temporal pattern with respect to amplitude level and interval duration. The

amplitude was either constant (−1 dB relative to full scale (dB FS)), fading in (linearly from −31 dB FS to 1− dB FS), or fading out (linearly from −1 dB FS to 31− dB FS). The pulse rate was either regular (intervals of 0.275 s), accelerating (intervals linearly from 0.5 s to 0.05 s), or decelerating (intervals linearly from 0.05 s to 0.5 s). The sounds were played back with a Tascam DR-07 portable digital recorder, from a M033N, Kemo amplifier and a UW30, Lubell underwater speaker (frequency response 100 Hz – 10 kHz), hanging from a rod above with a rope, in the middle of the experimental basin.

## Behavioral Measurements via 3D Tracking

The behavior of the "schools" of four fish were recorded with five GoPro cameras (HERO3, HERO3+, HERO4, and HERO4+), which were evenly placed alongside the edge of the basin wall (see Demuynck et al. unpublished). Automatic tracking software (EthoVision XT, Noldus Information Technology) was used to extract the positions of each fish within the camera field of view, and subsequently to calculate the mean position of the group. Additionally, the mean distance between individuals was determined as a measure for group cohesion. By using the overlap of the fields of view of two adjacent cameras, the 3D position of the group center (x, y, z) could be calculated in R (Fig. 1). In this way, average swimming speed, swimming depth, and thigmotaxis (distance from the wall, or the complementary measure: distance from the speaker in the center of the circular tank) were automatically extracted.

Response variation was assessed at two-time scales (Fig. 2). Short-term responsiveness was measured as the difference between the 10 s bin just before the onset of the stimulus and a 10 s bin after the onset. Long-term responsiveness was measured as the difference between the 5 min bin before the start of a series of ten exposures of a treatment and a 5 min bin during the treatment period (Fig. 1). The silent periods between treatments were used as control (sham) before and during data, at both timescales. The change in behavior was determined (during – before) and compared during the exposures with the silent controls. To gain insight into the potentially changing response pattern over the ten consecutive exposures, the changes in behavior were tested with an ANOVA, in which the number of the pulse train was the explanatory variable, independent of the stimulus type and position in the series of eight exposure periods over the two days. In a similar way, the behavioral changes were tested for the number of exposure treatments in the sequence of eight, four on each day (here, treatment number was the explanatory variable in the ANOVA).

## Permits and Ethical Notes

This experiment was conducted in accordance with the Dutch Experiments on Animals Act and approved by the Dutch Central Commission Animal Experiments (CCD) under no. AVD1060020171085.

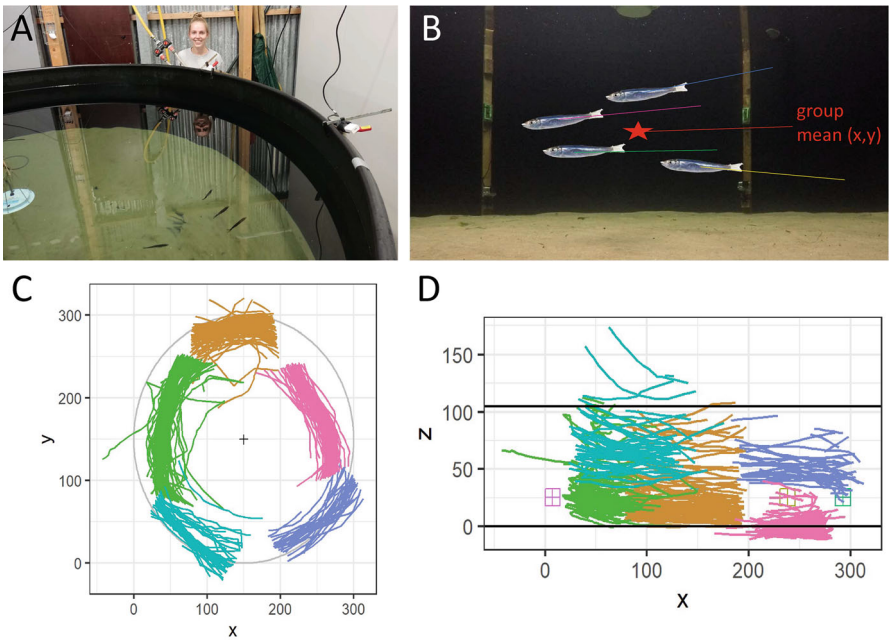

**Fig. 1** Overview of methodological steps for the behavioral assessment of responsiveness to sound stimuli by Atlantic herring: (**a**) Experimental basin with four juvenile herring, speaker in the center, and first author FD behind; (**b**) schematic representation of automatic tracking of the four fish to calculate group positions (indicated with red asterisk); (**c**) top view of 3D-tracking results of group averages for five different camera-pairs (each in different color) with x and y dimensions in cm; (**d**) side view of 3D-tracking results of group averages for five different camera-pairs (each in different color), with x and z dimensions in cm. Note that in (**c**) and (**d**) some tracks go outside of the basin (gray circle in **c** and horizontal black lines in (**d**), and that tracks of different camera-views are not perfectly connected. However, this was considered for the analyses, which looked at relative behavioral changes within certain time bins

## Results

The four fish of each group were typically swimming close together, relatively close to the tank wall (within 5–20 cm) (Demuynck et al. unpublished). The immediate responsiveness to the playback of sound stimuli typically included one, two, three, or all four fish showing a turning response, more than during the control periods (quasibinomial generalized linear model: intercept (control) = −2.41, slope = 3.07, $p < 0.001$). The immediate response to a sound exposure (first pulse train) at group level, not taking stimulus variant into account, was a significant decline in depth (ANOVA: $F1,44 = 5.60$, $p = 0.022$) and a nonsignificant trend for an increase in thigmotaxis (ANOVA: $F1,45 = 3.195$, $p = 0.081$). Group cohesion (ANOVA: $F1,44 = 1.628$, $p = 0.209$) and swimming speed did not change at the small timescale (ANOVA: $F1,44 = 0.836$, $p = 0.365$). Furthermore, none of the

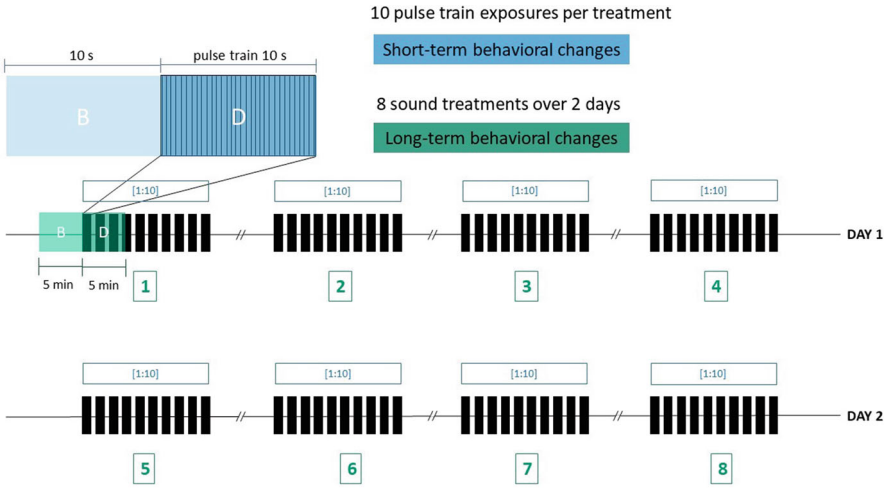

**Fig. 2** Overview of sound stimuli exposure design and two timescales of data processing. In the top left corner, the vertical lines in the black rectangular box represent the 35 pulses of a single pulse train variant (each pulse train was 10 s long). Each treatment period consisted of the playback of a single variant ten times. There were eight treatment periods in total, four on each of the two exposure days per group of four fish (n = 9, which were tested in sequence). The short-term response (in blue) was measured as an immediate change from a 10 s bin just before sound onset to a 10 s bin during the sound stimulus. The long-term response (in green) was measured as the change in behavior between a 5 min bin before the treatment periods and a 5 min bin during the treatment period (covering multiple 10 s stimulus playbacks in the overall 15 min treatment duration)

short-term behavioral measures revealed significant variation or change over time response in the ten subsequent exposures within a 15 min treatment period (ANOVAs: depth $F_{1,240} = 0.452$, $p = 0.502$; speed $F_{1,238} = 0.028$, $p = 0.868$; and group cohesion $F_{1,238} = 0.001$, $p = 0.976$, thigmotaxis $F_{1,241} = 2.07$, $p = 0.151$) (Fig. 3). The analyses of the longer-term response, not taking stimulus variant into account, revealed no significant changes in depth (ANOVA: $F_{1,91} = 0.216$, $p = 0.644$), speed (ANOVA: $F_{1,91} = 0.144$, $p = 0.705$), group cohesion (ANOVA: $F_{1,91} = 2.582$, $p = 0.112$), or thigmotaxis (ANOVA: $F_{1,91} = 0.836$, $p = 0.228$). None of the behavioral measures at this timescale showed a significant change or nonsignificant trend over time: There was no effect of treatment order, for the eight treatment periods over the two exposure days (ANOVAs: depth $F_{1,44} = 0.315$, $p = 0.577$; speed $F_{1,44} = 0.232$, $p = 0.632$; group cohesion $F_{1,44} = 0.0$ $p = 0.99$; and thigmotaxis $F_{1,44} = 1.078$, $p = 0.305$) (Fig. 3).

## Discussion

The groups of four herring significantly responded to sound exposures in the indoor conditions of our experimental setup. As an immediate response, the fish typically turned a few times, swam deeper, and showed a nonsignificant trend for swimming

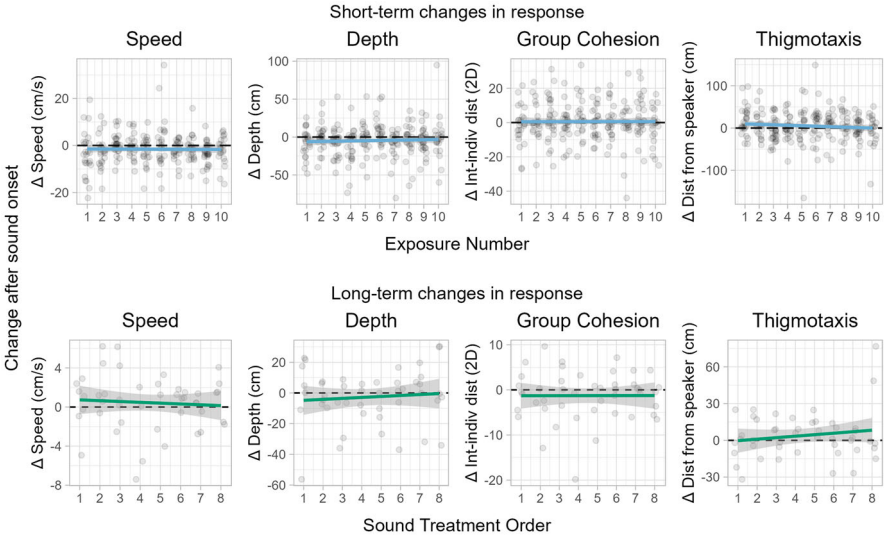

**Fig. 3** Results on persistence in behavioral responsiveness of Atlantic herring over repeated playback of sound stimuli (independent of specific pulse train variant) at two timescales. The short-term changes in response over ten sequential exposures during a treatment period are depicted in the top panel. None of the behaviors showed a significant change over the ten repeated exposures within the 15 min treatment periods. The long-term changes in response over eight sequential treatment periods, spread over two exposure days, are depicted in the lower panel. None of the other behaviors showed significant change over eight repeated tests

closer to the wall. None of the behavioral measures changed over subsequent exposures. The herring did not change their longer-term response, and their behavior also did not change significantly over the eight treatment periods over the two exposure days. These results indicated that after the initial, clear effect on turning rate and swimming depth, the four fish resumed swimming in the same baseline. Furthermore, the current analyses show that fading responsiveness, due to habituation, sensory adaptation, or motor fatigue, was not an issue for our measurements, at either timescale. This shows that the current experiment can be used to compare responsiveness among stimuli that varied in temporal patterns of change in amplitude and interval duration, despite the modest responsiveness in absolute sense (Demuynck et al. unpublished).

## Nature of Response Patterns

The immediate behavioral response patterns of our small artificial schools of four Atlantic herring included a significant response in turning and swimming depth, and a nonsignificant trend in thigmotaxis. Turning may be an important component for schooling behavior and has been described to be mainly related to the position of the nearest fish in a shoal (Katz et al. 2011). This could explain why turning behavior,

when increased during sound playback, was often displayed by all fish in the group. Increased turning during sound may be due to an increase in "alertness" or stress caused by the disturbance. A diving down response was expected as it is often found in other studies on captive fish, such as Atlantic herring (Doksæter et al. 2009, 2012a), European seabass (*Dicentrarchus labrax*) (Neo et al. 2014, 2018; Hubert et al. 2020), and in several marine fish in the wild (Sara et al. 2007; Handegard et al. 2010; Hawkins et al. 2014). The moderate, but significant nature of the vertical shift in the current study may indicate a moderate effect on anxiety or a spatial restriction of our relatively shallow basin conditions. Thigmotaxis, also called "wall-hugging," is a well-known measure of anxiety in laboratory studies in fish, especially zebrafish (*Dania rerio*) (see Schnörr et al. 2012; Kalueff et al. 2013). In our setup, closer to the wall also meant further away from the speaker. However, the fish were swimming relatively close to the wall most of the time as baseline behavior already, which seems to be a typical swimming pattern in captivity of pelagic fish in particular. Consequently, very little resolution remained for moving closer or away from the wall. This may be the reason for only a limited movement in the first exposure of the ten within an exposure period. While other studies have reported anxiety-related increases in group cohesion among schooling fish, forming tighter instead of less tight schools in conditions of apparent threat (Neo et al. 2014, 2015; but see Hubert et al. 2020), the results from this study lack any significant effect on group cohesion. However, even if the fish would have been swimming significantly closer together, this behavioral response does not appear to be advantageous for the efficiency of an ADD. On the contrary, like swimming downward, tighter schooling behavior may mean that they would stay at a particular location for longer. However, more studies on free-swimming fish in the wild are needed to confirm such an interpretation.

## Potential for Spatial Avoidance

As addressed above, the nonsignificant trend in thigmotaxis concerned an initial shift away from the speaker. Although this may be interpreted as a subtle spatial avoidance response, the effect was not significant, and it is not likely related to acoustic avoidance of the speaker in the center. Very little sound pressure level variation is expected over the scale of movement of the fish in response to the sound exposure, and they are relying on particle motion for directional hearing anyway (Popper and Fay 2011; Radford et al. 2012). Particle motion fluctuations in level may be similar sound pressure, but the directional patterns are highly complex in captive, shallow-water conditions, especially close to the basin wall and surface (Rogers et al. 2016; Hubert et al. 2016; Campbell et al. 2019), and are unlikely to provide useful information to the fish about speaker source location. Furthermore, despite the large size of the basin relative to the fish size and number, the fish may be restricted in revealing natural escape behavior in our captive conditions. Spatial avoidance in the wild can therefore not be excluded, but the current results should not be considered as evidence for a tendency of horizontal escape behavior. If anything, the thigmotaxis response may be related to a rise in anxiety. Whether a general rise in

anxiety yields any spatial avoidance in natural conditions at sea for herring or other pelagic fish remains to be investigated in situ.

## Conclusion

Atlantic herring in captive conditions responded to exposure of acoustic pulse trains as reflected by immediate turning behavior and by swimming deeper. Additionally, they showed an immediate response at small scale in swimming closer to the wall, although only to a moderate extent and this pattern was not significant. Consistent behavioral values across sequences of ten repetitions of the same stimulus were not surprising because of the overall low responsiveness. Nevertheless, it is argued that the nonsignificant trend in change in thigmotaxis may be an indication of a modest, initial rise in anxiety. At a larger scale, fish did not show any behavioral response to the sound treatment, which was persistent across eight treatment periods over the duration of two exposure days. The results indicate that a suitable behavioral assay was used to assess a variety of behavioral measures quantitatively and automatically, to evaluate relative variation in responsiveness to sound in juvenile Atlantic herring as a model species for pelagic fish. The methodology was sufficient to distinguish a response from no response at modest response levels. Responsiveness in captivity should not be translated directly to application potential of ADDs in pelagic fish at sea, but the increased turning behavior and trend in thigmotaxis may warrant further testing of ADD efficiency with fish in the field.

**Acknowledgments** This study was a part of the APELAFICO project, funded by NWO (NWA.1236.18.004) and Rijkswaterstaat. We thank Tom van Tilburg and Daniël Mirck for their help with this project during their internships. We thank the staff of Stichting Zeeschelp for the technical support during the experiment.

**Abstract**

Anthropogenic noise is globally recognized as a stressor for animals. However, despite evidence of detrimental effects of noise exposure on fish, knowledge about chronic effects on critical early life stages is still scarce. Using a split-brood design to exclude the genetic effect, African cichlids (*Maylandia zebra*) from the same brood were exposed to boat noises (~120 dB) and to control condition (~100 dB) for 12 weeks, starting when mouth-brooding females released their young. Treatment fish were exposed to motorboat noises from 9 a.m. to 6 p.m. to mimic a typical daily boating activity. Larvae total length and foraging activity were measured in weeks 1 and 12. The study did not find a significant effect of chronic boat noise exposure on these variables. However, whether noise has any impact within the studied period or after week 12 is not clear. Future work will focus on analyzing the data weekly over the 12 weeks exposure period to further substantiate the current results. Addressing the effect of anthropogenic noise on early life stages may have implications for our understanding of the effect of this pervasive stressor on aquatic organisms.

## Introduction

Anthropogenic underwater noise from commercial shipping, oil and gas exploration, naval operations, fishing, and construction work has been shown to have increased low-frequency ambient noise at an average rate of 2.5–3 dB/decade since the 1960s (McDonald et al. 2006; Miksis-Olds and Nichols 2016). The higher concentration of human activities in some areas increases the noise above the ambient level not only locally but also away from the source. As many anthropogenic activities generate low-frequency sound, it propagates over long range, making it a particularly pervasive pollutant (Miksis-Olds and Nichols 2016). Underwater sounds carry important information such as cues from the surrounding environment or from other animals. Aquatic animals use these acoustic information for communication, navigation,

mating, foraging, agonistic displays, territorial defense, and reproduction (Kasumyan 2009). However, the hearing frequency range of most marine animals overlaps with anthropogenic noise, such as boat noise (Erbe et al. 2014; Merchant et al. 2020; Nikolopoulos et al. 2016). Underwater anthropogenic noise negatively affects aquatic animals, for example, by masking important acoustic information (Clark 2009; Clark et al. 2009; Codarin et al. 2009; McCauley et al. 2003) or impairing hearing by causing permanent and/or temporary hearing threshold shifts (Kastak et al. 2008; McCauley et al. 2003) or cause physiological changes including stress effects and changes in behavior (Popper and Hawkins 2019).

There are few studies focused on the effects of chronic noise during fish development (Faria et al. 2022). Early life experiences have been shown to have impacts on adult behavior, and the effects could be complex and long lasting (Carlson 2017). However, as increasing noise made by humans alters the underwater soundscape, it is expected that it will affect the early life stages of aquatic organisms, which are generally regarded as the most sensitive period in the whole life span. Fish during early life stages suffer high mortality even under normal environmental fluctuations and challenges (Catalán et al. 2020) and increased mortality could have profound consequences on populations (Slabbekoorn 2019). The limited studies on the impact of anthropogenic noise during the developmental period in aquatic animals point to species-specific effects. For example, noise was shown to decrease growth rate and increase overall stress responses in Lusitanian toadfish embryos (Faria et al. 2022); increase the heart rate of damselfish embryos (Fakan and McCormick 2019; Jain-Schlaepfer et al. 2018); increase heart rate, yolk sac use, and cortisol levels of the zebrafish larvae (Lara and Vasconcelos 2021); reduce feeding success in winter flounder larvae (*Pseudopleuronectes americanus*) (Gendron et al. 2020); and reduce the settlement of coral reef fish larvae (Simpson et al. 2016). Noise effects are also dependent on exposure duration. It is notable that most studies on anthropogenic noise effects are focused on the acute or relatively short-term exposure, likely due to long-term experiments being harder to carry out. There is evidence that long-term anthropogenic noise negatively affects animals (Barber et al. 2010; Crino et al. 2013; Kusku 2020), but knowledge about the chronic effects of noise on critical early life stages (larvae and/or juvenile period) is still scarce.

*Maylandia zebra* is an African cichlid living on the sediment-free rocky coast in Lake Malawi. This species is able to produce sounds during social interactions, such as territory defense (Bertucci et al. 2010; Chabrolles et al. 2017) or mating (Simões et al. 2008). This is an aggressive species with well-established dominance hierarchies. Maternal mouth-brooding is also an important feature of the species, lasting for 3 weeks before the female releases the larvae. Due to increased human activities and development of fishing and tourism industries in lake Malawi (Allison and Mvula 2002; Makochekanwa 2013), man-made noise has become a pollutant of concern. As *M. zebra* is an established study model in behavior and bioacoustics (Amorim et al. 2019; Bertucci et al. 2010; Chabrolles et al. 2017; Mellor et al. 2011), it provides an excellent opportunity to assess the effects of long-term anthropogenic noise on growth and behavior during the early life stages. This chapter investigates the impacts of chronic anthropogenic noise on growth and foraging during a critical developmental period and hypothesizes that long exposure to boat noise acts as a stressor in the early life stages and has the potential to affect growth and foraging.

## Materials and Methods

### Females and Juveniles Rearing Conditions

*Maylandia zebra* were purchased from Oxyfish (Verlinghem, France) and raised in stock tanks (l × w × h: 120 × 60 × 50 cm) at ENES laboratory (Saint-Etienne, France). Fish in each holding tank was fed daily with commercial cichlid food (JBL NovoRift sticks and Tetra flakes). All tanks were equipped with an external filter (Tetra EX filter, Tetra GmbH, Melle, Germany), aeration, and PVC tubes as shelters. The water temperature was maintained at 25 ± 1 °C with a pH of 8.0 and a 12:12 h light:dark cycle.

Stock tanks were checked daily for females at the beginning of the mouth-brooding period, which were then isolated individually. The mouth-brooding period lasted for 3 weeks after which the mouth of the female was gently opened by using round-head tweezers to release all larvae. These were transferred immediately into experimental aquaria (L × l × h: 30 × 20 × 20 cm). The aquaria were equipped with PVC tubes as shelters, sand as substrate (Aquasand Nature, Zolux déco), and aeration. Each aquarium was equipped with an underwater loudspeaker developed by Fonseca and Maia Alves (2012) and placed in the middle of the aquarium (see below). Experimental fish were fed daily with commercial food (JBL NovoMalawi sticks for Malawi cichlids, JBL NovoRift, and cichlid flakes, Tetra).

### Noise Playback

Motorboat sounds were originally recorded by V. Médoc in the Grangent lake (45°45′07.54″N, 4°25′56.47″E, Loire, France) at 1-m depth (hydrophone Aquarian Audio Products H2a-XLR, AFAB Enterprises, Anacortes, WA, USA; sensitivity: −180 dB re. 1 V $\mu Pa^{-1}$, frequency response within ±4 dB in the range 20 Hz–4.5 kHz, connected to a ZOOM H4 Handy recorder). Twenty-five original boat sounds were excerpted and linearly faded at both ends using Audacity 3.1.3 (http://audacity.sourceforge.net) to make them emerge from silence, before being used in the playbacks.

The aquaria background noise was around 100 dB re. 1 μPa and was used as the control condition in the experiment. To keep this background noise level, no underwater filters were installed in the experimental and control aquaria. Instead, one-third of the water was changed every 2 days.

Boat noise, played back through a DENON PMA-100M amplifier connected to a TASCAM US-366 preamplifier and controlled by a laptop running Audacity, was delivered through the abovementioned underwater loudspeaker. The loudspeakers were placed in the middle of each experimental aquarium, including the control aquaria but here without connecting them to the laptop. The excerpts of boat noise playbacks were adjusted to 120 dB re. 1 μPa before broadcasting to the fish. All modified boat noise was played back and then recorded by a pre-calibrated chain composed of a H2A-HLR hydrophone placed 3 cm away from the speaker and

connected to a ZOOM H4 recorder. Sound pressure levels of playbacks were calculated by integrating the average power spectra of the recorded sound files.

Audio tracks used in the playbacks contained different boat sounds randomly positioned along nine 1-h audio files to mimic the variability in the daily activity of small leisure boats. In the remaining time of the audio tracks, there was no noise. The number of boats varied from 6 to 15 boats/track. The boat noise was broadcast to the boat noise fish treatment from 9 a.m. to 6 p.m., every day during 12 weeks.

## Experimental Design

Five clutches from five different pregnant females were used for the experiment ($n$ = 12–21 larvae). Following a split-brood design, larvae from each clutch were divided randomly into two groups and transferred directly into the aquarium assigned to either boat noise or control treatment, where they stayed for 12 weeks.

Once a week during the experimental period, a 10-min video of daytime foraging activity was taken by using a video camera (HD 1080p C920; Logitech International SA, Lausanne, Switzerland) positioned in front of the aquarium. The frame rate of the camera was set at 120 fps (frames per second). Fish were fed with commercial food pellets every day. During filming of the foraging activity, fish were fed to satiation. All the videos were analyzed with Behavioral Observation Research Interactive Software (BORIS; Friard and Gamba 2016) to extract the foraging behavior events. Each time one fish opened its mouth to catch the food pellet was counted as a proxy for eating. The total number of foraging events was divided by the number of fish in the aquarium to get the average foraging activity per fish. Behaviors were counted at the group level (the sum of the numbers of the behaviors of all fish in one aquarium) with the software, because the larvae were too small to be labeled or identified. Every week, the total length (TL) of each individual was measured. A transparent box with 0.5 cm grid paper on the bottom was prepared for measuring the total length. To disturb the fish as little as possible, all fish in one aquarium were taken out simultaneously with a net that spanned the width of the aquarium, and fish were then placed together in the measuring box. The water in the box was changed between measurements from different aquaria. A photo from the top of the box was taken to later measure the fish length using ImageJ (Rueden et al. 2017). This was possible since the water depth was about the body height of the fish. After taking the photo, the fish were immediately placed back in the aquarium. From the total length of each fish, the average TL of each group under the two different conditions was calculated at weeks 1 and 12, i.e., the start and the end of the experiment.

## Statistical Analyses

Statistical analyses were conducted using R (version 4.2.1). According to the Shapiro–Wilk test, only the foraging per fish at week 12 was non-normal. Therefore,

a Wilcoxon signed-rank test was used to test treatment effect on foraging at week 12, and a t-test was used on total length (weeks 1 and 12) and foraging at week 1.

## Ethics Notes

The research carried out comply with relevant guidelines and regulations, including French national guidelines, permits, and regulations regarding animal care and experimental use (approval no. D42–218-0901, ENES lab agreement, Direction Départementale de la Protection des Populations, Préfecture du Rhône).

# Results

## Total Length

At the beginning of the experiment, the average total length (TL) of the larvae from the boat noise condition was 1.39 (±SD, range: ±0.07, 1.33–1.50 cm), and the average TL of the larvae for the control condition was 1.39 (±0.07, 1.32–1.52 cm). There was no difference in TL at the beginning of the experiment ($p$ value = 0.97) (Fig. 1a). After 12 weeks of exposure to boat noise, the average total length (TL) of

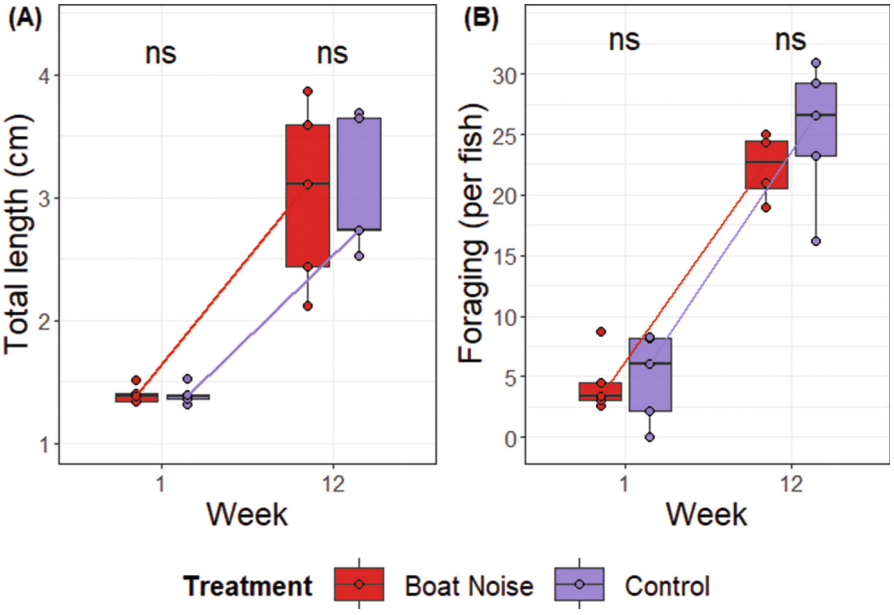

**Fig. 1** Effects of boat noise on total length (**a**) and foraging (per fish) (**b**) at weeks 1 and 12 of the experiment. Red represents fish exposed to boat noise condition, and blue represents fish exposed to control condition. Dots represent five different groups, and the boxes represent the 25th–75th percentiles

the fish under boat noise condition was 3.02 (±0.74, 2.11–3.86 cm), and the average TL of the control fish was 3.06 (±0.56, 2.52–3.69 cm). Total length of fish after 12 weeks of exposure to boat noise did not differ from the fish under control condition ($p$ value = 0.92, Fig. 1a).

### Foraging

Fish foraging activity was evaluated by the number of eating events per fish during the 10 min of filming. In the first week, the foraging activity per fish under the boat noise condition was 4.94 (±3.72, 0–8.33), while for the control condition, it was 4.44 (±2.47, 2.63–8.70). There was no significant difference in foraging per fish at the beginning of the experiment ($p$ value = 0.81, Fig. 1b). After 12 weeks of exposure, there were no foraging significant differences either ($p$ value = 0.84) (Fig. 1b) between fish under boat noise condition (25.21 ± 5.84, 16.17–30.86) and control condition (28.83 ± 14.74, 19–54.83).

## Discussion

### Growth

No significant effects were found after 12 weeks of boat noise exposure on both the total length and the foraging behavior of *M. zebra*. The lack of effects on growth is consistent with the findings for another cichlid (*Neolamprologus pulcher*) (Bruintjes and Radford 2014) in which 4 weeks of noise exposure did not affect hatching success or post-hatching larvae growth and survival. A study on rainbow trout (*Oncorhynchus mykiss*) juveniles reared under noise made by the intensive aquaculture systems for 5 months (Davidson et al. 2009) also suggested no impact in the growth and survival of the noise-exposed fish when compared to control. However, some other studies have shown that long-term noise exposure has detrimental effects on growth. For example, the total length of Lusitanian toadfish larvae (*Halobatrachus didactylus*) after 2 weeks of boat noise exposure was smaller than in the control condition (Faria et al. 2022). The larvae of freshwater sheepshead minnow (*Cyprinodon variegatus*) and killifish (*Fundulus similis*) exposed to high noise for 12 days were also smaller than those under quiet conditions (Banner and Hyatt 1973). Studies on larvae of Atlantic cod (*Gadus morhua*) showed that even larvae 2 days after hatching were smaller under noise than under control conditions, although there was growth compensation at later stages (Nedelec et al. 2015). Different effects on the total length under noise exposure might be species-specific, namely due to interspecific differences on fish hearing and the presence of a swim bladder or other resonant structures, which can cause different vulnerability to anthropogenic noise (Fay and Popper 2012; Fay et al. 2008). Differences in experimental procedures, including whether they are field- or lab-based (Popper and Hawkins 2019), the sound type (Bruintjes and Radford 2014; Kusku et al. 2020), boat type (Jain-Schlaepfer et al. 2018; McCormick et al. 2019), amplitude levels

(Lara and Vasconcelos 2021), and exposure duration (Popper and Hawkins 2019) could all have an impact on the fish's response to noise.

## Foraging

There was also no evidence that foraging activity was affected by chronic noise exposure during early life stages, when comparing that behavior between treatments on weeks 1 and 12. Although other studies have shown that foraging can be affected by additional man-made noise (Bracciali et al. 2012; Purser and Radford 2011; Voellmy et al. 2014), habituation, sensitization, and tolerance can occur in most animals after repeated and/or chronic noise exposure (Bejder et al. 2009). This suggests that young *M. zebra* fish may have habituated or gained tolerance to the added noise. However, as habituation should be the result of a longitudinal process, the comparison at only one time point (week 12) cannot provide strong evidence for distinguishing between habituation and tolerance (Bejder et al. 2009). Magnhagen et al. (2017) examined the effect of noise on foraging behavior in both roach and the Eurasian perch in the field. These authors found that perch can habituate to noise exposure as their feeding attempts first decreased and then increased gradually over the 5 days of the experiment (Magnhagen et al. 2017). However, the roach, which has higher hearing sensitivity, presented fewer feeding attempts than the perch and did not habituate to the noise during the experimental period (Magnhagen et al. 2017). The studies on perch and roach suggest that fish are able to habituate to anthropogenic noise or that the time needed for habituation has interspecific differences.

As hearing sensitivity in larvae and juveniles has not been studied in *M. zebra*, it is possible that the 120 dB boat noise level fell below hearing thresholds, thus not causing an effect. Noise is known to affect foraging behavior by directly reducing appetite (Charmandari et al. 2005) or indirectly through a reduction in activity and locomotion (Mendl 1999). It is also possible that it alters cognitive processes involved in food detection or distracts the attention of the fish (Chan and Blumstein 2011; Mendl 1999).

Only two time points were considered in this chapter, at the start and the end of the experiment, preventing from acknowledging possible effects of noise over the full 12 weeks period. Future analyses should focus on more time points within the long-term noise exposure. This will give a better insight regarding the effects of noise along the development of fish and on whether these effects are reversible or not.

**Abstract**

There is broad concern about the potential effects of anthropogenic sound on aquatic animals including fishes. While there have been a number of studies focusing on intense impulsive sounds, most, including all recent studies, have focused on pile driving and seismic air guns. Recently, however, several studies have examined the effects of exposure to explosives, using a dose-response approach, with animals at different distances from the source. Studies were conducted offshore of San Diego, CA, USA, in 2018 with Pacific sardines (*Sardinops sagax*) and in 2019 with Pacific mackerel (*Scomber japonicus*). Primary effects were damage to the swim bladder and kidney. These two injuries displayed a monotonic dependence with acoustic dose and range from the explosion for Pacific mackerel. In contrast, Pacific sardine injuries showed a non-monotonic dependence, with increased rates of injury both near the detonation and at 100–150 m that may have been due to rapid decompression of the swim bladder caused by near-simultaneous arrival of bottom and surface reflected waves. Overall, differences in injury rates between these two species may have been related to anatomy and/or to differences in sound propagation conditions between years which could have influenced injuries within a certain range of distances from the detonation.

Swim bladder · Kidney · Rupture

## Introduction and Background

Fishes can be injured or killed by underwater explosions (Yelverton et al. 1975; Dahl et al. 2020; Jenkins et al. 2022). Previous studies have related injury in fishes to the acoustic dosage from underwater explosions (Popper et al. 2014). Many of these studies, however, had few to no controls, restricted acoustic environments, inadequate sample sizes, and/or insufficient examination procedures (e.g., Hubbs and Rechnitzer 1952; Yelverton et al. 1975). Despite these shortcomings, this previous research, combined with more recent investigations (e.g., Settle et al. 2002; Govoni et al. 2003; Govoni et al. 2008), provides useful insight into the susceptibility of fishes to injury from underwater explosions. These studies demonstrated that swim bladder rupture occurs when it compresses and then rapidly over-expands, which can also result in damage to nearby organs and tissues. Moreover, swim bladder over-expansion can be intensified by the arrival of a negative pressure signal reflected from the water's surface creating a rapid pressure drop due to (Wiley et al. 1981) or convergence of surface and bottom reflected waves (Dahl et al. 2020).

The work discussed here examined nonauditory injuries on adult caged fishes located at different distances from an explosion using adequate sample sizes, detailed examination procedures, and ample controls. These studies were done in

open water, allowing relatively farther exposure geometries than possible in enclosed test locations.

The anatomical differences between different fish species could affect vulnerability to underwater explosions; these studies examined nonauditory injury to two species: Pacific sardine (*Sardinops sagax*) in 2018 (Dahl et al. 2020) and Pacific mackerel (*Scomber japonicus*) in 2019 (Jenkins et al. 2022). Additional exposures to Pacific mackerel were conducted in 2021. This chapter provides an overview of the experimental methods and findings for the first 2 years of this 3-year field effort. For more detailed results beyond what appears in this chapter, please refer to Dahl et al. (2020) and Jenkins et al. (2022). In addition, the ears of Pacific mackerel used in the study were also examined (Smith et al. 2022).

## Approach

This experiment was conducted on 4 trial days in October 2018 using Pacific sardines and 5 trial days in September 2019 using Pacific mackerel, with a single explosion each day. Pacific sardines had a mean standard length of 166 mm (SD 9 mm) and mean weight of 62 g (SD 11 g). Pacific mackerel had a mean standard length of 212 mm (SD 17 mm) and mean weight of 106.8 g (SD 27.9 g).

The explosive in 2018 consisted of 3.4 kg of C4 explosive, corresponding to 4.7 kg of trinitrotoluene (TNT), whereas 4.5 kg of C-4 (equivalent to 6.2 kg of TNT) was used in the 2019 trials. Detonations occurred at a depth of 10–11 m, near the middle of the water column. The detonations were conducted by Navy explosive ordnance disposal (EOD) personnel in accordance with the US Navy's Hawaii-SOCAL Environmental Impact Statement (www.hstteis.com) and associated permits.

All trials occurred approximately 5 km offshore from San Diego, California (USA), within the US Navy's Silver Strand Training Complex. All experimental cages were located along a transect with average water depth of 19.5 m (Fig. 1). Each

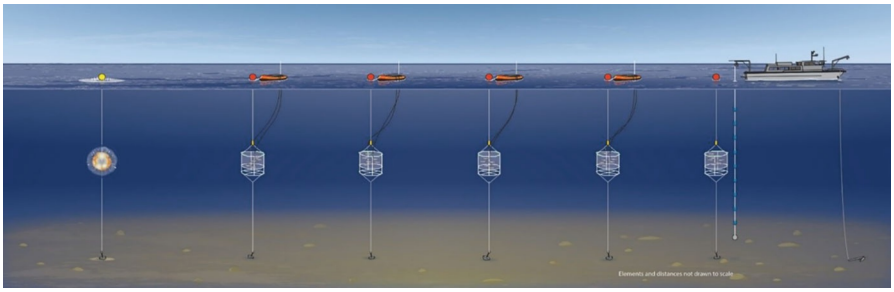

**Fig. 1** Basic layout (not to scale) for each explosive trial. Five cages are deployed midwater, with the explosion to the far left. Tourmaline blast sensors on the four cages closest to the explosion are cabled to instrument packs in the orange rafts. (Figure from Dahl et al. (2020))

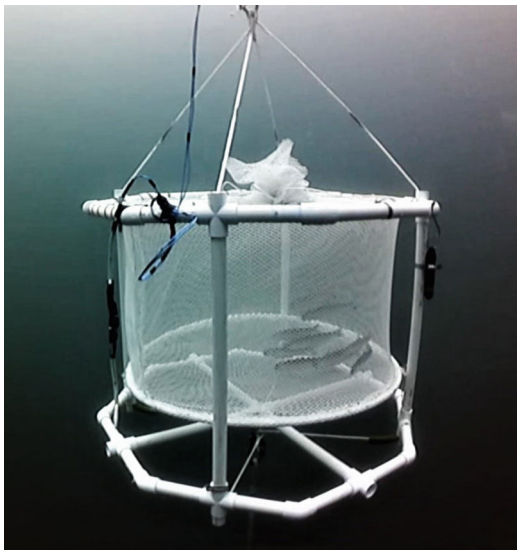

**Fig. 2** Photo of experimental cage captured by a remotely operated vehicle (ROV) just before the explosion. Details of the cage, instrumentation, and its suspension are discussed in Dahl et al. (2020) and Jenkins et al. (2022). On the right side of the cage is depth sensor with the pair of blast probes on the left. Pacific sardines are schooling in the cage. (Figure from Dahl et al. (2020))

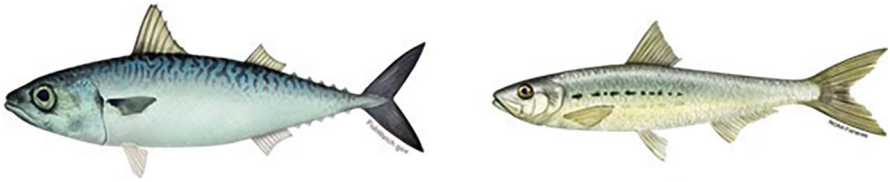

**Fig. 3** Illustrations of Pacific mackerel (left) and Pacific sardine (right) (https://www.fisheries.noaa.gov/species/pacific-mackerel and https://www.fisheries.noaa.gov/species/pacific-sardine)

cage (Fig. 2) was instrumented with either tourmaline blast sensors or autonomous hydrophone systems, depending on the expected received level.

Pacific sardine experimental cages ($n = 20$) were placed at distances ranging from 18 to 246 m, and Pacific mackerel cages ($n = 25$) were deployed at distances ranging from 21 to 807 m from the point of detonation. Control cages were placed at the same depth as experimental cages (mid-water) but retrieved prior to the detonation. Once all experimental fish cages were deployed, the EOD dive team detonated the explosives. Beginning approximately 15 min post-detonation, the test cages were recovered and all live fish were euthanized (Fig. 3).

Examination and dissection procedures were adapted from past studies (e.g., Casper et al. 2012; Halvorsen et al. 2012). This included measuring weight and length, external examination, and dissection of the abdominal and pericardial cavities to examine the organs and tissues. The fish's treatment was not known to the investigators performing examinations.

All procedures were approved by the Naval Information Warfare Center Pacific Institutional Animal Care and Use Committee (IACUC, protocol #131-2018), and

the Navy Bureau of Medicine and Surgery. The study followed all relevant US Department of Defense guidelines for the care and use of laboratory animals.

## Overall Findings

### External Effects

No differences in number or type of external injuries were seen between control and experimental animals. It is likely external injuries, such as fin tears or redness at the fin base, were the result of handling and transport prior to use. External injuries were not considered further.

### Internal Effects

Results showed five injuries that were significantly different between treatment and control Pacific sardines in 2018, including burst capillaries, fat hematoma, reproductive blood vessel rupture, swim bladder rupture, and kidney rupture (chi-square test $<0.05$ for pooled treatments versus pooled controls). For Pacific mackerel in 2019, kidney rupture, swim bladder rupture, blood pooling in swim bladder, swim bladder bruising, and blood pooling in abdominal cavity showed a significant difference between controls and treatments (Fisher's exact test of $p < 0.05$ for four or more treatment cages compared to pooled controls [see Jenkins et al. 2022]). In Pacific sardines, the reproductive blood vessel was an obvious blood vessel on the ventral surface of the swim bladder; similar reproductive blood vessel morphology was not observed in the Pacific mackerel. Eight of 209 experimental Pacific sardines were retrieved dead, and 24 of 253 Pacific mackerel were retrieved dead. As expected, most mortalities occurred closer to the detonation in cages with higher rates of injury.

Figure 4 provides the acoustic results from each test cage location for peak sound pressure level, sound exposure level (SEL), and pressure impulse. Received levels monotonically decreased with range during both experiments (2018 and 2019) as would be expected (Urick 1983). Although the size of the explosive varied between years, received levels as a function of range were similar.

Consistent with past findings (Gaspin 1975; Yelverton et al. 1975; Goertner et al. 1994), swim bladder and kidney rupture were the most prevalent injuries overall across the two study species and highly correlated with one another within years (Fig. 5). The kidney lies directly dorsal to the swim bladder in most teleost species. Thus, the proximity to the rapidly expanding and contracting swim bladder is the likely cause of kidney rupture. Similar conclusions were made for fish exposed to impulsive pile driving (Halvorsen et al. 2011, 2012).

Results show that both swim bladder and kidney rupture rates were high in Pacific sardines exposed within approximately 50 m of the source, as might be predicted; however, rates were much higher within this range for Pacific mackerel. Although a

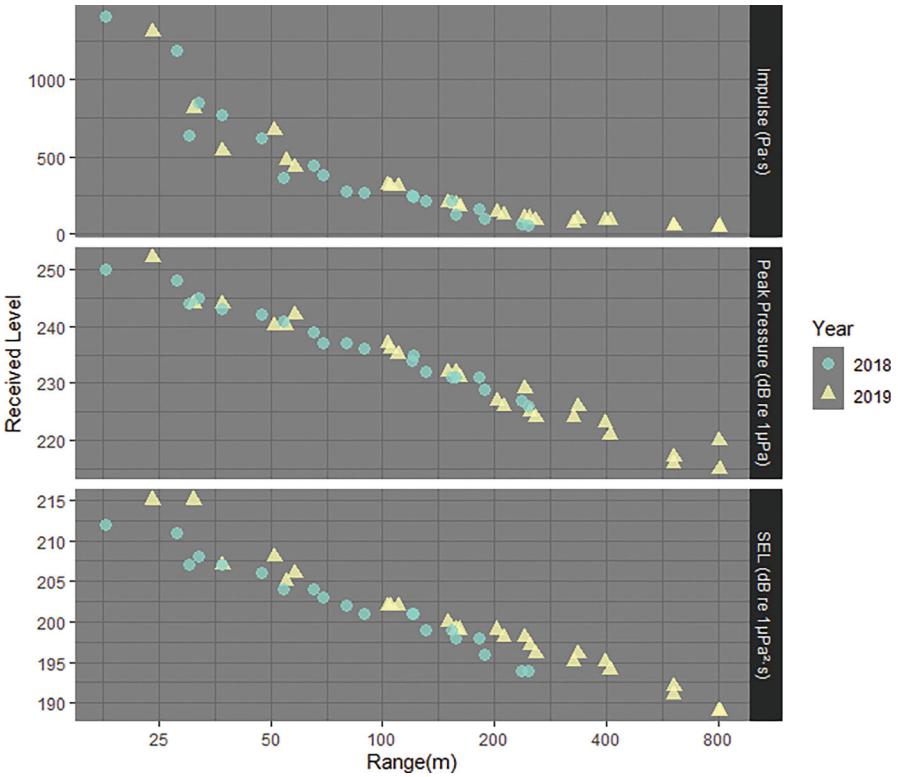

**Fig. 4** Received levels at each cage for 2018 (Pacific sardines) and 2019 (Pacific mackerel). Note the general monotonic transmission loss over the ranges sampled

larger explosive charge weight was used in 2019 than 2018, the resulting acoustic measurements at the cages were similar (Fig. 4). This suggests that the Pacific mackerel were more susceptible to injury than the Pacific sardines at the same acoustic dose.

Some of the observed differences might be attributed to differences in anatomy. Specifically, Pacific sardines are laterally flatter than the fusiform mackerel, while Pacific mackerel have a larger swim bladder (relative to body size) with a looser connection to the abdominal lining as compared to the sardines. The larger volume of air in the Pacific mackerel swim bladder may have contributed to more excitement of the air space by the impinging acoustic wave and the looser connection allowed for more motion causing more internal damage. Additionally, Pacific sardines used in 2018 had a large amount of abdominal fat not present in Pacific mackerel tested in 2019, which may have cushioned the internal organs and reduced incidents of injury in sardines.

Results for Pacific sardines also suggested a second range of severe injury to the swim bladder and kidney from about 100–150 m, while beyond that region, swim bladder and kidney rupture rates decreased to zero at the farthest ranges used. This effect was not observed in the same manner for the Pacific mackerel, where injuries

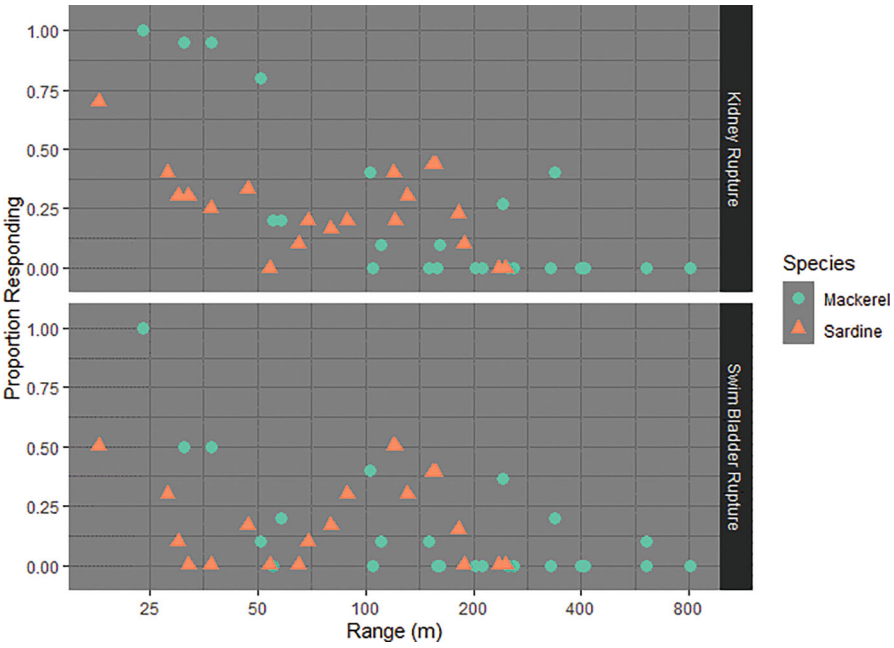

**Fig. 5** For Pacific sardines, rates of both kidney and swim bladder rupture initially fall off monotonically with increasing range; however, beyond about 50 m, the rate of injury again increases, attaining a maximum between 100 and 150 m. This was not the case with Pacific mackerel where injuries decreased across the entire range

generally decreased with increasing range, although there were instances of kidney rupture swim bladder rupture significantly higher than controls out to 333 m.

In previous research efforts on explosive and other impulsive effects on fishes, peak pressure, pressure impulse (Yelverton et al. 1991; Govoni et al. 2003, 2008), and SEL (e.g., Casper et al. 2012; Halvorsen et al. 2012) were dosage metrics used to predict injuries. It was anticipated that acoustic dosage would produce similar trends in this research. Pressure impulse, sound exposure level, and peak pressure were all generally good predictors of swim bladder and kidney rupture for both species, with injuries generally increasing with increasing acoustic dosage (Jenkins et al. 2022). However, Dahl et al. (2020) showed an increase in kidney and swim bladder ruptures at ranges between approximately 100 and 150 m for Pacific sardines which were correlated poorly with peak sound pressure level, SEL, and pressure impulse. Pacific mackerel did not experience a similar increase within these ranges.

Dahl et al. (2020) proposed a plausible explanation for the increased injuries in Pacific sardines within this range (100–150 m) observed in 2018. A rapid pressure drop caused by the near-simultaneous arrivals from the sea surface reflected and bottom bounce paths may have amplified the amount of swim bladder over-expansion per a process proposed by Goertner (1978) and Wiley et al. (1981). Sound speed profiles showed more mixing of near-surface water causing disturbance of the thermocline in October 2018 as opposed to September 2019 when

stratification of the water column was evident. This stratification may have disrupted the convergence of surface reflected and bottom bounce arrivals observed in 2018, thereby reducing the injurious effects to Pacific mackerel in 2019 from this phenomenon.

## Conclusions

This and past studies show that acoustic dosage metrics such as peak SPL, SEL, and pressure impulse are largely good predictors of injury in fishes exposed to underwater explosives (e.g., Yelverton et al. 1975; Wiley et al. 1981; Govoni et al. 2003). However, the 2018 study with Pacific sardines (Dahl et al. 2020) and in past studies (Yelverton et al. 1975; Wiley et al. 1981), potential waveguide effects were observed that increased injuries within certain ranges from the source that cannot be attributed to these acoustic doses alone. In the studies discussed here, exposures were conducted using similar methods to purposely limit factors, making results easier to understand; however, the timing of multipath arrivals at any given distance (i.e., fish cage) from the explosion was similar within a given year. Since the sound arrival waveform can vary with water depth, fish depth, explosive charge depth, and sound velocity profile, it is vital that future research varies these to better understand how these waveguide characteristics affect injury in fishes. Other significant variables to study in the future are different species/morphologies, exposure depth, explosion depth, bottom depth, and types of bottom. A follow-up study in 2021 using Pacific mackerel with a similar study design investigated the onset of recoverable injury, short-term survival, and the effect of fish depth on nonauditory injury. Analysis of the 2021 results is currently ongoing, and publications are in progress.

**Abstract**

Two recent studies of auditory temporary threshold shift (TTS) in a harbor porpoise at 25 and 28 kHz are compared to previously published results revealing a very large difference in sensitivity to TTS correlating with experimental paradigm. For fatiguing noise above 10 kHz, the TTS-onset thresholds measured with behavioral (psychophysical) methods following noise exposure to free-swimming porpoises are 40–60 dB higher than TTS-onset thresholds measured with auditory brain stem recordings on porpoises exposed while stationary. The uncertainty about sensitivity of porpoises to noise exposure above 10 kHz have very large implications for regulation of underwater noise and call for immediate further experiments. Such experiments should disentangle and quantify the confounding effects of exposure (stationary vs. free-swimming) and threshold measurements (behavioral vs. brain stem recordings), and the results are required

## Introduction

A recent review (Tougaard et al. 2022) showed good correspondence between experimental thresholds for onset of temporary threshold shift (TTS) in porpoises (Phocoenidae) and predictions from frequency-weighted sound exposure levels (SEL; from Southall et al. 2019) for fatiguing sounds below 10 kHz. For frequencies above 10 kHz, however, there were significant differences between predictions and experimental data. Since the publication of the review, two additional studies of TTS on harbor porpoises (*Phocoena phocoena*) induced by fatiguing sounds at 25 kHz and 28 kHz, respectively, have become available. These new results make it clear that TTS results for these frequencies fall into two categories: some with very low TTS-onset thresholds and others with very high TTS-onset thresholds. As noise exposure criteria related to injury typically are based on TTS-onset thresholds (used directly or extrapolated to thresholds for onset of permanent threshold shifts, PTS), it has significant implications for regulation of underwater noise, how these discrepancies between different experimental results are handled. The results are reviewed below, and possible explanations for the differences are offered and discussed.

## 25 and 28 kHz Experiments

Both experiments were conducted on the same animal (female harbor porpoise *Freja*) at the Fjord&Belt facility, Denmark, and included measurements of hearing thresholds by auditory brain stem responses on the porpoise exposed to brief fatiguing sounds of varying levels while stationary under water. One experiment used a single pure tone pulse at 25 kHz, approximately 600 ms in duration, as the fatiguing sound (Ruser et al. 2015; Andersson and Nöjd 2016), whereas the other study used a single 17-s sequence of 1024 tone pips, where each pip consisted of five cycles of a 28 kHz sinusoid, shaped with a raised cosine envelope (Schaffeld et al. 2022). TTS-onset thresholds, defined as the SEL required to elicit 6 dB of TTS, were estimated by fitting curves to the individual data points obtained at different SEL, with the method described by Finneran (2015). The TTS-onset threshold for the porpoise was 140.8 dB re 1 $\mu Pa^2s$ for both experiments, which translates into 140.3 dB re 1 $\mu Pa^2s$ and 140.5 dB re 1 $\mu Pa^2s$ VHF weighted (sensu Southall et al. 2019) for the 25 kHz and the 28 kHz fatiguing sounds, respectively. These two data points are shown in Fig. 1, on top of the data for very high-frequency (VHF) cetaceans plotted in the original Fig. 3 of Tougaard et al. (2022). The inclusion of the two additional TTS-onset thresholds at 25 and 28 kHz highlights a clustering of

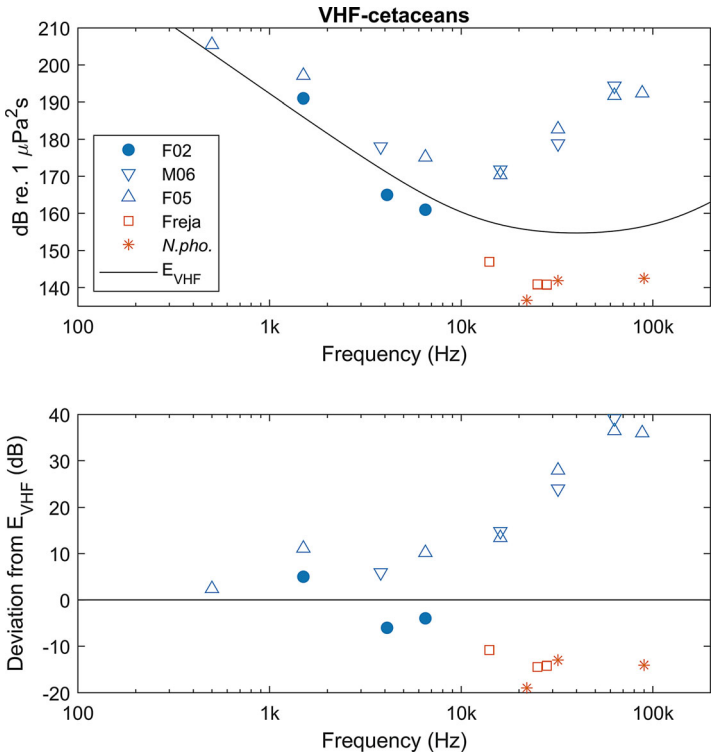

**Fig. 1** TTS-onset thresholds for porpoises exposed to non-impulsive sounds of different frequency. Color indicates experimental paradigm. Blue, exposure with fatiguing noise to free-swimming animals, thresholds measured by behavioral audiometry; orange, exposure to stationary animals, thresholds measured by auditory brain stem responses. Open symbols represent data not included in the most recent guidance regarding auditory weighting functions (Southall et al. 2019). Solid line is the VHF auditory exposure function of Southall et al. (2019)

the TTS-onset thresholds above 10 kHz in two groups. The first group consists of the data points on harbor porpoise *Freja* with fatiguing noise (pure tones up to 0.5 s duration) at 14, 25, and 28 kHz (Ruser et al. 2015; Schaffeld et al. 2019, 2022) together with the data points with fatiguing noise (pure tones up to 30 min long) at 22, 32, and 90 kHz on finless porpoises (*Neophocaena phocaenoides*, Popov et al. 2011). The second group is formed by the data points from harbor porpoises *M06* and *F05* with continuous fatiguing noise (1/6 octave band noise) at 16, 32, 63, and 88 kHz for 6 h (Kastelein et al. 2019a, b; 2020a, c).

## Discussion

Three data points were included by Finneran (2015) in his derivation of the VHF auditory weighting function, indicated by filled circles in Fig. 1. Although the measurements on *Neophocaena* (Popov et al. 2011) were available, they were not

included because TTS-onset thresholds could not be derived with the methodology otherwise used (interpolation based on data points on both sides of the level required to elicit 6 dB of TTS, the criterion used for TTS onset). Furthermore, the *Neophocaena* measurements were obtained by auditory brain stem recordings (ABRs), which are known to result in lower TTS-onset thresholds than behavioral thresholds (Finneran et al. 2007; Finneran 2015). However, three out of four data sets in total in Popov et al. (2011) provided good fits to the equation used for interpolation by Finneran (2015), and TTS-onset thresholds could be extrapolated (see details in Tougaard et al. 2022). These data points are included in Fig. 1 as stars.

When all currently available data on TTS-onset thresholds are included, as in Fig. 1, two main conclusions become evident. First, new data below 10 kHz (Kastelein et al. 2017; Kastelein et al. 2020b; Kastelein et al. 2021) are in good correspondence with the exposure function derived by Finneran (2015). Second, new data above 10 kHz cluster in two groups: one group with very high TTS-onset thresholds, 15 to nearly 40 dB above the exposure function; and a second group, 10–20 dB below the exposure function. The difference of 40–60 dB between the two groups is not trivial, as it amounts to a 4–6 orders of magnitude difference in the acoustic energy at TTS-onset threshold. A difference of 40 dB in sound exposure level (SEL) amounts to the difference in SEL of an exposure of 1-s pulse and 3 h, both with the same sound pressure level.

For several reasons it is important to understand what underlies the dichotomy of the thresholds above 10 kHz. The difference between the two groups of data points above 10 kHz is unlikely to be explained by differences between experimental animals. The lower-threshold group was obtained from three individuals and the higher-threshold group from two individuals at two different facilities many years apart, with both groups showing very little intragroup variation. This leaves two central differences between the groups as candidates for explaining the difference between groups: differences in the threshold measurement technology and differences in experimental protocol for exposure to the fatiguing noise.

## Threshold Measurements

The lower group of TTS-onset thresholds (Popov et al. 2011; Ruser et al. 2015; Schaffeld et al. 2019; Schaffeld et al. 2022) was measured by auditory brain stem responses, whereas the higher group was measured with behavioral audiometry (Kastelein et al. 2019a, b, 2020a, c). The measured amount of TTS for the same fatiguing noise depends on the way thresholds are measured, with auditory brain stem responses resulting in higher amounts of TTS measured than when measured by psychophysical methods (Finneran et al. 2007). The TTS also manifests itself at lower exposures in ABR thresholds than in behavioral thresholds (Finneran et al. 2007), resulting in lower TTS-onset thresholds. This difference likely lies in the way ABR thresholds are measured. Determination of thresholds from ABR data depends on a very persistent brain stem potential, allowing noise reduction by averaging across a large number of ABRs. A high-amplitude and stable ABR requires stable

recruitment of many nerve fibers but also that the nerves fire consistently, i.e., with stable latency. Recruitment of nerve fibers depends on the threshold of individual hair cells and synapses to the auditory nerve fibers, and changes are therefore likely to parallel changes seen in behavioral thresholds. Latency and especially variance in latency are unlikely to affect behavioral thresholds to any significant degree, as the animal's auditory system is not reliant on averaging across many neurons in the same way as an ABR measurement is. The lower TTS-onset thresholds seen in ABR measurements are therefore likely to be related to the fatiguing noise affecting timing of neural responses at levels where recruitment is not significantly affected. Near-simultaneous measurements of TTS by ABR and behavioral methods by Finneran et al. (2007) showed 20–25 dB more TTS, when measured by ABR for the same fatiguing stimulus (see Fig. 1 in Finneran 2015), which also was manifested as a 20–25 dB difference in TTS-onset thresholds (see Fig. 14 in Finneran et al. 2007). The difference in methodology for measuring TTS can therefore likely explain at least part of the difference between the two groups of results, but even if this can explain 25 dB of the difference, there is still 10–20 dB left unexplained.

## Delivery of Fatiguing Stimulus

The other main difference between the two sets of experiments, confounded with threshold measurement technology, is the way the fatiguing noise is delivered to induce TTS. In the high TTS-onset threshold group, the fatiguing noise was delivered to free-swimming animals over an extended exposure time (6 h), whereas much shorter exposures (up to 17 s for *Phocoena* but up to 20 min for the *Neophocaena* measurements) were made to stationary animals in the low TTS-onset threshold group. Could it be that the noise field of the free-swimming porpoise offered places in the tank with much lower exposure levels than assumed? This would mean that the cumulated sound exposure levels that free-swimming porpoises were exposed to are overestimated, leading to similar overestimation of TTS-onset thresholds.

## Resolving the Confounding Factors

No matter what caused the pronounced difference in TTS-onset thresholds, it must be a priority to resolve and understand this substantial discrepancy, as these data have important implications for management of underwater noise. The VHF auditory weighting function (inverse of the exposure function in Fig. 1) forms the foundation of assessment and regulation of noise exposure to VHF cetaceans in several countries (e.g., National Marine Fisheries Service 2018; Danish Energy Agency 2022). Depending on which data sets are included in establishing exposure limits, the current exposure limit (determined based on the VHF weighting function) could potentially be off with as much as up to 40 dB overestimation (including only the behaviorally determined thresholds) or down to 20 dB underestimation (including only the ABR thresholds).

Several experiments can be considered to test hypotheses about the cause of the observed differences in TTS onset and disentangle the confounding factors. An easy first would be to investigate changes to the spectrum of brain stem responses with TTS onset. Jitter in the timing of neural responses should have a more pronounced effect on the faster (mostly earlier) components than on the slower (mostly later) response peaks. The hypothesis would then be that there should be a low-pass effect on the auditory responses to the test signals, close to or at the level of the fatiguing sounds, where TTS sets in. Second, a partial switch of methods between experimental facilities seems a good start, i.e., combining noise exposures to stationary animals with behaviorally measured TTS and likewise conducting noise exposures with free-swimming animals followed by auditory brain stem recordings. This could be coupled with measurements in the same setup, but with different types of fatiguing noise: short exposures to loud pulses of noise versus long exposures to weaker, continuous noise, both with the same SEL. Furthermore, as no TTS-onset thresholds have been measured by auditory brain stem recordings in porpoises exposed to fatiguing noise below 14 kHz, it must be of importance to do this, to determine whether the difference between experimental protocols extends to lower frequencies as well.

**Abstract**

Down-the-hole (DTH) pile installation is a relatively new technology that uses percussive drilling to install piles, either by striking both the drill bit that cuts into the bedrock and the metal pile to advance the pile (DTH pile driving) or by striking only the drill bit, with no contact with the pile (DTH pile drilling). Recent studies have shown that DTH pile installation generates complex sounds containing both impulsive and non-impulsive features. In this chapter, kurtosis was used to quantify the impulsiveness of sounds from DTH pile installation for six marine mammal functional hearing groups. Results show that, during DTH pile driving, kurtosis values decreased as the distance to source increased. However, no clear trend was detected for kurtosis versus range during DTH pile drilling. Additionally, kurtosis values based on marine mammal auditory weighting functions generally were greater for species with enhanced low-frequency sensitivity (i.e., low-frequency cetaceans, pinnipeds, and sirenians) than unweighted values, whereas kurtosis values for mid- and high-frequency cetaceans were similar to, or in some cases less than, unweighted

## Introduction

In-water pile driving generates intense sounds that could adversely affect marine mammals (Branstetter et al. 2018; Kastelein et al. 2018). Conventional pile driving mechanisms include impact pile driving, where an impact hammer strikes the pile into the sediment, and vibratory pile driving, where a vibratory hammer pushes the pile into the sediment through oscillating forces. For both impact and vibratory pile driving, the hammers act directly on the pile heads, and acoustic characteristics and sound-generating mechanisms from these activities are well studied (Reinhall and Dahl 2011; Lippert et al. 2016). Specifically, impact pile driving produces short, impulsive sounds, with hammer strike rates of approximately 1 Hz; vibratory pile driving produces intermittent, non-impulsive sounds, with the vibratory hammer oscillating at a rate of approximately 20 Hz.

More recently, down-the-hole (DTH) pile installation has been increasingly used to install piles for marine and coastal construction projects. Instead of applying force on the pile head, a DTH hammer strikes a drill bit at the base of the pile and cuts into the substrate to advance the pile using a combination of percussive and drilling mechanisms. At the same time, drill cuttings and debris at the seabed are removed by an air-lift exhaust inside the pile (Bruce et al. 2013). Studies on the underlying acoustic characteristics have shown that two different techniques can be used during DTH pile installation: (1) DTH pile driving, in which the hammer strikes the drill bit, as well as the metal pile shoe at the base of the pile, and (2) DTH pile drilling, in which the hammer strikes only the drill bit with no physical contact with the pile or any pile shoe (Guan and Miner 2020; Guan et al. 2022a).

Given that sounds generated from DTH pile installation contain both impulsive components from hammer strikes and non-impulsive components from drilling and debris removal, they would be defined as complex sounds based on human psychoacoustics studies (Ahroon et al. 1993). However, current regulatory guidelines for marine mammal impact assessments involving underwater sound use a binary system to categorize sound types: impulsive and non-impulsive sounds. Separate thresholds are used to estimate noise-induced threshold shifts (NITSs) for marine mammals exposed to these two mutually-exclusive sound types (National Marine Fisheries Service 2018). There is no agreed-upon method for assessing marine mammal NITSs from exposure to complex sound, such as those generated during DTH pile installation.

Conversely, NITSs from exposure to complex sound have been relatively well studied in human psychoacoustic research over the past few decades (e.g., Lei et al. 1994). Instead of applying a binary approach to classify sound source types, researchers use a statistical measure of kurtosis to quantify the impulsiveness of the sounds and to evaluate any auditory effect in humans (Zhao et al. 2010). Under this approach, random noise with a Gaussian distribution has a kurtosis value ($\beta$) of 3. As impulsiveness increases, $\beta$ also increases due to the high variability of the acoustic pressures. Based on NITS research in chinchillas, $\beta > 40$ is considered fully impulsive for airborne sound (Hamernik et al. 2007).

In the past couple of years, researchers have begun to use kurtosis measurements of acoustic pressure to quantify the impulsiveness of anthropogenic underwater sounds (Martin et al. 2020), including unweighted sound from DTH pile installation (Guan et al. 2022b). This chapter further expands the use of kurtosis to quantify the impulsiveness of sounds from two DTH pile installation activities based on the six marine mammal functional hearing groups used by the US regulatory community, including low-frequency (LF) cetaceans, mid-frequency (MF) cetaceans, high-frequency (HF) cetaceans, sirenians (SI), otariids (OW), and phocids (PW) (Finneran 2016).

## Sound Levels and Impulsiveness from DTH Pile Installation

Underwater acoustic recordings were collected during a two-day DTH pile driving event for a dock replacement project off Biorka Island in August 2018 (Guan and Miner 2020) and during a two-day DTH pile drilling event for a cruise ship terminal construction project in Ward Cove near Ketchikan in June 2020 (Guan et al. 2022a). Both locations are in Southeast Alaska. Detailed descriptions of study areas, data collection methods (including details regarding data collection and recording equipment), and data analysis procedures are provided in Guan and Miner (2020) and Guan et al. (2022a). Tables 1 and 2 show the median sound levels from both studies, including single-strike sound exposure level (SEL) or $L_{E,ss}$, root-mean-square sound pressure level (SPL) or $L_{p,rms}$, peak SPL or $L_{p,pk}$, and cumulative SEL or $L_{E,cum}$.

Based on studies by Guan and Miner (2020) and Guan et al. (2022a), sound levels (SPLs and SELs) were generally higher during DTH pile driving of the two 18-inch piles than during DTH pile drilling of the two 33-inch shafts at the same distances (Tables 1 and 2, respectively). A simple explanation is that, during DTH pile driving,

**Table 1** Median sound levels and cumulative SELs for DTH pile driving of two 18-inch piles off Biorka Island, Alaska, from Guan and Miner (2020)

| | Pile F14 | | Pile E14 |
|---|---|---|---|
| Acoustic parameters | 10 m | 200 m | 10 m |
| Median $L_{E,ss}$ (dB re 1 μPa$^2$s) | 147 | 127 | 145 |
| $L_{E,cum}$ (dB re 1 μPa$^2$s) | 192 | 171 | 191 |
| Median $L_{p,rms}$ (dB re 1 μPa) | 162 | 140 | 161 |
| Median $L_{p,pk}$ (dB re 1 μPa) | 173 | 148 | 170 |

**Table 2** Median sound levels and cumulative SELs for DTH pile drilling of two 33-inch shafts in Ward Cove, near Ketchikan, Alaska, from Guan et al. (2022a)

| | Pile 137E | | | Pile 131 W | | |
|---|---|---|---|---|---|---|
| Acoustic parameters | 10 m | 200 m | 1300 m | 10 m | 90 m | 150 m |
| Median $L_{E,ss}$ (dB re 1 μPa$^2$s) | 138 | 122 | 109 | 142 | 127 | 124 |
| $L_{E,cum}$ (dB re 1 μPa$^2$s) | 185 | 170 | 150 | 193 | 180 | 177 |
| Median $L_{p,rms}$ (dB re 1 μPa) | 150 | 134 | 122 | 155 | 140 | 137 |
| Median $L_{p,pk}$ (dB re 1 μPa) | 158 | 143 | 130 | 163 | 149 | 147 |

the hammer struck the metal pile shoe, but during DTH pile drilling, it did not (Guan et al. 2022a).

In determining whether a specific sound type is impulsive or non-impulsive, a method proposed by Harris (1998) and adopted by Southall et al. (2007) compares the difference of the $L_{p,rms}$ of a 1-s sound clip to that of a 35-ms sound clip. If the difference is 3 dB or larger, then that sound is considered impulsive. Otherwise, it is considered non-impulsive. Using this method to examine the two DTH pile installation datasets from Alaska, the average sound-level difference was 3.40 dB for DTH pile driving and 2.05 dB for DTH pile drilling (Guan et al. 2022b). Sounds from DTH pile driving would have been considered impulsive, and those from DTH pile drilling would have been considered non-impulsive.

However, this method is difficult to implement and at times can be subjective, as time-gating of the signals for comparison is a tedious and sensitive process, especially when the signal-to-noise ratio is low. Additionally, sounds from DTH pile installation contain both impulsive (from hammer strikes) and non-impulsive (from drilling and debris pumping) components, and using kurtosis values that represent a continuum would be more appropriate than the current impulsive vs. non-impulsive binary approach to assess the impulsiveness of such sounds.

## Kurtosis Values for Marine Mammal Functional Hearing Groups

To compute kurtosis values, all acoustic recordings obtained during the measurements are divided into 60-s segments. A 60-s window duration was chosen for consistency with other studies that calculated kurtosis values for assessing the impulsiveness of various underwater sounds (e.g., Martin et al. 2020; Guan et al. 2022b). More importantly, Tian et al. (2021) showed that 60 s was an optimal window duration that allows for both efficient computation and high accuracy for noise-induced hearing loss in humans. If one or more hammer strike signals were present within the 60-s segment, the sound clip was classified as "hammer on"; otherwise, it was classified as "hammer off."

In calculating $\beta$ for each of the six marine mammal functional hearing groups, custom MATLAB (MathWorks Inc., Natick, MA, version R2021a) codes were developed using the following equation:

$$\beta = T{\cdot}f_s{\cdot}\sum_{i=1}^{N}[p(i)-\overline{p}]^4 / \left\{\sum_{i=1}^{N}[p(i)-\overline{p}]^2\right\}^2 \quad (1)$$

where $f_s$ is the sampling frequency, $T$ is the window duration, $p(i)$ is the frequency-weighted acoustic pressure for specific marine mammal functional hearing groups, and $\overline{p}$ is the arithmetic mean acoustic pressure for $p(i)$ within $T$.

The acoustic pressure for each marine mammal functional hearing group was determined based on the auditory weighting function developed by Finneran (2016)

$$W(f) = C + 10\,log_{10}\left\{\frac{(f/f_1)^{2a}}{\left[1+(f/f_1)^2\right]^a\left[1+(f/f_2)^2\right]^b}\right\} \quad (2)$$

where $C, f_1, f_2, a$, and $b$ are constants that define the shape of the function for each functional hearing group. To ensure that the original time series information was preserved, computations of frequency-weighted acoustic pressures were conducted using Fourier and inverse Fourier transforms in linear space.

Table 3 presents median $\beta$ for each marine mammal functional hearing group during DTH pile driving when the hammer was on and off, and Table 4 includes similar results during DTH pile drilling. Unweighted $\beta$ also are included for DTH pile driving and DTH pile drilling. For unweighted sounds previously reported by Guan et al. (2022b), median $\beta$ ranged from 10.4 to 30.0 during DTH pile driving and from 4.2 to 5.8 during DTH pile drilling (Tables 3 and 4, respectively).

The results show that for DTH pile driving, $\beta$ values were overall much greater than 3 but less than 40 (Table 3), indicating sounds from DTH pile driving were somewhere between non-impulsive and fully impulsive. Additionally, $\beta$ for DTH pile driving showed clear differences between hammer on and hammer off, with much greater values when the hammer was active (Table 3). However, although $\beta$ for DTH pile drilling were generally greater than 3, they were overall less than those from DTH pile driving, which indicate sounds emitted during DTH pile drilling were less impulsive than those during DTH pile driving. In addition, there was no clear trend in $\beta$ between hammer on and off during DTH pile drilling (Table 4). Furthermore, for DTH pile driving, decreases in $\beta$ were observed as the distance from the pile increased, which indicate that the sound was becoming less impulsive as it propagated away from the source (Table 3). This trend was not observed for DTH pile drilling (Table 4).

When comparing kurtosis values among different marine mammal functional hearing groups, weighted $\beta$ for LF cetacean, SI, OW, and PW were greater than unweighted values at various distances during DTH pile driving (Table 3). This trend likely is due to the fact that most acoustic energy from DTH pile installation was in the low-frequency (<2 kHz) range, which corresponds to the more sensitive hearing range of these functional hearing groups (Guan and Miner 2020). Similar patterns also were observed for LF cetacean, OW, and PW during DTH pile drilling at all distances except 1300 m. These findings could have implications regarding auditory perception and the potential for resulting auditory damage.

## Kurtosis as a Parameter for Marine Mammal Threshold Shifts from Sound Exposure

For marine mammal impact assessments involving sound exposure, the binary scheme that categorizes sounds into two mutually-exclusive types continues to be used: impulsive and non-impulsive sounds. Although research on marine mammal NITS has only focused on animals being exposed to one of these two sound types (Guan and Brookens 2021), animals are rarely exposed to purely impulsive or purely non-impulsive sounds in the wild. In addition to the scenario presented with sounds emitted during DTH pile installation, coastal construction activities often involve simultaneous impact and vibratory pile driving or drilling (e.g., Department of the Navy 2022a), simultaneous rock hammering and drilling (e.g., Department of the Navy 2022b), or impact pile driving from a barge that operates dynamic positioning.

As impulsive sounds propagate through the ocean environment, multipath and scattering render the sound less impulsive. Marine mammals also are unlikely to remain within the immediate vicinity of impulsive sources (i.e., an impact hammer or seismic airgun arrays), in most circumstances. As such, the sounds they are exposed to likely would be complex sounds.

It has been shown that, given the same $L_E$, exposure to complex sounds produces more severe hair cell damage than continuous Gaussian sound in human and terrestrial mammals (Lei et al. 1994; Hamernik et al. 2007). However, whether marine mammals exposed to complex sounds would experience similar effects as terrestrial mammals is unknown, as temporary threshold shift studies conducted thus far have exposed animals to either purely impulsive or purely non-impulsive sounds.

Therefore, there is a critical need to obtain NITS data on marine mammals that are exposed to complex sound at different degrees of impulsiveness. Studies also are needed to review the current binary scheme used to classify sound source types and to establish appropriate standards for classifying sound types based on metrics of impulsiveness from different sound sources.

## Conclusion

Kurtosis values were used to quantify the impulsiveness of sound generated during DTH pile driving and DTH pile drilling at two locations in Southeast Alaska. Using $\beta$ to evaluate impulsiveness, which ranges from 3 for non-impulsive Gaussian sound to greater than 40 for fully impulsive sound, sounds generated during DTH pile installation were in the continuum between the two extremes. $\beta$ values during DTH pile driving were all greater than those during DTH pile drilling. Thus, sounds from DTH pile driving were more impulsive than those from DTH pile drilling. This finding likely is due to the DTH hammer directly striking the metal pile shoe during DTH pile driving, resulting in more impulsiveness to the sounds emitted. Additionally, for DTH pile driving, a decrease in $\beta$ with increasing distance was observed, which is consistent with the common understanding that multipath and scattering reduce the impulsiveness of an impulsive signal (Urick 1982).

Among the six marine mammal functional hearing groups, $\beta$ values tend to be greater for groups that are more sensitive to low-frequency sounds – such as LF cetaceans, SI, and both pinniped groups – than those of unweighted sounds. This trend also is consistent with previous studies that determined the majority of acoustic energies from DTH pile driving and DTH pile drilling were within the low-frequency range (Guan and Miner 2020; Guan et al. 2022a).

Currently, assessments regarding the impacts of sound on marine mammals are based on a binary scheme that categorizes sound source types as either impulsive or non-impulsive. There is no mechanism to evaluate marine mammal auditory impacts from exposure to complex sound, such as exposure from DTH pile installation or from a real-world construction activity that includes a combination of impulsive and non-impulsive sources. Studies on human and terrestrial mammal NITS have shown that under the same amount of $L_{E,cum}$, increased impulsiveness can cause more hair cell damage than exposure to non-impulsive Gaussian sound. Therefore, research is needed to investigate whether marine mammal exposure to complex sound follows a similar pattern to that of human and terrestrial mammals and to establish impact assessment guidelines that reflect the real-world sound exposure environment.

**Acknowledgments** The authors thank Robert Miner Dynamic Testing of Alaska Inc.; Turnagain Marine Construction, Inc.; and Solstice Alaska Consulting, Inc., for supporting the collection of the acoustic recordings. The authors also appreciate the constructive comments from Paulina Chen, Rodney Cluck, Yoko Furukawa, Peter Thomas, and Sonal Nagpal on the book chapter.

**Abstract**

Since first described as moans or squeals, pulsed calls of killer whales (*Orcinus orca*) have been extensively studied. Most research focused on their social functions, such as maintaining contact by members of family groups or hunting parties, recognizing members of different communities of the same ecological type (killer whale ecotypes are differentiated by food preferences [Ford, Killer whale: *Orcinus orca*. In: Encyclopedia of marine mammals. Academic, pp 650–657, 2009]), or members of populations from different ecotypes. Social learning and intergenerational social transmission of call structure are seen as the main drivers for stability of group- or population-specific repertoires of stereotyped calls that appear to change very slowly over generations. Other ecological drivers potentially influencing call stability have been given less attention, including the influence of propagation loss and ambient noise on structural conformity. The stereotypic structure of calls (ordered occurrence of distinct components), however, allows identification of groups and populations at considerable distances. In order for calls to be recognizable at greater distances, their structure needs to allow reliable propagation in differing ambient noise conditions. Model simulations of variation in automated call detection range suggested that different spectral call frequencies are responsible for optimal detection in environments with different ambient noise levels. In a number of experimental field trials, the influence of noise on propagation of calls from two different populations of fish-eating killer whales was examined. The goal of these experiments was to determine if call structure allows some degree of compensation from noise masking. Preliminary results of the field experiments presented here showed that the propagation of dominant frequencies of calls, which varied between call components of call types, showed variations in propagation distances. The propagation was correlated with the ambient noise levels present at different receiver locations, such as upper or lower parts of the water column. Furthermore, the use of certain buzz-type call components, which are common initial components of many killer whale calls, differed in propagation, especially when they were used as standalone calls by members from a subpopulation spending more time in noisy environments. Spectral energy differences in calls, however, are currently not considered when anthropogenic noise impact, an identified threat for this endangered population, is assessed.

## Introduction

It is generally assumed that animal communication signals and the physiological receiver capacities have coevolved to create reliable information transmission through air, water, and substrate, in order for the sender of a signal to manipulate the receiver's behavioral response and for the receiver to gain information about the sender's intent (Endler 1993). The critical information for an understanding of the impact of anthropogenic noise on animal communication therefore needs to consider the adaptive structure of the signal that evolved to minimize propagation loss of relevant information between sender and receiver, taking the hearing and perception abilities of the receiver to recognize the signal into account to better understand both quality and magnitude of impact that the noise signature has on signal transmission loss, hearing, and perception. In this ongoing research project, the goal is to better understand the effects of noise interference on call propagation and the role of adaptive call design in masking escape in killer whales.

## Potential Evolutionary Influences of Ambient Noise on Stereotypic Killer Whale Call Structure

Killer whales produce a variety of communication signals including whistles (Ford 1989; Thomsen et al. 2001, 2002), which can have a stereotypic design (Riesch et al. 2006) and may be ultrasonic for humans (Samarra et al. 2010), as well as amplitude-modulated pulsed calls, which have been early on described as "squawks" (Schevill and Watkins 1966) or "screams" (Steiner et al. 1979) and which often occur as "discrete" call types due to their stereotypic design (Moore et al. 1988; Ford 1991; Strager 1995; Miller and Bain 2000; Yurk et al. 2002; Deecke et al. 2005; Filatova et al. 2007; Schall and Van Opzeeland 2017; Wellard et al. 2020). In the literature, both terms "calls" and "whistles" are sometimes used interchangeably to describe pulsated sounds. The contours within the spectrogram of a whistle depict primarily the frequency modulation of the sound types, while the contours in a spectrogram of a call or moan can be the result of both frequency and amplitude modulations. The latter is due to a signal processing artifact that produces spectrographic sidebands as a result of the pulse repetition rate (Watkins 1966). This confusion generally does not negatively influence the recognition of the discrete structure of a call but needs to be considered when the goal is to determine the negative effects of noise on call propagation because the fundamental frequency of a pulsated call is not automatically the contour with the lowest frequency in the spectrogram but can be one of the multiples of that frequency. If one assumes that the fundamental frequency is carrying information relevant to caller and receiver, one needs to look at the impact of noise on each of the multiple contours of a call because higher frequencies generally attenuate more than lower frequencies over distance and can be affected

by masking noise in higher-frequency bands. Higher frequencies of killer whale calls also tend to transmit more directionally than lower frequencies (Schevill and Watkins 1966; Miller 2002, 2006). This feature allows killer whale calls to reduce the impact of masking noise when the noise is not between the caller and the intended receiver of the call, while masking is pronounced when the noise source is opposite to the receiver from the caller's location. Directionality plays an important role in acoustic disturbance in areas where sound exposure to anthropogenic sounds is not omnidirectional, which is mostly the case in nearshore environments where foraging often takes place for some species, such as killer whales.

## Killer Whale Call Structure

Killer whale calls contain one or more distinct frequency components (Fig. 1), which are responsible for the discreteness of recognizable call types (Ford 1984). The number of distinct components varies and can exceed more than five in some populations, for which the term "compound" call was developed (Strager 1995).

Different call components tend to experience different propagation loss in part due to differences in directionality of components (Miller 2002) but also because of differences in spectral sound energy distributions (Fig. 2).

The depicted source-level (SL) distributions (Fig. 2), obtained from recordings made with a suspended hydrophone from a small vessel when whales were in close proximity and from acoustic recordings and movement tags attached to whales via suction cups (Dtags), may underestimate the relative contribution of HFCs because of

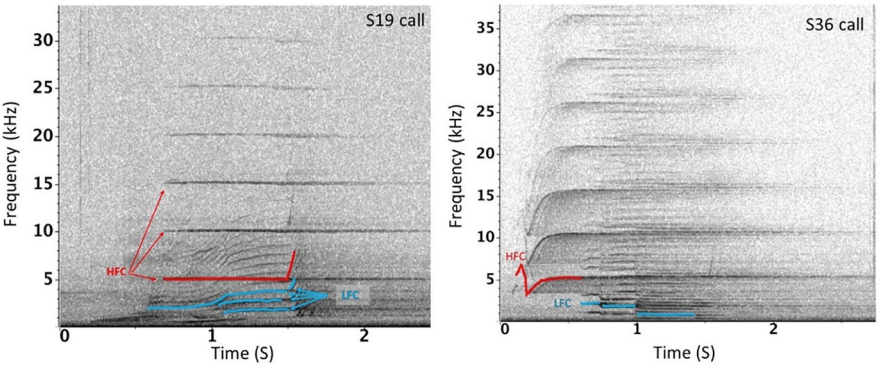

**Fig. 1** Spectrograms of two discrete calls of a population of fish-eating killer whales called Southern Residents. HFC (in red) indicates the presence of a high-frequency component, while LFC (in blue) indicates the presence of a low-frequency component. HFCs can overlap LFCs (two-voiced calls) or in sequence with LFCs. Calls can have more than one LFC but generally only one HFC. All spectrograms were produced using RAVEN Pro acoustic analysis software (Version 1.6, Cornell Lab of Ornithology)

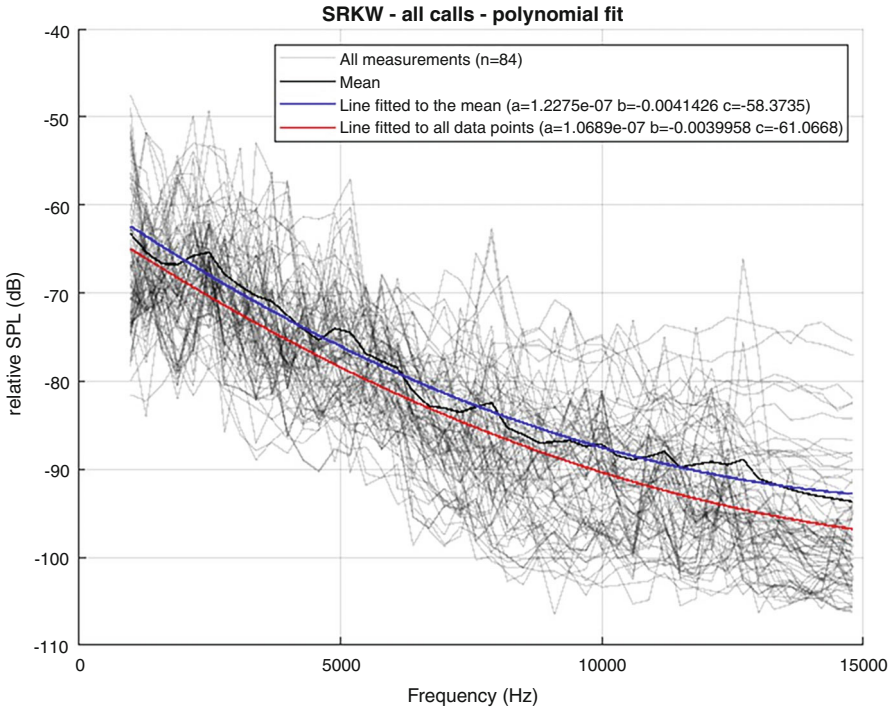

**Fig. 2** Relative spectral distribution of killer whale call source levels averaged over 300 Hz bands across a 1–15 kHz range and based on high signal-to-noise ratio (SNR) calls recorded from small vessels and from retrieved acoustic data collected during Dtag deployments

the directionality of HFCs. Both acoustic data acquisition methods may not have captured the received levels of directional signals appropriately. The recordings made from a vessel were done using an omnidirectional sensor, while the Dtag was placed behind the blowhole below which sound is generated in odontocetes (Cranford et al. 1996). Nevertheless, the distribution shown in Fig. 2 indicates a greater variation in SLs for higher frequencies. The importance of signal transmission quality is generally not realized when applying broadband source and received levels in acoustic impact assessments because these assessments focus on total exposure dosage. Neither will assessments that weigh impact across the frequency range of hearing sensitivities because they assume the impact is the same for all frequencies.

Aside from HFCs and LFCs, killer whale calls also contain burst-pulse components with lower pulse rates that aurally appear as buzzing sounds. These buzzes can either occur at the beginning of a discrete call (Ford 1991; Yurk 2005) or are produced as separate calls (Fig. 3).

Buzzes may play a much more important role in killer whale communication than previously thought and may be especially important when ambient sound levels are high because the HF parts of the transmitted burst-pulse are loud and directional.

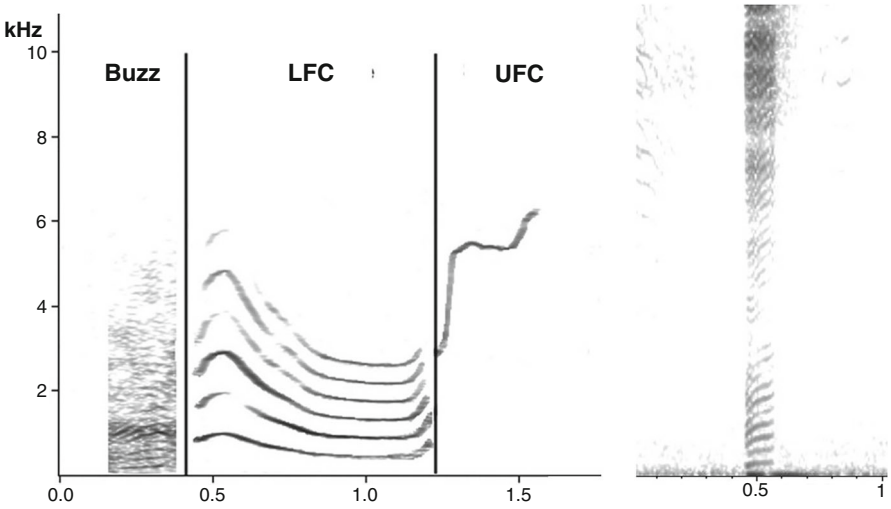

**Fig. 3** Discrete calls with initial buzz component (left) or consisting of a single buzz component (right)

## Experimental Study of Call Component Propagation Under Varying Noise Conditions

\Samples of prerecorded discrete killer whale calls were emitted via an underwater sound projector (M 18C 6.0, Geospectrum Technologies Inc.) mounted on a triangular-shaped metal frame together with either an analogue hydrophone (M36, Geospectrum Technologies Inc) or a digital hydrophone (OceanSonics) tethered to a vessel via a cable to determine the source level of the emitted signals (Fig. 4). The frame was lowered from the vessel, and the calls were recorded at various distances by a drifting acoustic buoy (CAB, SMRU Consulting) with two RESON TC 4014 suspended hydrophones at depths of 12 and 17 meters and a sea-bottom-mounted passive acoustic (PAM) mooring containing a digital recorder (AMAR, JASCO Applied Sciences) (Fig. 4). The CAB recorded WAV files with a sampling rate of 125 kilocycles per second (kcps), which provided an effective frequency range of recorded sounds from 10 Hz to 60 kHz. The bottom-mounted PAM mooring deployed at a location in Juan de Fuca Strait, British Columbia (Fig. 5), at a depth of 120 meters recorded WAV files at 256 kcps via M36 hydrophone, which provided an effective recording range of 10 Hz to 128 kHz. The projected sound files were WAV files with a sampling rate of 48 kcps allowing transmission of sounds up to a 24 kHz. The M18 projector had an effective transmission frequency range of 1–40 kHz, with a peak resonance frequency at 12.4 kHz and maximum source level of 218 dBV re. 1 μPa. Transmission did not exceed 175 dB re. 1 μPa peak pressure.

The source levels of the emitted calls were adjusted via a 600 W sound amplifier to assure that the signal emission stays within the ranges of broadband source levels reported in the literature (Miller 2006; Holt et al. 2011). Because the vessel and the acoustic buoy were both drifting during the sound emissions, the distance between

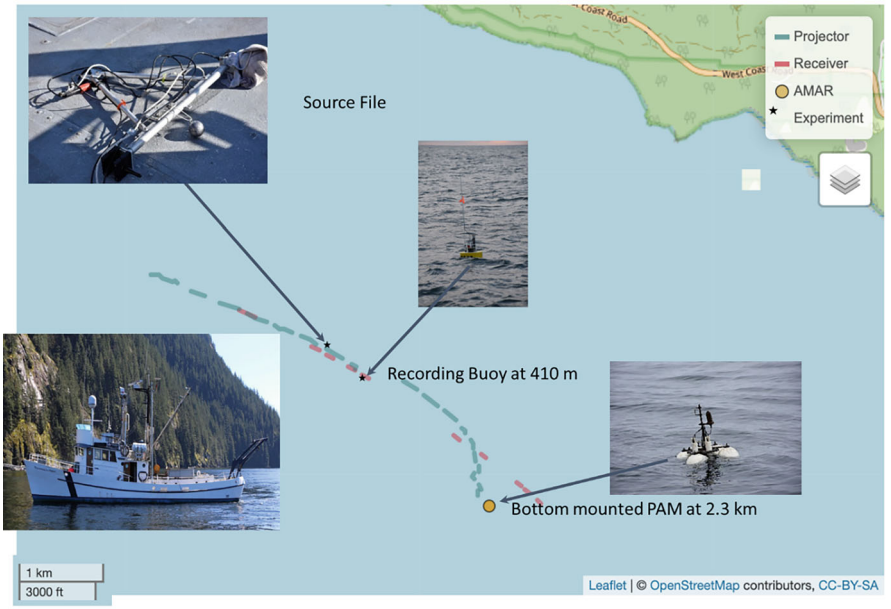

**Fig. 4** Image at top left: frame with mounted projector (covered by towel) and hydrophone at 1 m distance from projector; image at center: drift buoy with PAM and transmitter; image at bottom right: bottom-mounted PAM mooring (surfacing during retrieval); image at bottom left: vessel from which the projector was deployed. Depicted are the paths of the projector frame versus the drifting buoy and the respective locations of drifting PAM and bottom-mounted PAM during one sound emission experiment

sound projector and recording stations varied with time and was measured via GPS transmitters on both platforms and verified via laser range finder readings when possible. The exact position of the acoustic mooring on the sea bottom was determined via triangulation using acoustic pinging. The emitted sounds consisted of calls with LFCs and HFCs and buzzes. The recorded files were aurally and spectrographically inspected for the presence of calls or call components. The received sound pressure levels (RL) of contours of calls or components were determined and compared to the corresponding source sound pressure levels to allow for signal propagation loss (PL) calculations. Parallel to the signal PL assessment, ambient noise sound pressure levels (NL) at the receiver location were calculated.

The emitted sounds contained killer whale calls from three populations inhabiting the waters off British Columbia, Canada, and Washington State, USA. Two of the populations were of a killer whale ecotype that specializes on foraging fishes, particularly larger salmonid species (resident killer whales), while the third set of calls was from an ecotype that specializes on marine mammal prey (Biggs killer whales). Resident killer whales appear to use discrete calls to maintain contact and group cohesion over distances of several kilometers (Ford 1989; Miller 2002). The estimates of PL of calls over ranges of hundreds of meters to several kilometers and the influence of ambient sound on call RL are the target of this study.

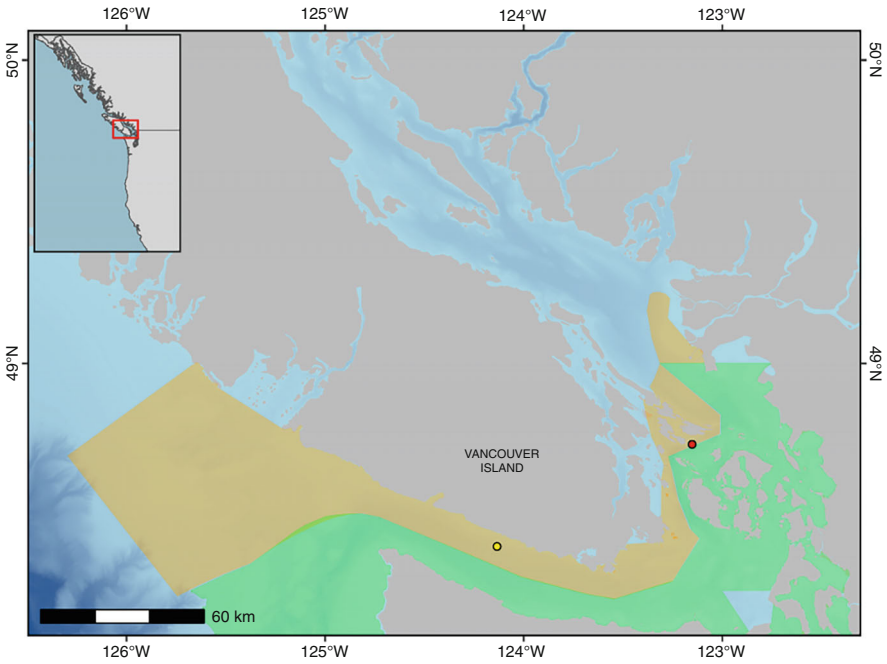

**Fig. 5** Map of designated critical habitat areas for SRKW in transboundary Canadian (beige) and US (green) waters. The yellow and red dots mark the locations of call propagation loss experiments for which spectrographic examples are shown in Figs. 6 and 7

The call propagation loss experiments took place within the designated critical habitat of one of the resident killer whale populations called Southern Resident killer whales (SRKW) that are considered endangered due to their low numbers (73 individuals (https://www.whaleresearch.com/orca-population)). Identified threats to SRKW include disturbance from anthropogenic noise sources (Fisheries and Oceans Canada 2018).

The area designated as critical habitat for SRKW (Fig. 5) is used regularly by SRKW year-round and is characterized by high commercial and noncommercial vessel traffic and other human activities and has higher ambient noise levels compared to more remote locations of the coast.

SRKW can be considered familiar with high ambient noise levels resulting from both natural sources such as wind, rain, and other precipitation and anthropogenic sources (Burnham et al. 2023). In the following sections, some interesting examples of how different call components propagate under varying noise conditions are presented.

## Call Propagation Loss Examples

Below are two examples of call propagation losses from two sequences of calls including buzzes from the SRKW population. These examples are from an experiment in Juan de Fuca Strait in March of 2019. Juan de Fuca Strait is the waterway at

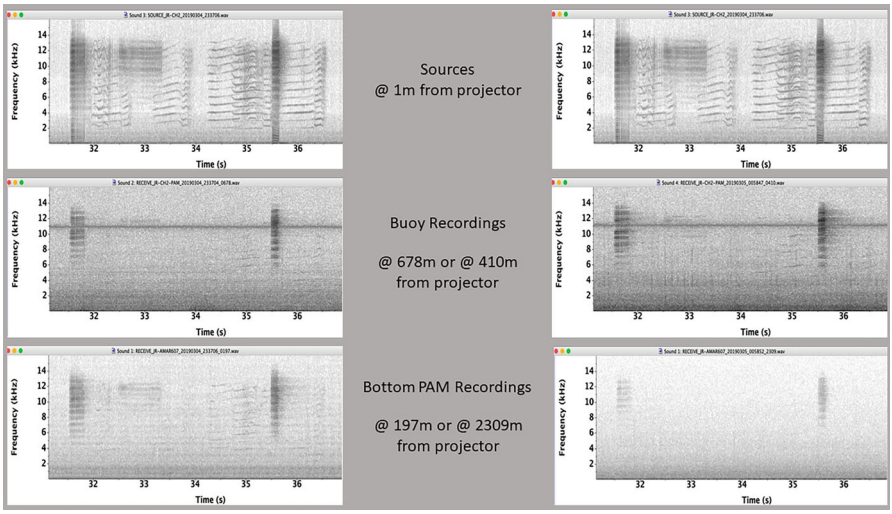

**Fig. 6** Call propagation loss between projector and two different receivers during two experiments using the same SRKW call sequences. Spectrograms at the top are the source sound levels of the call sequences. The spectrograms in the middle are received sound levels at two hydrophones suspended from a buoy (<20 m water depth). The two spectrograms at the bottom show received levels at a single hydrophone mounted on an acoustic mooring at an approximate water depth of 120 m

the bottom of Fig. 5. The experiment took place about 5 km from the shore of Vancouver Island in the North (Yellow dot in Fig. 5). The closest shipping lane for commercial vessels transiting was about 4 km away. Typical duration of sound transmissions was 6 min and transmissions were repeated up to ten times during each trial while drifting.

In the example shown in Fig. 6, the received ambient noise levels appear to be higher in the upper water layers (<20 m) than at the sea bottom at this location (>100 m). Lower frequencies are more readily masked by ambient noise, which at close distances may be dominated by the noise from the idling research vessel, but also appear to propagate less effectively between surface and bottom (recording at 197 m lower left spectrogram). Buzzes with distinct energy peaks in higher frequencies (>10 kHz) propagated better in the upper water layers and were the only calls/call components visible in the spectrogram of the associated recording at the sea floor at distances greater than 2 km.

Figure 7 shows the results from a second call propagation loss experiment also taking place in March 2019 near the confluence of three waterways called Swanson Channel, Boundary Pass, and Haro Strait (Fig. 5 – red dot). The area is used by SRKW and by commercial vessels traveling to and from the Port of Vancouver using Boundary Pass, Haro Strait, and Juan de Fuca Strait. Some commercial vessels also travel up and down Swanson Channel but less often. Commercial vessels passed the recoding buoy at ranges of <2 km. Significant small vessel traffic was a prominent feature in this area and occurred during the experiment.

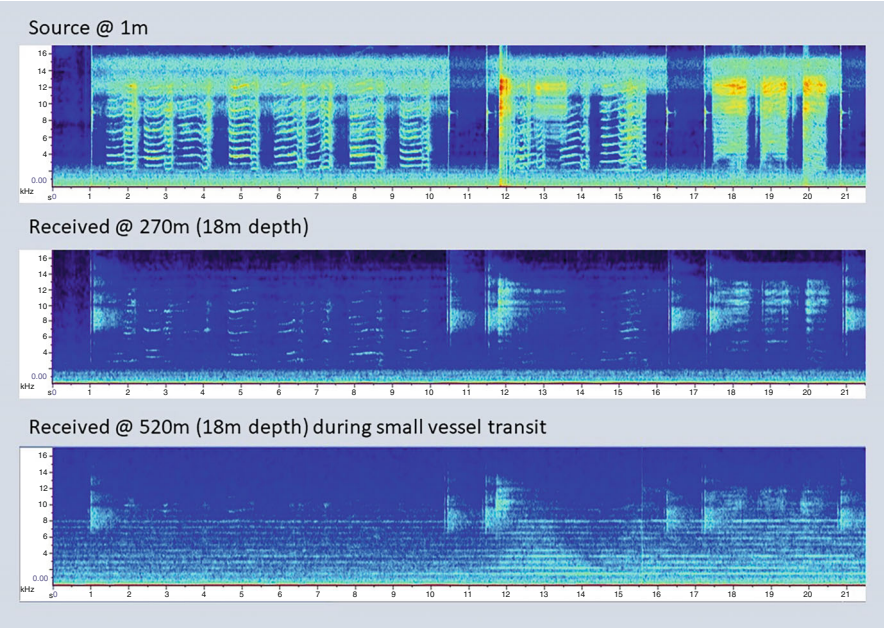

**Fig. 7** Propagation loss of SRKW call sequences in Swanson Channel/Boundary Pass with small vessel passing closer than 1 km of the recorder (bottom spectrogram). Received call sequences are recorded in the upper water column (<20 m) via a buoy with integrated PAM. Broadband signals at the beginning of call sequences are artifacts

The sound source in the bottom spectrogram in Fig. 7 is from a small vessel passing by the acoustic buoy closer than 1 km. When ambient noise levels at a receiver location were low (e.g., Fig. 7 – center spectrogram), most call components propagated according to the modeled propagation loss relative to their spectral source levels over distance (e.g., several hundreds of meters). LFCs, HFCs, and buzzes were detectable at distances of several kilometers in recordings made by hydrophones located at depths less than 20 m. At all distances, detectability decreased proportionally with the level of ambient noise present in frequency bands containing peak energy levels of LFCs, HFCs, and buzzes. However, when ambient noise was high because sources (i.e., vessels) were closer (<1 km) to the recorder, primarily buzzes were detectable because of their higher source levels in higher frequencies.

## Relevant Considerations for Anthropogenic Noise Impact Assessments on Killer Whales and Potentially Other Odontocetes

The frequency structure, i.e., spectral design of the calls, appears to play an important role in the propagation loss and detectability of calls, especially in environments with higher ambient noise levels. This matches results of a modeling study conducted by Mouy et al. (2020). The modeling study suggested that often higher

sound frequencies than the frequency with highest amplitude (around 1 kHz, Fig. 2) had the greatest influence on positive detection via an automated detector classifier (DC) and therefore play an important role for call detection (Fig. 8).

Call source levels appear to decrease linearly with increasing frequencies below 5 kHz (Fig. 2). However, the frequencies responsible for furthest detection range are not always the lower frequencies at every geographical location or location within the water column (Figs. 6 and 8). The call source level distribution may be influenced by the shape of the hearing sensitivity curve of killer whales (Fig. 9), which may have adapted to natural ambient noise variation, especially in the upper water column. Resident killer whales spend more time in the upper 20 m of the water column than at depth (Wright et al. 2017) and are therefore more likely to vocalize in these upper water layers. Future analysis of the call propagation loss experiments, using a more extended dataset, will show if these preliminary findings are more generally valid.

When ambient noise is low, LFCs of calls, as well as energy peaks of Buzzes at frequencies below 5 kHz, may travel the furthest. When ambient noise levels are higher, call components such as HFCs and Buzzes with energy peaks in higher frequencies may contribute more toward call detectability over greater distances due to typical low-frequency content of ambient noise from natural and anthropogenic sources.

Resident killer whales live in stable matrilineal groups and maintaining contact while traveling and foraging appears an important factor to maintain social cohesion (Bigg et al. 1990; Ford 1989). Because resident killer whales tend to search and capture prey individually but share prey afterward (Ford and Ellis 2006, 2014), the distance over which these killer whales can maintain contact may determine the area over which they can effectively search for food. Under high ambient noise levels, call components such as buzzes and directional HFCs may allow whales to maintain acoustic contact. HFCs and buzzes may also determine the distance over which the

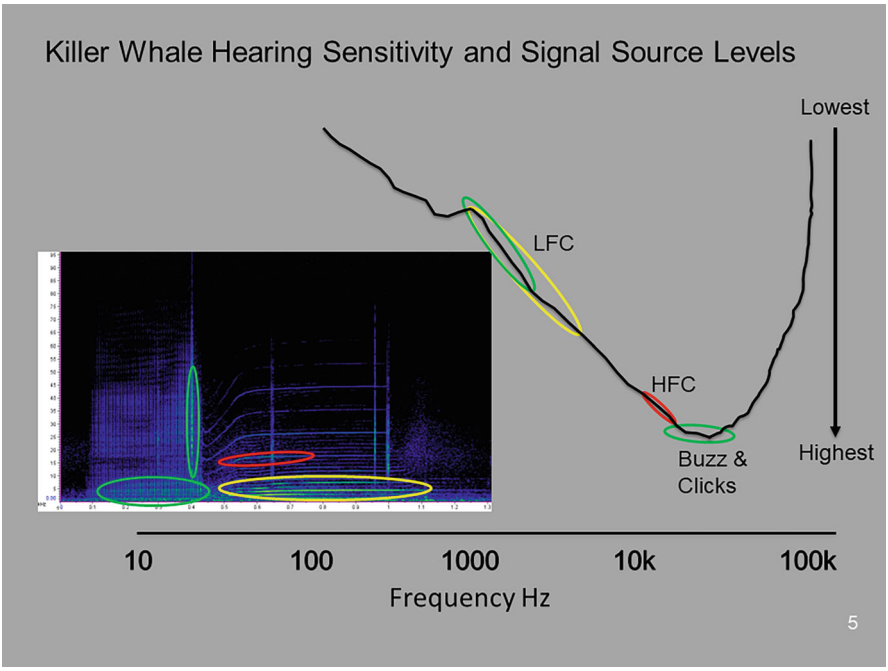

**Fig. 9** Killer whale call spectrogram and hearing sensitivity curve with projected areas containing peak signal source levels of call components including buzzes. The sensitivity curve is an adaptation based on reported hearing sensitivities of killer whales in captivity summarized by Branstetter et al. 2017

whales can spread out when traveling (Miller 2002). The call structure appears to allow killer whales to maintain contact under different propagation conditions and when ambient sound varies, hence call structure has adapted to the acoustic environment in which the whales forage, travel, and socialize. This adaptive call design allows whales to compensate for increased ambient sound levels not only by speaking louder (Holt et al. 2009), but perhaps also by paying attention to different call components.

While many anthropogenic noise impact assessments for killer whales and other cetaceans pay attention to the broadband received "noise dose" (e.g., Williams et al. 2014), the call structure and the respective source levels of call components rather than the broadband source level may need to be taken into account to accurately assess impact of noise in frequencies that are important to killer whales and to determine when noise impact becomes impossible to mitigate by the whales. Numerical broadband vessel noise measurements are skewed toward the frequencies in which the noise signature is the highest, which is typically below 250 Hz for vessel noise (Southall et al. 2017). Furthermore, most anthropogenic noise assessments rely on sound-level measurements taken at greater depths (e.g., the sea bottom in waterways used by large commercial vessels) at which the measurement of noise

generated by these vessels can be assessed accurately (MacGillivray et al. 2019). However, these measurements may not always reflect noise exposure levels relevant to killer whales in upper water layers and the impact on signals traveling between upper and deeper water layers correctly. Vessel noise appears to propagate well in the water layers in which they are generated, which is typically in the upper 20 m of the water column. Furthermore, vessel noise also propagates well at higher frequencies especially in shallow waters (Hermannsen et al. 2014) and in particular noise generated by smaller vessels may dominate the ambient noise in higher frequencies over short distances (Hermannsen et al. 2019). Small vessels may be around the whales more often than large commercial vessels and often closer to the whales. The impact of noise from these smaller vessels may need to be assessed based on their contribution in those higher frequencies. The limits to noise compensation due to the adaptive call design needs to play a bigger role in acoustic impact studies in order to correctly determine the extent of negative acoustic impact on whales and dolphins.

**Acknowledgments** We are grateful for the support we received from Rianna Burnham and James Pilkington during the fieldwork operations. We also like to thank Peter Van Buren for his support with the design and maintenance of our fieldwork equipment. This work was in part funded by the Government of Canada's Ocean Protection Plan provided through the Whale Detection and Collision Avoidance (WDCA) initiative.

**Abstract**

Pingers and acoustic harassment devices (AHDs) are used by industries (e.g., fisheries, aquaculture, and offshore wind development) all over the world to mitigate harmful impacts on marine mammals such as the harbor porpoise (*Phocoena phocoena*). This review compares different devices and their effects specifically on harbor porpoises and gives recommendations with regard to which device to use for the desired outcome. Pingers mainly emit acoustic signals at sound pressure levels between 115 and 155 dB re 1 µPa (rms) @ 1 m at frequency ranges between 2.7 and 160 kHz, whereas AHDs mainly emit signals at sound pressure levels between 172 and 194 dB re 1 µPa (rms) @ 1 m at frequency ranges between 1 and 150 kHz. Therefore, harbor porpoises generally show a smaller avoidance radius around pingers than around AHDs. Selecting an appropriate device should not only depend on the cost and user-friendly installation, but primarily on the desired range of the acoustic signals, keeping the size of the area to be exposed to sound and the duration as small as possible (e.g., pingers for a minimum deterrence distance of 100–300 m and APDs for a minimum deterrence distance of 500–750 m). Factors including habituation and effects on species other than the target species need to be considered in choosing mitigation devices

and monitored on a regular basis. When selecting an appropriate device in a targeted manner, pingers and AHDs are a good tool to deter harbor porpoises from an area where they may suffer harm, such as hearing damage or entanglement in fishing nets.

## Introduction

Harbor porpoises (*Phocoena phocoena* L., 1758) are the most common cetacean in the North Sea (Hammond et al. 2013, 2017) with approximately 345,000 individuals inhabiting the area (Hammond et al. 2017). This species has a distinct hearing range from below 1 kHz to about 180 kHz with the lowest hearing threshold of about 33 dB re 1 µPa between 100 and 140 kHz (Kastelein et al. 2002). Below 16 kHz and above 140 kHz, sensitivity decreases by about 10 dB and 260 dB per octave, respectively, resulting in a sharp increase in the hearing threshold (Kastelein et al. 2002). Within the range of their best hearing sensitivity, i.e., around 130 kHz, are their click frequencies of echolocation (Møhl and Andersen 1973; Teilmann et al. 2002).

Therefore, threats to this species do not only include chemical contamination (Berggren et al. 1999; Weijs et al. 2010; Mahfouz et al. 2014), predation by grey seals (Van Bleijswijk et al. 2014; Leopold et al. 2015; Podt and IJsseldijk 2017), prey depletion due to overfishing and habitat destruction (MacLeod et al. 2007), and gillnet fisheries leading to bycatch (Berggren 1994; Vinther and Larsen 2004; Bjørge et al. 2013), but also noise pollution (Pirotta et al. 2014; Culloch et al. 2016; Wisniewska et al. 2018). Specifically, sound emissions can affect their behavior and lead to a temporary hearing threshold shift (TTS) or permanent hearing threshold shift (PTS) (Kastelein et al. 2011; Tougaard et al. 2015, 2022). For very-high-frequency cetaceans such as harbor porpoises, a TTS-onset threshold of 153 dB re 1 µPa$^2$s and a PTS-onset threshold of 173 dB re 1 µPa$^2$s are assumed as sound exposure levels (weighted) for nonimpulsive noise such as signals of most pingers and AHDs (Southall et al. 2019).

For deterrence of marine mammals from the danger area and thus mitigation of these threats, pingers and acoustic harassment devices (AHDs) are used all over the world around aquaculture facilities and other fishery activities, during offshore wind farm construction and before detonations. Namely, these devices aim to deter all animals from a certain area by emitting acoustic signals. Pingers emit acoustic signals at similar frequency ranges, but higher sound pressure levels than AHDs. Pingers can thus significantly reduce the risk of bycatch (Palka et al. 2008; Dawson et al. 2013; Larsen and Eigaard 2014). In contrast, AHDs can prevent hearing damage from impulsive noise such as pile driving from offshore wind farms or

detonations by deterring the animals further away than pingers (Brandt et al. 2013a; Popper and Hawkins 2016).

However, some studies suggest that also AHD signals can lead to a TTS and that these devices can thus have a much stronger deterrent effect than intended (Schaffeld et al. 2019; Findlay et al. 2021; Todd et al. 2021). Therefore, this review compares different devices and their specific effects on harbor porpoises and gives recommendations in regard to which device should be used for specific outcomes.

## Considering Studies with Different Methods

Studies of interest to this review were identified based on the criteria of (a) using pingers and/or AHDs as source of sound; (b) analyzing their effects on harbor porpoises; and (c) specifying avoidance distances. In total, this review includes 29 studies which partly include different types of pingers and AHDs. However, most of these studies only report individual details on avoidance distances, with varying degrees of avoidance reactions (e.g., closest observed approach as opposed to maximum zone of deterrence). The avoidance distances summarized in this review are therefore based on individual recordings. Besides, even with pingers and AHDs from the same production series, some variation in output is likely (Kastelein et al. 2010). Therefore, the results of this review should not be considered as total range of possible avoidance distances.

The studies included in this review are based on different methodologies; with their own strengths of weaknesses, these need to be taken into account when interpreting "apparent responses." Thus, for the purpose of this review, the methods were categorized as follows:

1. Noise propagation modeling: By combining the hearing range of harbor porpoises and the sound characteristics of a device, the radius around the pinger or AHD where the animals may avoid and/or hear the signals can be acoustically modeled (e.g., Northridge et al. 2010; Todd et al. 2019).
2. Passive acoustic monitoring (PAM): Detection rates using devices such as Cetacean Porpoise Detectors (C-PODs) provide an indication of harbor porpoise presence since the animals use their echolocation system almost continuously – also during sound exposure (Akamatsu et al. 2007; Brandt et al. 2013b; Haelters et al. 2015; Wisniewska et al. 2016).
3. Visual observations: Visual observations such as theodolite tracking can be an effective tool to monitor the behavioral response of harbor porpoises to pinger and AHD activation within a limited radius (e.g., Koschinski et al. 2003; Kyhn et al. 2012; Brandt et al. 2013a).

As all methods have their advantages and disadvantages; this review considers the results of studies using different methods to summarize current knowledge on the effects of pingers and AHDs on harbor porpoises. In total, 8 studies are based on noise propagation modeling (1 with pingers, 5 with AHDs, and 2 with both types),

10 studies are based on passive acoustic monitoring (5 with pingers and 5 with AHDs), and 11 studies are based on visual observations (3 with pingers and 8 with AHDs).

## Deterrence Effect of Different Kinds of Pingers and AHDs

All the pingers and AHDs considered in this review emit acoustic signals in a frequency range between 2.7 and 160 kHz (Table 1) and 1 and 150 kHz (Table 2), respectively. The frequency ranges greatly vary among the individual devices of a certain type, but less so between pingers and AHDs on average.

The sound pressure level, however, greatly differs between pingers and AHDs. All reviewed pingers emit acoustic signals between 115 and 155 dB re 1 µPa (rms) @ 1 m (Table 1). In contrast, all analyzed AHDs emit acoustic signals between 172 and 194 dB re 1 µPa (rms) @ 1 m (Table 2). Accordingly, AHDs produce higher sound pressure levels.

Due to the different frequencies and sound pressure levels, harbor porpoises are deterred to different extents depending on the type of pinger or AHD. Even though the avoidance distances summarized in this review are based on individual recordings and should not be considered as total range of possible avoidance distances, it is clearly visible that harbor porpoises generally show a smaller avoidance radius around pingers than around AHDs (Fig. 1). Namely, the closest observed approach during pinger operation is between 0 and 0.294 km, porpoises then showing strong avoidance behavior and severe disturbance and discomfort (Table 1), whereas the closest observed distance during AHD operation is between 0.017 and 1.9 km (Table 2). Furthermore, during pinger operation most harbor porpoises are deterred within 0–0.6 km, showing behavioral disturbance (Table 1). In contrast, during AHD operation most harbor porpoises are deterred within 0.01–4 km (Table 2). So in overall, AHDs deter porpoises farther away than the pingers considered here. But also between individual devices of pingers and AHDs there are large differences in the radius of disturbance depending on the frequency and sound pressure level (Fig. 1).

## Impact of Using Pingers and AHDs

Both individual fitness and ecological community structure can be affected by underwater noise (Southall et al. 2007, 2019). The source, the path and as well as the receiver affect how marine mammals react to underwater noise in each case (Erbe et al. 2016). For the source, such as the pinger or the AHD in this case, key factors are the source level, frequency, and temporal characteristics like the duration and number of operations within a short period. The path and associated environmental factors such as bathymetry, seabed sediment characteristics, and water column properties will determine whether sound is rather absorbed or reflected (Farcas et al. 2016). For the receiver, i.e., the animal's behavioral response, important factors

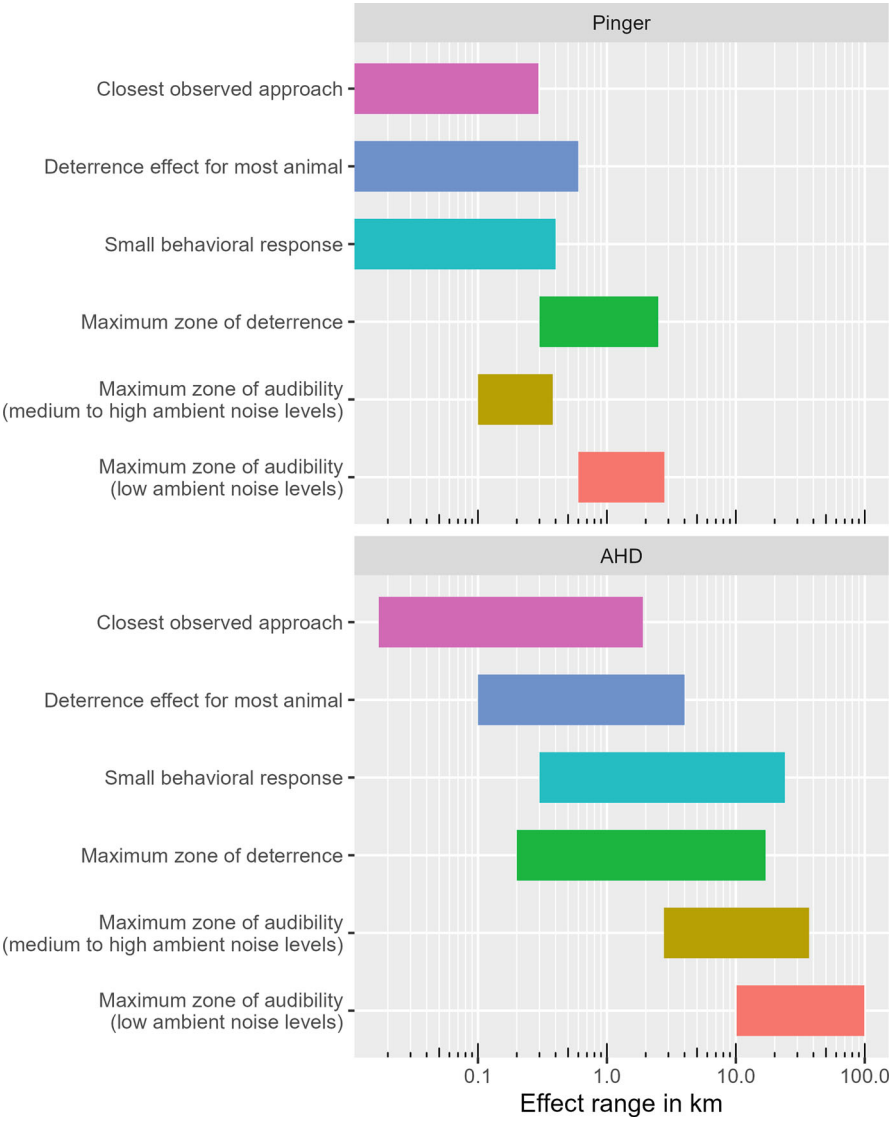

**Fig. 1** Deterrence ranges of harbor porpoises for pingers and AHDs listed in Tables 1 and 2 and according to the intensity of disturbance. Since most of the studies included in this review only report individual details on avoidance distances, with varying degrees of avoidance reactions (e.g., closest observed approach as opposed to maximum zone of deterrence), and since even with pingers and AHDs from the same production series, some variation in output is likely (Kastelein et al. 2010); the results of this figure should not be considered as total range of possible avoidance distances

include hearing ability, the behavioral context, distance to the source, previous exposures, demographics, and food availability (Erbe et al. 2016). Harbor porpoises, for example, are more likely to be displaced if suitable foraging opportunities are available in other areas without noise (Carlström et al. 2002). Therefore, harbor porpoises react to acoustic signals from pingers and AHDs in their individual contexts.

However, pingers generally deter harbor porpoises up to several hundred meters as they mainly emit sound up to pressure levels of 155 dB re 1 µPa (rms) @ 1 m (Table 1). AHDs, in contrast, lead to farther-reaching disturbance; they deter most animals up to a few kilometers away from the device (Table 2). Small behavioral responses during AHD operation, such as small changes in the surfacing rate, swimming pattern, and distance toward the AHD, even occur up to 21.7 km, and their acoustic signals are still audible to harbor porpoises up to 37 km when considering medium to high background noise levels (Todd et al. 2019; Thompson et al. 2020). This far-reaching disturbance is caused by the sound characteristics of AHDs: AHDs were primarily developed to reduce economic losses at fish farms due to seal predation (Fjälling et al. 2006; Graham et al. 2009; Harris et al. 2014) and were thus adapted to the hearing ability of seals during development. Grey seals, for example, usually communicate in a frequency range between 0.1 and 0.4 kHz, some of them with upsweeps up to 4.7 kHz (Au and Hastings 2008), while harbor seals have their best hearing ability between 0.5 and 40 kHz (Kastelein et al. 2009). Therefore, seal scarers mostly emit acoustic signals between 1 and 25 kHz at sound pressure levels up to 194 dB re 1 µPa (rms) @ 1 m (Table 2), resulting in signals being transmitted over long distances (Erbe et al. 2022).

Due to the sound characteristics of most AHDs, these devices appear to have the potential to induce a TTS (Schaffeld et al. 2019). For example, Hiley et al. (2021) calculated that harbor porpoises suffer a TTS in up to 704 m distance around an Airmar dB Plus II AHD when operating for 30 min, whereas Todd et al. (2021) calculated a TTS in up to nearly 31 km distance when the same kind of device operated for 24 h. These calculated threshold shifts might differ in reality, as environmental factors such as bathymetry, seabed sediment characteristics, and water column properties affect sound propagation (Farcas et al. 2016). However, due to the TTS potential of AHDs, it is discussed whether some devices are appropriate for the specific outcome.

Particularly in Scotland, the number of AHDs around aquaculture sites has rapidly increased in recent years (Cabinet Secretary for Rural Affairs and Islands 2022) with a suspected overuse (Todd et al. 2021). Namely, cumulative effects of AHDs can generate noise over large areas. Assuming a single device being installed at each site, Findlay et al. (2021) calculated that 23% of a certain Special Area of Conservation for harbor porpoises is exposed to AHD noise levels sufficient to cause a TTS. In the worst case scenario, 0.9% of the special area of conservation is exposed to AHD noise levels sufficient to induce a PTS.

However, alteration of sound pressure levels, frequency, and operational mode can reduce AHD impact (Todd et al. 2021). Accordingly, acoustic porpoise

deterrents (APDs) such as the FaunaGuard Porpoise Module were specifically designed for the deterrence of harbor porpoises (van der Meij et al. 2015). These devices emit acoustic signals in frequency ranges between 60 and 150 kHz at sound pressure levels up to 172 dB re 1 µPa (rms) @ 1 m (Table 2). APDs consequently show significantly larger propagation losses compared to other types of AHDs (Rosemeyer et al. 2021). Most harbor porpoises are thus still deterred up to about 0.75–1 km, but the maximum zone of deterrence is considered to be 2.5 km (Table 2). APDs are therefore not considered to cause far-reaching disturbance such as observed with other types of AHDs (Voß et al. 2023).

## Recommendations for Using Pingers and AHDs

This review shows that there are a variety of pingers and AHDs with different effect ranges, so device selection has to be carefully considered depending on the objective of use and overuse should be avoided. Selecting an appropriate device should not only depend on the cost and user-friendly installation, but primarily on the desired range of the acoustic signals, keeping the size of the area to be exposed to sound and the duration as small as possible.

Therefore, pingers are recommended for small-scale deterrence where about 100–300 m is sufficient, such as continuous pinger operation at fishing nets for avoiding bycatch. However, the response of harbor porpoises to pingers and AHDs needs to be monitored permanently to early notice if harbor porpoises show signs of habituation, as has been suggested in other studies (Cox et al. 2001; Carlström et al. 2009; Kyhn et al. 2015). Moreover, other species such as seals may perceive pingers as "dinner bells" and thus prefer to swim to nets with active pingers, leading to increased bycatch rates for these species (Carretta and Barlow 2011; Wargo Rub and Sandford 2020) and depredation events. Therefore, pingers should be chosen which are emitting noise outside the best hearing range of other resident marine mammal species such as seals and dolphins (Königson et al. 2022). In this way, these other species can only hear the acoustic signals at very short distances and are not attracted to them, so that no increase in bycatch rates for these species is to be expected.

For several years, additional research has been conducted on devices that synthetically simulate signals of harbor porpoises with which the animals usually warn each other. These so-called Porpoise Alarm (PAL) devices are also designed to keep porpoises away from nets and thus reduce bycatch. In a field study of three types of signals, two types were observed to increase the distance to the device by 23 and 32 m, respectively, and thus to deter the animals, whereas one type was observed to attract harbor porpoises with a decrease in distance of 29 m (Culik et al. 2015). The type that produced the largest increase in harbor porpoise deterrence (i.e., by 32 m) was tested in Western Baltic gillnet fisheries and resulted in a 64.9% decrease in the expected bycatch rate, and even 79.7% at a gear spacing of less than 210 m (Chladek et al. 2020). In contrast, in a field study in Iceland, no significant difference was observed between the PAL and control sets, and almost all of the harbor porpoises captured in the PAL sets (11 out of 12) were large adult males, while the sex ratio in

the control sets was 7 males and 4 females, suggesting that adult males may be attracted to the PAL sets (ICES 2018). Therefore, whether PAL devices can be used as pinger replacements on nets in any region to keep harbor porpoises away while avoiding the "dinner bell" effect on seals, and whether harbor porpoises habituate to the sounds or even might be attracted needs further investigation.

APDs are recommended for a minimum deterrence distance of 500–750 m. During the construction of offshore wind farms in Germany, for example, the sound exposure level is legally required to be below 160 dB re 1 $\mu Pa^2$ s at a distance of 750 m from piling locations (BMU 2013). Due to the continuous development of noise abatement systems, many construction projects now comply with this threshold or even fall below it. Beyond this distance, it is assumed that harbor porpoises no longer suffer hearing injuries, so deterrence of the animals up to 750 m and thus deploying an APD for this purpose is sufficient. Voß et al. (2023) indicated that it is sufficient for the APD to be switched on for about 20–25 min, as after this time effectively no detections were registered within this radius. Thus, it can be assumed that the APD deterred nearly all harbor porpoises from the danger area. To minimize potential habituation of harbor porpoise to the APD signals, it is recommended that the device should be active for around 25 min and no more than 30 min (Voß et al. 2023). For the same purpose, e.g., the FaunaGuard Porpoise Module uses different complex signal sequences (van der Meij et al. 2015). Furthermore, as these devices emit sounds outside the best hearing range of seals (NOAA National Marine Fisheries Service 2018), no effect of APD operation on these animals is assumed.

In case of other impulsive noise sources such as detonations, significantly higher sound exposure levels than with pile driving may occur at 750 m. During a high-order detonation of unexploded ordnance (UXO) with a charge mass of 140 kg TNT equivalent in the Danish North Sea, Salomons et al. (2021) measured a sound exposure level of 170.2 dB re 1 µPa (rms) at a distance of 12 km. The authors calculated that harbor porpoises might have suffered PTS up to about 4 km distance. During another high-order UXO detonation with a charge mass of 201.5 kg TNT equivalent in the Scottish North Sea, a sound exposure level of 160 dB re 1 µPa (rms) at a distance of 55 km was calculated (Robinson et al. 2022). Keeping the noise level as low as possible should be prioritized. For example, noise abatement systems and low-order detonations, using a smaller charge to disrupt and/or consume the UXO than high-order detonations, are recommended. In some cases, however, harbor porpoises still need to be deterred over a wider area than possible with APDs. Therefore, an APD should be used first, and in addition after about 25 min another kind of AHD which causes a farther-reaching deterrence. Deploying an APD for 25 min before deploying another type of AHD will prevent harbor porpoises from staying within 750 m distance to the other kind of AHD (Voß et al. 2023), thus avoiding TTS caused by AHDs such as seal scarers. According to Findlay et al. (2021), for example, animals would suffer a TTS after 85 s of operation of an Airmar AHD, assuming an animal is 100 m away from the Airmar AHD when it is switched on, and that it swims away from the AHD at a constant speed of 4.3 m/s. In this calculation, even an increased swimming speed was already assumed, since harbor porpoises usually swim at an average speed of 0.5–1.2 m/s without noise exposure

(Culik et al. 2001; Otani et al. 2001; Kastelein et al. 2018), but were, e.g., observed to swim up to 10 m/s during pinger operation (Brennecke et al. 2022). Since longer APD operation times only led to a moderate extension of the effect range, with a maximum of 2.5 km effect range for the longest available operation times (35–40 min; Voß et al. 2023), another kind of AHD is recommended thereafter, which causes a farther-reaching deterrence. An Airmar AHD, for example, is assumed to be able to deter most animals up to a distance of 3.5 km (Olesiuk et al. 2002). Assuming a swimming speed of 0.9 m/s with constant direction away from the AHD location, this device is recommended to operate for about 60 min to ensure that all harbor porpoises have moved away from a radius of 3.5 km around the detonation location and at the same time do not become used to the sounds and return. If a larger deterrence radius than 3.5 km is necessary, the animals must be gradually deterred, e.g., firstly, by 25 min of APD operation at the location of the detonation, then by 60 min of other kinds of AHD operation at the location of the detonation, and finally, by continuation of other kinds of AHD operation at the location of the detonation, but also by other kinds of AHD operation 2.5 km north, east, south, and west to the location of the detonation.

In general, pingers and AHDs are good tools to deter harbor porpoises from an area where they may suffer harm, such as hearing damage or entanglement in fishing nets. However, the appropriate device must be carefully selected for the specific purpose, i.e., there must be neither too little deterrence nor excessive usage. Furthermore, factors such as habituation and effects on species other than the target species need to be considered and monitored on a regular basis.

**Abstract**

Although beaked whales remain a cryptic and elusive family, much has been learned about their dive and foraging behavior in the last few decades through the use of passive acoustic monitoring (PAM) and a variety of tagging methods. Species-specific echolocation pulses can be used to acoustically track individuals and groups, and biologging tags provide information on dive and movement behavior. These technologies have also provided a window into how beaked whales behaviorally respond to Navy mid-frequency active sonar, which in turn may elucidate maladaptive behaviors that could lead to stranding. This chapter reviews existing knowledge about beaked whale behavioral responses to anthropogenic sound sources in general, and to Navy sonars in particular. By understanding the breadth of ways beaked whales behaviorally respond, the scientific community can continue to work toward recognizing and mitigating responses that could lead to stranding, as well as determining the population-level implications of impacts on individuals.

## Introduction

Beaked whales (family: Ziphiidae) are one of the most ubiquitous but elusive families of cetaceans, distributed globally from Antarctic to Arctic waters (Macleod et al. 2006) but are rarely visually observed due to their cryptic surface behavior. Less than 20 years ago, very little was known about beaked whale behavior, distribution, or abundance, with many species described based on a few records of stranded animals (Dalebout et al. 2002; Macleod and Mitchell 2006), while only a few abundance estimates based on visual surveys existed (Barlow et al. 2005). In fact, as recently as a decade ago, there were concerns that some populations were declining, such as Cuvier's beaked whales (*Ziphius cavirostris*) in Southern California (Moore and Barlow 2013), which was hypothesized to be due in part to the use of naval sonar in the region. However, the discovery that beaked whales produce echolocation pulses unique to each species (Baumann-Pickering et al. 2013a; Johnson et al. 2006; Zimmer et al. 2005) has led to an explosion of Passive Acoustic Monitoring (PAM) and biologging efforts to identify the distribution and abundance of beaked whales globally. The main driver of this increased focused was a series of mass strandings of beaked whales in the 1990s and 2000s, where naval Low- and Mid-Frequency Active Sonar (LFAS and MFAS) were a plausible, if not likely contributing factor (e.g., Cox et al. 2006; D'Amico et al. 2009; U.S. Department of Commerce, U.S. Department of the Navy 2001; Filadelfo et al. 2009; Frantzis et al. 2002; Simmonds and Lopez-Jurado 1991). Therefore, in addition to learning more about basic questions, such as foraging and diving behavior, occurrence patterns, and abundance, researchers have been striving to assess the behavioral responses of beaked whales to MFAS to help global navies better understand and mitigate their impacts. This chapter is a review of the current knowledge and future direction of beaked whale behavioral responses to MFAS.

In the last two decades, researchers have definitively identified the echolocation pulses for 12 different species of beaked whales, including Cuvier's beaked whales (Frantzis et al. 2002; Zimmer et al. 2005), Blainville's beaked whales (*Mesoplodon densirostris*; Johnson et al. 2006; Madsen et al. 2013; Rankin and Barlow 2007), Arnoux's beaked whales (*Berardius arnuxii;* Barlow et al. 2021a; Rogers and Brown 1999), northern bottlenose whales (*Hyperoodon ampullatus;* Hooker and Whitehead 2002), Gervais' beaked whale (*Mesoplodon europaeus*; Gillespie et al. 2009), Longman's beaked whale (*Indopacetus pacificus*; Rankin et al. 2011), Baird's beaked whale (*Berardius bairdii*; Baumann-Pickering et al. 2013b; Dawson et al. 1998) Sowerby's beaked whale (*Mesoplodon bidens*; Cholewiak et al. 2013), True's beaked whale (*Mesoplodon mirus;* DeAngelis et al. 2018), and Shepherd's beaked whale (*Tasmacetus shepherdi*; Leunissen et al. 2018). Most recently, the BW37V

pulse was described by Griffiths et al. (2019) and was confirmed to be Hubb's beaked whale (*Mesoplodon carlbubbsi*) in 2021 (Ballance et al. 2023). Several echolocation pulses that have been recorded globally have yet to be linked to a source species (Barlow et al. 2021a; Baumann-Pickering et al. 2013a, 2014; Hildebrand et al. 2015; Giorli et al. 2018; LeBien and Ioup 2018; Manzano-Roth et al. 2022; McCullough et al. 2023; McDonald et al. 2009; Stanistreet et al. 2017; Trickey et al. 2015), although based on known distributions of beaked whale species, some linkages have been inferred. These PAM efforts have found several species to be far more broadly distributed than previously known (Barlow et al. 2021a; Griffiths and Barlow 2016; Stanistreet et al. 2017), new beaked whale habitats have been discovered (Yack et al. 2013), and it has been recognized that some population abundances may not be decreasing after all (e.g., Moore and Barlow 2017), are higher than previously estimated based on visual surveys alone (Barlow et al. 2021b), or may even be increasing (DiMarzio et al. 2020). Additionally, in the last decade, at least four new species or potential new species have been identified, including Deraniyagala's beaked whale (*Mesoplodon hotaula*; Dalebout et al. 2014), Sato's beaked whale (*Berardius minimus*; Brownell and Kasuya 2021; Yamada et al. 2019), and Ramari's beaked whale (*Mesoplodon eueu*; Carroll et al. 2021), along with an as-yet unidentified beaked whale off Baja California, Mexico (Barlow et al. 2022).

In addition to the increase in PAM efforts for beaked whales, the advent of biologging tags, including acoustic recording tags, satellite tags, and time-depth recording (TDR) tags, has led to our improved knowledge about foraging dive behavior. Early tagging studies revealed extreme deep diving depths in Blainville's and Cuvier's beaked whales (Baird et al. 2006; Johnson et al. 2004; Tyack et al. 2006; Zimmer et al. 2005). These pioneering studies determined that Blainville's and Cuvier's beaked whales dove to depths of 600–1900 m for durations of up to an hour, and that these deep foraging dives were interspersed with shallower dives of 100–400 m for a period of 60–90 min. Studies with sound and movement tags (i.e., DTAGs, Johnson and Tyack 2003) found that beaked whales produced echolocation pulses only on their deep foraging dives and only once the animals were deeper than 200–500 m, and produced buzzes associated with prey capture attempts (Johnson et al. 2004; Tyack et al. 2006). As more tag types were developed, additional studies built upon these early findings. Dives of previously unimaginable depth and duration were recorded (Schorr et al. 2014; Quick et al. 2020), and our understanding of the full dive cycle structure was further refined. The full dive cycle duration is defined as the time from the onset of one deep foraging dive to the next. Within that period occurs the deep foraging dive and an Inter-Deep-Dive Interval (IDDI) comprised of a series of intermediate "bounce" dives without foraging clicks interspersed with shallow surfacing bouts (Falcone et al. 2017; Minamikawa et al. 2007; Shearer et al. 2019; Tyack et al. 2006). The descent rate of the deep dive tends to be faster than the ascent rate with a higher fluke rate, and the vertical angle is steeper during the descent than the ascent (Baird et al. 2008; Tyack et al. 2006). The presence of bounce dives and the longer, slower ascent from the deep foraging dives are theorized to be mechanisms by which beaked whales avoid predators (Aguilar de

Soto et al. 2018; Bernaldo de Quirós et al. 2019; Hooker et al. 2009). Furthermore, beaked whales in a group dive with a high level of synchrony both in movement and vocal behavior until they reach their foraging depths, and then forage separately while remaining within a few hundred meters of each other (Aguilar de Soto et al. 2018, 2020; Cioffi et al. 2021; Alcázar-Treviño et al. 2021). As additional species have been tracked via tags and PAM, most dive characteristics hold true, although variability has been discovered among species. For example, the Cross Seamount beaked whale is the only species to forage solely at night (or at least to produce that specific echolocation pulse at night), and also appears to only dive to a few hundred meters depth to forage (Manzano-Roth et al. 2022; McCullough et al. 2023). In some regions, Baird's beaked whales may also forage at shallower depths of 400–700 m (DeAngelis et al. 2023), although in other regions they have been found to dive to depths comparable to Blainville's and Cuvier's beaked whales (Minamikawa et al. 2007; Stimpert et al. 2014). Sowerby's beaked whales dive to similar depths as other beaked whales, but their deep dives are shorter, their clicking and movement is more rapid, and their faster stroke rate leads to a higher ascent speed than found for sympatric Blainville's beaked whales (Visser et al. 2022). In addition, Sowerby's beaked whales perform fewer intermediate dives, instead spending more time near the surface (Visser et al. 2022). Additional information, including dive cycle periodicity, temporal and seasonal patterns in diving behavior, and the foraging behavior of individuals in groups has continued to be elucidated through tagging and PAM studies (Arranz et al. 2011; Barlow et al. 2020; Barlow and McCullough 2022; Cioffi et al. 2021; Henderson et al. 2016).

Beaked whale dive behavior has evolved as a behavioral and physiological adaptation to the preferred prey of this family of odontocetes. Beaked whales forage primarily, and in some cases exclusively, on meso- and bathy-pelagic squid and mid-water or benthopelagic fishes that do not undergo diel vertical migrations (MacLeod et al. 2003; MacLeod and D'Amico 2006; Smith et al. 2021; Visser et al. 2021). Differences and specializations among species may indicate niche separation in sympatric species (MacLeod et al. 2003; Visser et al. 2021, 2022) or geographic divergence in species with prey overlap (MacLeod et al. 2003). Sympatric species may further partition shared habitat by diving to different depths (McSweeney et al. 2007; Naito and Mitani 2007). Beaked whales occur in all waters deeper than about 1 km but appear to be particularly common in habitats with steep slopes and complex bathymetry, including submarine canyons and seamounts (Arranz et al. 2011; Hazen et al. 2011; Johnston et al. 2008; Lanfredi et al. 2016; MacLeod and Zuur 2005). These habitats in turn have been found to aggregate prey via interactions between deep sea currents and seafloor topography (D'Amico et al. 2001; MacLeod and D'Amico 2006; MacLeod and Zuur 2005), and areas of frequent beaked whale foraging activity have been found to have more dense concentrations of preferred prey than similar adjacent habitats (Benoit-Bird et al. 2020; Southall et al. 2019). Dynamic oceanographic features have also been found to correlate with beaked whale occurrence, such as the deep maximum oxygen layer (Lanfredi et al. 2016), or salinity and temperature in specific layers that may structure prey distribution (Hazen et al. 2011), although these relationships are less well studied. While

future shifts in distributions of beaked whale populations related to climate change are likely as prey ranges change (e.g., Hooker et al. 2019), little work has been done to investigate these possible shifts. Macleod (2009) included beaked whale species in their assessment of potential global changes to marine mammal distributions relative to climate change. They hypothesized that out of the 21 species considered, 6 would experience a range expansion, 8 a range shift, and 5 a range contraction, depending on if they were cold- or warm-water limited, and that 12 of these shifts would not be favorable to the species (Macleod 2009).

All this baseline information on distribution, habitat use, and foraging behavior is crucial when assessing and understanding behavioral responses to anthropogenic stressors, particularly in the case of naval sonar. This specific noise type, along with seismic airguns to a lesser extent, has been linked to several global cetacean mass stranding events that predominantly included beaked whales, particularly Cuvier's beaked whales. In the late 1990s and early 2000s, there was a series of mass strandings that were associated with multi-national navy training events that utilized LFAS and MFAS (Cox et al. 2006; D'Amico et al. 2009; U.S. Department of Commerce, U.S. Department of the Navy 2001; Fernandez et al. 2005; Frantzis 1998; Jepson et al. 2003; Martín et al. 2004; Simmonds and Lopez-Jurado 1991). Typically, operational MFAS uses a series of tonal pulses in the frequency range of 1–10 kHz (e.g., Henderson et al. 2022b), while LFAS uses frequencies less 1 kHz, although this varies by country. Ultimately, there appeared to be several major factors that, when occurring together, greatly increased the likelihood of a mass stranding of cetaceans. These included the use of multiple ships with sonar in a bathymetrically complex environment with limited egress for the whales; the presence of a strong surface duct or acoustic waveguide; the sonar source occurring within the depth of the surface duct; the activity occurring in an area where the shoreline is within 10s of km of the 1000 m isobath; and vessels moving faster than 5 knots (D'Amico et al. 2009; D'Spain et al. 2006; U.S. Department of Commerce, U.S. Department of the Navy 2001). Many international navies have adjusted their mitigation policies and changed areas of military readiness activities in response to these findings, and some have entered into regional multi-national agreements to further help reduce potential impacts on marine mammals, with an emphasis on beaked whales (e.g., Dolman et al. 2009, 2011; NATO 2018). In the Canary Islands, where MFAS use has been banned altogether, no additional atypical beaked whale stranding events have occurred (Fernández Rodríguez et al. 2012), while in the Mediterranean Sea and other regions, beaked whale strandings continue to occur (Podestà et al. 2016; Simonis et al. 2020). While Faerber and Baird (2010) pointed out that a lack of strandings in Hawai'i may not necessarily mean animals weren't impacted, just that a stranding response has not been detected due to differences in geography of the islands, a series of aerial surveys were flown in Hawai'i after seven US Navy training events, and no stranded animals were observed (Deakos et al. 2017).

The current best explanation for beaked whale strandings associated with anthropogenic events is the onset of decompression sickness (DCS), which seems to be a result of a combination of behavioral and physiological factors (Bernaldo de Quirós

et al. 2019; Fahlman et al. 2014; Hooker et al. 2012). Deep diving cetaceans such as beaked whales and sperm whales (*Physeter macrocephalus*) may already live at the edge of nitrogen supersaturation due to the long durations of their deep dives coupled with a long time spent at intermediate depths (Hooker et al. 2012). As discussed in detail below, behavioral response studies of beaked whales have found that these whales most often respond to MFAS by ceasing to forage, but remaining at depth while moving away from the sound source when the exposure starts during a foraging dive. Alternately, in areas with an extended shallow shelf, the directional movement into shallow depths could result in animals' inability to behaviorally regulate their dissolved gasses by diving. The avoidance behavior may also include an increase in aerobic effort with increased fluke rates (e.g., DeRuiter et al. 2013), which may increase $CO_2$ levels (Hooker et al. 2012), further coupled with a stress or flight-or-fight response. Increased $CO_2$ levels could in turn initiate nitrogen bubble formation in already supersaturated tissues, leading to DCS (Fahlman et al. 2014; Hooker et al. 2012). Coupling this physiological response with the behavioral response of longer deep dives and more time at intermediate depths as animals avoid the MFAS source, particularly in individual animals that may already have risk factors or be otherwise compromised, could be the perfect storm of factors that lead to stranding (Bernaldo de Quirós et al. 2019). Therefore, while long deep dives are part of the normal beaked whale behavioral repertoire (Schorr et al. 2014; Quick et al. 2020), when the existing nitrogen supersaturation is exacerbated by additional factors, stranding may occur in some individuals (Hooker et al. 2012), especially in the circumstances of close proximity to shore and limited egress (D'Spain et al. 2006). In necropsied animals that may have stranded in relation to MFAS use, there were seven consistent factors that seemed to be reliable diagnostic features indicative of DCS (Bernaldo de Quirós et al. 2019). These included one or more animals stranding in good body condition and with recent food in their stomachs; the presence of many gas bubbles made up of nitrogen (and some $CO_2$); fat hemorrhages; multi-organ gas and fat emboli; "disintegration" of interstitial tissue; and multi-organ hemorrhages in lipid-rich tissue (see Bernaldo de Quirós et al. 2019 for more details). Stranded animals presenting one or two of these features could often be linked to other causes of death, and bubble formation has also been found in other species unrelated to MFAS exposure (Bernaldo de Quirós et al. 2019; Fernandez et al. 2017; Moore et al. 2009); therefore, rapid assessment of stranded animals is critical in determining the cause of the strandings. There is ongoing research about the potential for occurrence of DCS in beaked whales and the link to naval MFAS activity, which is outside the scope of this review but is crucial in the understanding, mitigation, and prevention of future occurrences (Bernaldo de Quirós et al. 2019; Díaz-Delgado et al. 2018; Fahlman et al. 2021; Podestà et al. 2016).

## Behavioral Response Research

As discussed in Harris and Thomas (2015), research on beaked whale behavioral responses to sonar has utilized a few different approaches. There have been focused behavioral response studies (BRS) and controlled exposure experiments (CEE) on

individual tagged whales exposed to both simulated/scaled sources and real naval sonars. There have been opportunistic studies with tags, PAM, and combinations of both to identify behavioral responses of beaked whales to real world testing and training activity on active US Navy ranges. Finally, analyses of aggregated data from both data types have been conducted, where responses are modeled using data from a number of animals or risk functions created using the received levels of the sonar at the animals. While other reviews have been conducted on the impacts of anthropogenic noise or specifically sonar on marine mammals in general (Cox et al. 2006; Hildebrand 2005; Nowacek et al. 2007; Southall et al. 2007, 2016), this review is focused specifically on beaked whales that have been exposed to both real and simulated MFAS signals that are representative of real naval sonars. The sonar waveform used by different countries varies but is typically made up of one or more frequency-modulated (FM) or continuous wave (CW) pulses of varying bandwidths, durations, and interval periods (Henderson et al. 2022b). For example, the simulated waveform used in US-based BRS studies was typically characterized by an FM upsweep followed by two CW tones, with an overall bandwidth of 550 Hz from 3.2 to 3.75 kHz, 1.4 sec duration, and 25 sec interval period (Tyack et al. 2011). In contrast, the European-based 3S studies used an FM upsweep of 1 kHz from 6 to 7 kHz for the MFAS signal, and an FM upsweep or downsweep of 1 kHz bandwidth from 1 to 2 kHz (or 2–1 kHz), all of 1 sec duration and 20 sec interval period (Miller et al. 2011). In addition, exposures to other signal types, such as playbacks of killer whale (*Orcinus orca*) vocalizations, or echosounders, are also discussed in order to put the responses to MFAS in a broader context. Killer whale whistles are made up of a CW waveform and can occur from 1.5 to 18 kHz, while pulsed calls range from 250 Hz to over 30 kHz, with most energy in the 1–6 kHz band (Ford 1989; Deecke et al. 2005). Killer whales also produce a high-frequency modulated downsweep signals that occur between 20 and 27 kHz (e.g., Simonis et al. 2012). Echosounder pulses are typically short duration FM pulses at one or more specific frequencies, but often with broadband energy directed in a narrow beam (Risch et al. 2017). This review seeks to summarize and synthesize the current state of knowledge of beaked whale behavioral responses to MFAS, as well as the direction this field is moving with some ongoing studies. Note that all reported received levels are given in dB re 1 uPa root-mean-square (RMS) unless otherwise specified.

## Behavioral Response Studies/Controlled Exposure Experiments

Starting in 2006, researchers began conducting controlled experiments on tagged focal whales, where variables such as distance to the animal, presence of other conspecifics, source level of the signal, and received level at the animal could be controlled or known, and received levels and behavioral responses could be measured as accurately as possible. Several new types of descriptive and statistical analyses were developed or applied during these studies, including the severity response scale, the Mahalanobis statistic, behavioral change-point analyses, and Hidden Markov Models (HMMs) (Antunes et al. 2014; DeRuiter et al. 2013; Southall et al. 2007; Wensveen et al. 2019).

One of the first true controlled exposure experiment on beaked whales was a joint tagging and PAM effort on the AUTEC range in the Bahamas in 2007 and 2008 (Tyack et al. 2011). A Blainville's beaked whale was tagged with a DTAG and exposed to playbacks of simulated 0.55 kHz bandwidth MFAS from 3.2 to 3.75 kHz, ramped up to a maximum received level of 147 dB re 1 μPa. When the received level reached 138 dB re 1 μPa, the whale stopped echolocating and began swimming away from the source and ascending slowly. In fact, a similar response has been observed for most tagged beaked whales exposed to MFAS in subsequent BRS and opportunistic studies (e.g., DeRuiter et al. 2013; Falcone et al. 2017; Miller et al. 2015; Stimpert et al. 2014). A similar change in behavior and long, slow ascent was also observed for the same whale when exposed to playbacks of mammal-eating killer whale vocalizations in the 2–5 kHz band (Allen et al. 2014; Tyack et al. 2011), and to a second whale also tagged with a DTAG and exposed to a playback of a pseudo-random noise (PRN) signal, also in the 2–5 kHz band. The whale responded to the killer whale vocalizations at just above the detectability level of 98 dB re 1 μPa, while the response to the PRN occurred at 142 dB re 1 μPa. The PRN signal was used in this and other BRS studies as a control signal to determine if the animals are responding to received level alone or to acoustic characteristics of the sonar signal that may be perceived as similar to killer whale vocalizations (Miller et al. 2022; Tyack et al. 2011), thus indicating their response to sonar is similar to an anti-predator response.

Another set of CEEs called the Sea mammals, Sonar, and Safety (3S) project was conducted by an international team of scientists in European waters off Norway starting in 2006 and was initially focused on killer whales and herring (*Clupea harengus*) (Doksaeter et al. 2009; Kvadsheim et al. 2007; Miller et al. 2011) due to an apparent decrease in the presence of both species after an incidental exposure to Norwegian sonar. Sperm whales and long-finned pilot whales (*Globicephala melas*) were added as focal species in the first years of the study. During a follow-on effort, called $3S^2$, humpback whales (*Megaptera novaeangliae*), minke whales (*Balaenoptera acutorastrata*), and northern bottlenose whales (*Hyperoodon ampullatus*) were also added as focal species. One northern bottlenose whale was tagged with a DTAG during the main $3S^2$ effort (Kvadsheim et al. 2015; Miller et al. 2015; Sivle et al. 2015). In 2015 and 2016, an additional effort called 3S-ORBS (Off-Range Beaked Whale Studies) was focused on northern bottlenose whales in an acoustically pristine environment that had not likely been previously exposed to sonar (Miller 2015; von Benda-Beckmann et al. 2019; Wensveen et al. 2019). In the $3S^2$ experiment, the northern bottlenose whale was exposed to 1 kHz bandwidth FM upsweeps from 1 to 2 kHz for 35 min to a maximum cSEL of 162 dB 1 $\mu Pa^2s$. The exposure started while the whale was on a shallow 100 m dive and was about 5.4 km from the source. The whale initially surfaced for several breaths and then moved toward the source, with the received level at about 98 dB re 1 μPa. The whale dove while still approaching the source, and then at 130 dB re 1 μPa it turned away from the source and began diving deeper. The transmission stopped when the whale was 2074 m deep, but the whale continued diving to 2339 m where it finally began its

ascent. No foraging clicks were produced during this very long and deep dive. Following this dive, the animal dove in a series of shallow dives, as it continued very directional movement away from the source vessel for another 7 h and 35 km before the tag detached. A similar response was observed for another northern bottlenose whale tagged with a DTAG and exposed to a 1–2 kHz upsweep that was within 1 km of the animal (Wensveen et al. 2019). This whale stopped producing foraging clicks and began diving at a high speed while moving away from the source during and after the exposure for a total of 6.5 h, although this animal did resume foraging before the tag came off. A third northern bottlenose whale was exposed to a signal from 3.4 to 3.9 kHz at a distance of 17 km. This whale also dove deeper and began moving away from the source; it continued moving away without clicking for 7.5 h and almost 37 km. A fourth northern bottlenose whale was also tagged with a DTAG and exposed to the 1–2 kHz upsweep at close range; however, there was a transducer failure during this exposure and the received level never rose above 100 dB re 1 μPa. In fact, this whale approached the vessel and circled it throughout the exposure, and then began foraging within 24 min after the exposure ended (Wensveen et al. 2019). In addition to these whales tagged with DTAGs, nine other whales in the area and associated with the "focal" tagged whales were tagged with Wildlife Computers satellite tags. Received levels for these whales were modeled using propagation modeling (see von Benda-Beckmann et al. 2019 for details). These tags allowed the researchers to model behavioral responses to the sonar exposures at a variety of distances out to 346 km; most tagged animals within 28 km appeared to avoid the sound source at received levels of 117–126 dB re 1 μPa with at least one of the satellite tagged animals in apparent association with an animal with a DTAG and demonstrating very similar dive and avoidance behavior. Two of the satellite tagged whales at 38 and 346 km did not respond, but the received levels may have been at or well below detection thresholds (Wensveen et al. 2019). The 3S study continued with 3S3, focused on sperm and pilot whales and included a Norwegian Navy vessel, and will continue further in 2023 with 3S4.

The next series of controlled exposures of both simulated and real sonar signals to beaked whales occurred in Southern California (SOCAL Behavioral Response Study) and was conducted from 2010 through 2016 (Southall et al. 2014, 2015, 2016). While this study was largely focused on blue (*Balaenoptera musculus*) and fin (*B. physalus*) whales, beaked whales and delphinids were also included as focal species. This was the first CEE study to utilize real US Navy ships to conduct exposures at longer distances, along with the simulated source that had a lower source level and therefore had to be deployed within a few kilometers of the whales. This study also used the PRN signal to compare responses against the 3–4 kHz MFAS signal. Two Cuvier's beaked whales and one Baird's beaked whale were tagged with DTAGs and exposed to the simulated source. One Cuvier's beaked whale and the Baird's beaked whale were both conducting foraging dives with echolocation pulses when the CEE started, while the other Cuvier's beaked whale had started to dive on what was likely a deep foraging dive. Both foraging whales stopped clicking, and all three whales increased their fluke rates and increased their

swim speeds as they moved away from the source and conducted deeper, longer dives with slow ascents (DeRuiter et al. 2013; Stimpert et al. 2014). Received levels at the time of the responses were 98 dB re 1 μPa and 127 dB re 1 μPa for the two Cuvier's beaked whales and 127 dB re 1 μPa for the Baird's beaked whale. In all three exposures, the sound source was stationary and within 3 km of the animals. One of the Cuvier's beaked whales also had an incidental MFAS exposure from a US Navy ship conducting an exercise about 118 km away, and RLs from this exposure were in the range of 78–106 dB re 1 μPa. Interestingly, the whale did not appear to respond to this MFAS, which provided some initial insight into the role that source distance may play as a context cue for these species (DeRuiter et al. 2013; Southall et al. 2016). When a real US Navy ship was utilized in the same study a few years later, it was positioned 70 km away from a tagged Cuvier's beaked whale (a distance that was chosen based on modeled propagation through the region) and received levels were 100–120 dB re 1 μPa. No behavioral response was observed for the tagged animal from this distant source (Southall et al. 2014, 2016).

The most recent large-scale BRS study was conducted in the Atlantic Ocean off North Carolina from 2017 to 2022, following many of the protocols and lessons learned from the SOCAL BRS project (Southall et al. 2018). Both DTAG and satellite tags were deployed on Cuvier's beaked whales and pilot whales in order to maximize the numbers of animals exposed and the distances between the source and the animals. Real US Navy ships were utilized again, following the same paradigm as in Southern California, where the ship was positioned relative to the known locations of the tagged animals using propagation modeling to achieve the desired range of received levels. Satellite tags lack the motion sensors that allow the fine-scale movement analyses conducted using DTAG data, and also provide down-sampled dive data relative to DTAGs, making their recorded data more coarse. However, satellite tags can be deployed for weeks or even months, which provides a longer duration baseline and follow-on period for comparison with the exposure period. Furthermore, Bouchet et al. (2021) determined that the increased uncertainty in the data obtained through satellite tagging can be reduced through a larger sample size, and this study reached much larger sample sizes than earlier studies that relied on DTAGs alone. Analyses are ongoing and so final publications on behavioral response results are still forthcoming. However, new statistical and modeling methods have been developed to successfully analyze the satellite tag dive data in a manner comparable to the DTAG data. For example, Schick et al. (2019) explored improved methods of estimating positional uncertainty in satellite tag data in order to improve received level estimates. Hewitt et al. (2022) developed methods to detect a behavioral response in satellite tag dive data using a kernel density analysis when comparing the data to a large aggregate of baseline data. Using this method, changes in dive behavior similar to those observed with DTAGS have been detected, including extended deep dives after an exposure and reduced follow-on deep dives, which is presumed to indicate an extended cessation of foraging (Hewitt et al. 2022). Finally, a great deal of baseline behavioral and social data have been analyzed, providing a framework against which behavioral responses can be compared (e.g., Cioffi et al. 2021; Shearer et al. 2019; Quick et al. 2020).

## PAM Data on US Navy Ranges Coupled with Tags

Another approach to investigating behavioral responses to MFAS is to conduct tagging on an active US Navy range, thereby conducting an opportunistic behavioral response study to real world training activity. This type of effort has been conducted at three different US Navy ranges: the Atlantic Undersea Testing and Evaluation Center (AUTEC) in the Bahamas, the Southern California Offshore Acoustic Range (SOAR), and the Pacific Missile Range Facility (PMRF) in Hawai'i. As these efforts can often be repeated in the same area over long periods, they have the added benefit of the potential to provide additional information about the populations that are present in the area rather than just focusing on individuals. Photo-id catalogs and long-term abundance trends can be developed, which allow for inference on repeated exposures and population level impacts (e.g., Baird et al. 2011, 2012, 2018; Claridge 2013; DiMarzio et al. 2020; Falcone et al. 2009). Satellite tags have been used more often in these studies than DTAGs or other sound and movement recording tags, and therefore received levels have to be modeled rather than measured. However, new tag technologies are being developed to get longer-term deployments of days to weeks in tags with sound and movement recording capabilities that will provide valuable new insights into beaked whale behavior (Falcone et al. 2022; Sweeney et al. 2022).

At the AUTEC range in the Bahamas, along with the two Blainville's beaked whales that were tagged with DTAGs described above, a third animal was tagged with a Wildlife Computers satellite tag prior to a US Navy training exercise that was conducted on the range (Tyack et al. 2011). For the 3 days prior to the exercise, the whale's track remained within a mean of 37 km to the center of the range, whereas during the 72 h of the exercise that mean distance extended to 54 km from the center of the range. In the first 3 days after the exercise, the distance dropped to a mean of 29 km, and then again to a mean of 13 km in the next 3 days. The maximum estimated received level by the tagged whales during the training exercise was 146 dB re 1 μPa (Tyack et al. 2011). This was repeated on an additional six Blainville's beaked whales tagged with satellite tags through 2015, who were exposed to a total of four multi-ship training events (Joyce et al. 2019). Four of these whales also moved away from their initial locations by 28–68 km, although only three animals were on or near the range at the onset of MFAS. The other four animals were 10–73 km away from the range, and while two of them did move further away, the two more distant whales did not avoid the area. Propagation modeled received levels at depths of 5 and 100 m were estimated for the tag tracks that were smoothed with a continuous time random walk model (*crawl* in R, Johnson and London 2018), with maximum estimated exposures of 145–172 dB re 1 μPa. Estimated received levels were reduced as the animals moved away from the range. The three animals that had been on or near the range at the onset of the exposure period returned to the range within 1.7–3.9 days after the training ended. Finally, two (out of the seven total) satellite tags were equipped with depth sensors in order to examine dive behavior. While both animals continued to conduct deep dives during the exposure period, one animal did not conduct the very deep dives that were recorded before and after the exposure, and also conducted more mid-depth

(400–800 m) dives than were recorded before or after the exposure (Joyce et al. 2019). These tag data were also combined to develop a discrete-space continuous-time model of exposure in order to estimate transition rates as animals avoided the MFAS by moving outside the range as well as their return to the range over time (Jones-Todd et al. 2022).

A long-term study of habitat use and dive behavior has been conducted on Cuvier's beaked whales that inhabit the SOAR range in Southern California (Falcone et al. 2009). Dive behavior of individual tagged animals has been observed (e.g., Schorr et al. 2014), with detailed information on surfacing bout durations, shallow and deep dive depths and durations, and overall IDDI rates and inter-individual variability. Some of the longest and deepest dives on record for Cuvier's beaked whales were identified in this dataset, and the researchers acknowledged that while these could be within the normal dive repertoire of this species, these dives took place on an active US Navy range where MFAS and other anthropogenic noise regularly occurs (Schorr et al. 2014). In fact, the longevity of this study and the frequent occurrence of MFAS led to the development of models using the aggregated dive behavior of 16 satellite tagged animals to test for changes in foraging dive behavior relative to two types of MFAS (Falcone et al. 2017). This was one of the first efforts to look at helicopter-dipping MFAS in addition to the typical ship hull-mounted MFAS that has been the focus of most BRS efforts. This study used Generalized Additive Mixed-effects Models (GAMMs) to look for changes in dive behavior relative to both sources. For the helicopter-dipping MFAS, both deep and shallow dive durations increased as the proximity to the source decreased, although four unusually short and shallow deep dives were recorded as well. Although dive duration increased with source proximity, dive durations for both types of dives decreased as the amount of temporal overlap increased. The shallow dive duration increased more for helicopter-dipping MFAS than for hull-mounted MFAS and increased the most when both sources were active. The shallow dives also tended to be deeper when they were longer overall as would be expected, but were less deep during exposures of both types of MFAS, while surface intervals were longer and more variable during both types of exposures (Falcone et al. 2017). These results indicate that Cuvier's beaked whales may react more strongly to lower-powered sources (such as helicopter-dipping MFAS) at closer distances, possibly due to the more unpredictable nature of their deployment. Finally, overall IDDIs became longer with both source types at closer distances. The baseline IDDIs in this population range from 33 to 680 min, with a mean duration of 175 min, equating to approximately 7–8 foraging dives per day (Falcone et al. 2017; Schorr et al. 2014). In the overall dataset, there were 37 IDDIs longer than 300 min; 70% of these included the presence of one or both types of MFAS, indicating possible loss of foraging opportunities. While this study is the first to look at multiple types of MFAS, as well as the impacts of MFAS on different facets of dive behavior, it must be noted that all of the GAMM models also included other variables, including time of day, other dive variables, and region, which were also significant in the models and therefore affected dive behavior. Further, a follow-on study that modeled dive behavior relative to additional environmental variables, such as sun angle and

seafloor depth, found that although MFAS was present during at least 10.4% of the time the tagged whales were on SOAR, the effect of MFAS on most dive variables was less than 4% except for IDDIs, which continued to be longer in the presence of MFAS (Barlow et al. 2020).

Another long-term tagging and observation study has been conducted on the PMRF range off Kaua'i, Hawai'i, as well as throughout the Hawaiian Islands (Baird et al. 2008, 2009, 2018, 2019; Henderson et al. 2021; Schorr et al. 2009). This study has examined the behavior and residency patterns of a variety of odontocete species that occur in Hawaiian waters, including Cuvier's and Blainville's beaked whales. Resident populations of both species have been identified in the waters off the Big Island of Hawai'i (Baird et al. 2009; Schorr et al. 2009), in addition to a potential offshore population of Blainville's beaked whales (Baird et al. 2011), and both species have been detected acoustically on the PMRF range (Henderson et al. 2016; Martin et al. 2022, 2023). In 2021 and 2022, three Blainville's beaked whales were tagged with Wildlife Computers satellite tags prior to multi-ship training events on the range (Baird et al. 2021). These data are currently being analyzed, but dives from these whales appear to match acoustically detected dives on the range before the training events (Henderson and Baird, unpublished data), and the movements of the animals during the training events will provide insight into the behavior of these animals when they move off the range. These movements appear to be similar to those found at AUTEC, with animals moving off the range during the period of MFAS use and then returning to the range within a few days, although avoidance distances are only on the order of 10–12 km (Baird et al. 2021).

## Aggregated PAM Data and Risk Function Modeling

Finally, the vocal behavior of beaked whales relative to MFAS activity can be recorded using PAM to provide another type of observational study without tagging. While this type of study lacks the ability to identify individual responses, or to observe animals that cease vocalizing, it has the benefit of being able to assess behavioral responses over much larger spatial and temporal scales than tagging studies of individual whales. For example, multiple High Frequency Acoustic Recording Packages (HARPs) have been deployed throughout the Southern California Bight since 2006 (Baumann-Pickering et al. 2018). Among many other signals, these instruments have recorded MFAS, as well as Cuvier's beaked whale clicks, and potential impacts by MFAS on Cuvier's beaked whale echolocation can be modeled using these long-term datasets (Baumann-Pickering et al. 2018). Similarly, bottom-mounted Autonomous Multichannel Acoustic Recorders (AMARs) were also deployed off the Scotian Shelf in Eastern Canada from 2015 through 2017 and opportunistically recorded a large, multi-national naval training event (Stanistreet et al. 2022). Echolocation clicks from both sperm whales and four species of beaked whales (Cuvier's, Sowerby's, northern bottlenose, and an unidentified beaked whale) were recorded before and after the training event and at the same time the previous year. Clicks during the event were significantly

reduced for sperm whales and were reduced for both Cuvier's and the unidentified beaked whale although not significantly due to a low sample size (Stanistreet et al. 2022). PAM conducted on US Navy ranges can also assess both vocal behavior and changes in spatial use relative to the training activity over short and long timeframes. These data can also be utilized to develop received level-based risk functions of behavioral response to MFAS (Harris et al. 2015, 2018; Jacobson et al. 2022; Moretti et al. 2014; Tyack and Thomas 2019).

At the AUTEC range in the Bahamas, Blainville's beaked whale group vocal periods (GVPs) were recorded before, during, and after two multi-ship training events (McCarthy et al. 2011; Tyack et al. 2011). Significantly more GVPs were recorded before the MFAS activity than during, while GVPs remained low for 35–65 h after the MFAS activity, beyond which the number of GVPs returned to similar or higher levels than before (McCarthy et al. 2011). There was also a spatial change to the pattern of GVPs recorded on the range, such that before and after the training activity GVPs were distributed across the range, although predominantly occurred in the southwestern corner of the range. However, during MFAS activity, the reduced number of GVPs that occurred on the range were pushed to the edges of the range, with little to no acoustic activity at the center of the range. Estimated received levels for the groups that continued to forage ranged from 101 to 157 dB re 1 μPa, with a mean of 128 dB re 1 μPa (McCarthy et al. 2011; Tyack et al. 2011). Data from a third multi-ship training event at AUTEC was used to develop a behavioral response function based on a generalized additive model (GAM) that estimated the probability of a group of Blainville's beaked whales initiating a foraging dive in the presence of sonar (Moretti et al. 2014). The resulting risk function estimated a 20% probability of disturbance at 130 dB re 1 μPa and a 95% probability of disturbance at 180 dB re 1 μPa, with a 50% probability of disturbance at 150 dB re 1 μPa.

A similar reduction in the detection of GVPs during periods of MFAS activity and change in spatial distribution to the edges of the range has also been observed for another population of Blainville's beaked whales found on the PMRF range in Hawai'i (Henderson et al. 2019; Jacobson et al. 2022; Manzano-Roth et al. 2016). The risk function modeling conducted by Moretti et al. (2014) at AUTEC was repeated using data recorded on PMRF from six multi-ship training events (Jacobson et al. 2022). This was done to compare the responsiveness of another range-associated population of Blainville's beaked whales in a separate ocean basin with a different environment that did not have the deep ocean basin and limited egress found at AUTEC. This risk function differed in that it modeled three periods: the period before training activity, an initial 2–3 day period of training activity during which hull-mounted MFAS was not used but other noise sources were present, and then the 2–4 day period of training that included MFAS use. While both phases of the training activity occurred at AUTEC as well, that initial phase was not explicitly modeled and was included in the "before" period. In addition, received levels were modeled for the beaked whales in Hawai'i at an assumed dive depth of 1000 m, compared to the 100 m depths used in the Moretti et al. (2014) risk function model. Finally, in the PMRF model, the probability of a GVP occurring was only modeled

between 100 and 165 dB re 1 μPa, rather than the 80 to 200 dB re 1 μPa scale used in the AUTEC model. The resulting 50% probability of a disturbance occurred at 132 dB re 1 μPa; however, this was relative to the 44% decrease in GVPs that had already occurred in the first period of training that did not include MFAS. In fact, in a separate behavioral change-point analysis using GVP data aggregated from 16 multi-ship training events conducted at PMRF, the most significant decrease in GVPs occurred at the very start of that initial phase of training that does not include MFAS (Henderson et al. 2019; Martin et al. 2020). A follow-on analysis was conducted to look at the specific sources that may be leading to that initial decrease, including the closest point of approach (CPA) and approach angle of submarines and surface vessels, and the CPA, approach angle, and estimated received level of active training torpedoes. As this analysis was conducted outside of a classified environment, it was necessarily coarse, with CPAs of the three sources only estimated per half hour and per general hydrophone location, and with approach angles estimated relative to the hydrophone in 90-degree quadrants (approach, away, or parallel). No GAMs were significant for any of those variables relative to a decrease in GVPs unless the intercept was excluded from the model (Henderson et al. 2022a). Further analyses are planned that will use finer resolution spatial and temporal scales as well as single-source training events in order to determine what causes that initial drop in GVPs.

Other beaked whale species are also acoustically detected at PMRF, including Cuvier's beaked whales, Longman's beaked whales, and the unidentified species that produces the Cross-Seamount echolocation pulse (Martin et al. 2022; McDonald et al. 2009). A long-term analysis of Cross Seamount beaked whale GVPs found a similar spatial and behavioral response to Blainville's beaked whales, in that GVP detections were reduced during the biannual multi-ship training events and were compressed to a narrower, shallower region of the range, but returned to baseline levels within 3 days after the training ended (Manzano-Roth et al. 2022).

## Other Acoustic Sources

Behavioral responses to other acoustic sources have also been found for beaked whales via opportunistic and observational studies. A Cuvier's beaked whale that had been tagged with a DTAG was passed by a vessel during one of its foraging dives with a maximum broadband received level of 136 dB re 1 μPa and a CPA of 700 m (Aguilar de Soto et al. 2006). The broadband noise from the vessel had the potential to mask the beaked whale's echolocation pulses, while the energy in the 2–8 kHz band was 24 dB higher than noise in that band during other foraging dives, which was hypothesized could impact beaked whales if they were particularly sensitive to sound in that bandwidth (Aguilar de Soto et al. 2006). However, there were no changes in dive behavior, including depth, duration, or descent and ascent speed during this dive relative to the other dives recorded for this animal, so all impacts suggested by this analysis were hypothetical. In contrast, a true CEE of vessel noise was conducted with Blainville's beaked whales on the AUTEC range (Pirotta et al. 2012). A vessel was directed to approach hydrophones where GVPs

were being detected, and at the onset of echolocation pulses turned on their engines to full power for 2 min, up to six time per GVP. GVP durations did not change relative to the ship noise, but the number of hydrophone changes (indicating movement of the group) was reduced for groups close to the ship. This suggested that while the groups continued foraging, they significantly reduced their horizontal movement, or changed to a more directed movement, during the dive at distances up to 5.2 km from the ship (Pirotta et al. 2012).

During visual and acoustic cetacean surveys of the North Atlantic Ocean, many fewer acoustic detections of beaked whales occurred on days when a Simrad EK60 echosounder (operating simultaneously at frequencies of 18, 38, 70, 120, and 200 kHz) was active (Cholewiak et al. 2017). Fewer groups were also observed visually on days when the echosounder was active, but generalized linear models (GLMs) of sighting data found sea state and region to be the only significant variables for visual detections. In contrast, the GLMs of acoustic data found echosounder activity and region to be the significant predictors of beaked whale detections, with only seven acoustic events, or 4% of all detections, occurring when the echosounder was active (Cholewiak et al. 2017). In contrast, two 12 kHz multibeam echosounder surveys were conducted on the SOAR range in Southern California, and the number of Cuvier's beaked whale GVPs increased during and after the surveys relative to the number of GVPs detected before the surveys (Kates Varghese et al. 2020). There was also not a spatial change in where the GVPs were detected on the range during the surveys in 2017, and while the main area of foraging activity shifted during the 2019 survey, there was no reduction in the number of GVPs (Kates Varghese et al. 2021). A similar echosounder study was conducted at AUTEC in 2008, and observations of GVPs were opportunistically observed during another survey in 2015; both efforts found a similar lack of impact to Blainville's beaked whale foraging dives (Benoit-Bird et al. 2020; Hazen et al. 2011; Vires 2011). It may be that beaked whales inhabiting naval ranges are exposed to anthropogenic sound sources so often there is some degree of habituation (although see the discussion on site fidelity [e.g., Forney et al. 2017] below), leading to a lack of response to a highly directional echosounder, whereas in the North Atlantic beaked whales are less frequently exposed to these types of sounds and are therefore more reactive. Alternately, all of the studies on naval ranges used single frequency echosounders, while the vessel in the Atlantic Ocean survey used a multibeam echosounder with five frequencies; therefore, the increased responsiveness could have been due to the number and higher frequencies of the sources.

In addition to echosounders, evidence from gillnet mortality studies found that 10–12 kHz acoustic pingers affected beaked whale behavior positively (Carretta and Barlow 2011). In that study, the number of beaked whales entangled in gillnets was reduced to zero when pinger use became mandatory in a US west coast drift gillnet fishery. The effect of pingers in reducing bycatch was much greater for beaked whales than for any other cetacean species, indicating that they may be more sensitive to novel sound sources than other species.

Finally, new sources of acoustic noise are still being introduced that may be of concern. Acoustic ultrasonic antifouling devices are starting to be utilized by cruise

ship lines and other commercial vessels, and a preliminary investigation found an apparent response by Cuvier's beaked whales at Guadalupe Island off Baja, Mexico (Trickey et al. 2022). Both visual sightings and acoustic detections were reduced when a vessel was present at the island and using the antifouling device in the summer of 2019; no similar reduction in detections occurred in the following summer of 2020, when commercial vessels were not operating due to the COVID-19 pandemic. Nor was there a similar decrease in activity in the presence of other vessel noise or echosounders alone, so the reduction could not be linked to any other anthropogenic noise than the antifouling devices (Trickey et al. 2022). As commercial vessels in general, and cruise ships in particular, are found globally, this may become a prevalent source of noise impact as more companies adopt this technology.

## Other Factors that May Facilitate or Mediate Behavioral Responses

As mentioned, one hypothesis as to why beaked whales respond so strongly to naval MFAS is the sounds' possible similarities with killer whale vocalizations (Zimmer and Tyack 2007), as some killer whale ecotypes are known to prey on marine mammals (Jefferson et al. 1991) and vocalizations occur in a similar bandwidth as MFAS (Deecke et al. 2005; Ford 1989). This was first tested during the CEE conducted at AUTEC; one of the tagged Blainville's beaked whale was exposed to a playback of mammal-eating killer whale vocalizations during the foraging dive that directly followed the exposure to simulated MFAS (Allen et al. 2014; Tyack et al. 2011). The killer whale vocalizations were bandwidth limited to 2–5 kHz in order to match the bandwidth of the simulated MFAS. As soon as the received level of the playback was detectable above background noise levels, at 98 dB re 1 μPa, the animal stopped clicking and made the longest and slowest ascent that was recorded out of 32 other dives recorded on the range. The beaked whale continued to swim away from the playback location for an additional 10 h, which was a longer duration response than for any of the MFAS exposures described above in this and all other CEEs (e.g., DeRuiter et al. 2013; Miller et al. 2015; Stimpert et al. 2014). Similarly, killer whale vocalization playbacks were conducted with northern bottlenose whales, as well as long-finned pilot whales, humpback whales, and sperm whales, during the 3S CEEs (Miller et al. 2022). Northern bottlenose whales responded similarly to the killer whale vocalizations as they did to the MFAS exposures with a cessation of foraging, and thus the response to MFAS was hypothesized to be an anti-predator response. In fact, Aguilar de Soto et al. (2012, 2018, 2020) further hypothesized that beyond the strong response to MFAS, much of the typical baseline beaked whale dive behavior is an adapted anti-predator response, including not producing echolocation clicks in the first and last several hundred meters of a deep foraging dive's descent or ascent, the high level of vocal synchrony among group members once they do start echolocating, and the horizontal movement during the ascent phase of the dive. However, the long-slow ascent phase of a deep foraging dive has also been hypothesized to serve as a means to facilitate gas exchange (Hooker et al. 2012). Similarly, the increase in shallow dives and reduced time at the surface observed for

Cuvier's beaked whales during the day may serve as a visual anti-predator response (Baird et al. 2008; Barlow et al. 2020), while also functioning as a mechanism for gas exchange, lactic acid processing, or digestion (Baird et al. 2008; Hooker et al. 2009). However, extended time at intermediate depths could also lead to DCS (Bernaldo de Quirós et al. 2019; Zimmer and Tyack 2007) indicating a trade-off between anti-predator strategies and prevention of DCS.

In contrast, it has been theorized that animals with strong site fidelity, or animals with poor body condition, may not avoid an area with an acoustic stressor, such as MFAS, if their foraging habitat is limited to the exposed area or if the trade-off of additional foraging is worth the increased risk (Forney et al. 2017; Frid and Dill 2002; Siegal et al. 2022). However, most of the northern bottlenose whales tagged during the 3S studies demonstrated behavior assumed to indicate an anti-predator response, regardless of body condition (Miller et al. 2015; Siegal et al. 2022; Wensveen et al. 2019). In the Bahamas, it has been suggested that the Blainville's beaked whale population at AUTEC acts as a sink for the greater region, as more females without calves were observed compared to a less noise-impacted area at the nearby island of Abaco (Claridge 2013; Moretti 2019). Prey availability and richness seem comparable across these two areas (Benoit-Bird et al. 2020), which seems to indicate that differences in prey abundance alone are not a driving factor in the continued use of the range. However, in multiple surveys prey availability did match the areas of highest beaked whale foraging activity at AUTEC (Benoit-Bird et al. 2020; Hazen et al. 2011), indicating there is a relationship between beaked whale presence and prey abundance. Similarly, the area of preferred foraging habitat on the SOAR range in Southern California also seems to have a higher concentration of nutrient rich prey (Southall et al. 2019) than in adjacent areas. In fact, Southall et al. (2019) estimated that Cuvier's beaked whales foraging in their preferred habitat on the SOAR range would only need to conduct a mean of 6 dives per day to reach their energetic requirements, while Schorr et al. (2014) estimated that population conducts at least 7–8 dives per day, therefore possibly exceed their daily requirements. However, Cuvier's beaked whales that have been tagged near the SOAR range have demonstrated they are capable of and frequently conduct long-distance movements away from the range as part of their normal behavioral repertoire; therefore, they are also not restricted to that high impact foraging area (Schorr et al. 2014). Furthermore, they often return to the area after these long-distance excursions, and many individuals have been photographically recaptured over several years (Curtis et al. 2021; Falcone et al. 2009). Recent abundance estimates of this population, based on 11 years of mark-recapture data, put the number at 121 animals (71–219), with this being likely a portion of the overall population of the California Current Ecosystem, with a survival rate of 95% and calf percentage of 4.7–6% (Curtis et al. 2021). Although the annual rate of change was estimated as −0.8%, the survival estimate of this population is higher than that for a population in the Canary Islands where MFAS use was banned (Reyes Suárez 2018) and is comparable to the estimate at Abaco in the Bahamas (Curtis et al. 2021; Claridge 2013). However, the percentage of calves in the SOAR population is low (as is the case in Abaco), thus resulting in the negative overall growth rate.

Therefore, in all of these disparate beaked whale populations, while an immediate change in foraging dive behavior may indicate an anti-predator response that may continue for several hours, the animals continue to return to these habitats to forage. This may be due to high concentrations of preferred prey, or other as-yet undefined habitat characteristics. While these data demonstrate individual responses, and in some cases repeated exposures of individuals that could result in multiple lost foraging opportunities, population-level impacts have not yet been conclusively identified. In areas where prey concentrations are rich and estimations of the number of foraging dives needed in a day to reach energetic requirements are lower than the typical number of dives actually conducted per day (e.g., Benoit-Bird et al. 2020; Southall et al. 2019), it is difficult to say what might be the population level impacts of missed foraging opportunities. For example, for Blainville's beaked whale range-associated populations (e.g., Henderson et al. 2019, 2022a; Joyce et al. 2019; Manzano-Roth et al. 2016; Martin et al. 2020), it could be that the typical avoidance behavior observed on naval ranges during training activity are learned anticipatory responses rather than a subsequent response after an exposure. This may be why those responses are initiated at the start of activity, even before the onset of MFAS, and routinely last for up to 3 days past the activity. These generalized avoidance responses could indicate moves to comparable (or better, or worse) prey patches but not be hallmarks of lost foraging opportunities. Alternately, as suggested for AUTEC, high prey concentrations could lead to a continued use of the range, even though there are population-level impacts (Claridge 2013; Benoit-Bird et al. 2020; Moretti 2019), creating a local population sink that is continuously refilled by the larger regional population. The ongoing long-term efforts at these locations will hopefully provide answers to these questions as more photo-id and dive data are collected. Furthermore, there is ongoing effort to use these data in bioenergetic models that can then be utilized in Population Consequences of Disturbance (PCOD) models (e.g., Czapanskiy et al. 2021; New et al. 2013). PCOD models integrate what is known about life history demographics, behavior, and resources, along with impacts to individuals resulting from behavioral responses, such as missed foraging opportunities or poor body condition, to estimate the impacts of disturbance at the population level. Several PCOD studies are ongoing for beaked whales and other cetaceans to evaluate population level effects of noise exposures (e.g., Booth et al. 2020, 2022; Pirotta et al. 2018; Pirotta 2022).

## Summary and Conclusions

Advances in biologging and PAM capabilities, coupled with concerns over beaked whale stranding events, have led to a focus on beaked whale occurrence, distribution, habitat use, and behavior. Researchers have sought to understand how and why beaked whales respond to MFAS, and how these responses could lead to a stranding. When exposures occur during deep foraging dives, the primary response by beaked whales is to cease foraging but remain at depth while moving away, sometimes vigorously, from the direction of the source. Beaked whales exposed to MFAS

during other phases of their dive cycle may also dive deep to avoid the source or may remain at the surface or at intermediate depths while moving away. The avoidance behavior may last for hours as an immediate response, or for days as a general avoidance of an area, while a return to foraging behavior and resumption of the typical dive cycle may take several hours, potentially leading to missed foraging opportunities. These responses seem conserved across the few species for which data have been collected. The general response also appears consistent for individuals with frequent exposures to MFAS and other anthropogenic noise as well as for individuals found in more acoustically pristine environments. The continued work with real naval sonar vessels, exposures to other MFAS sources, exposures from multiple sources simultaneously, and with additional species are all ongoing and will provide further critical insight into the nuances of these complex behavioral responses.

While our knowledge on beaked whale baseline behavior and behavioral responses to MFAS have been greatly expanded in the last two decades, there is still much to learn. More controlled exposures of different real-world MFAS sources at varying distances are needed in order to truly characterize the separate but co-mingled impacts of source type, received level, and source distance on the strength and type of responses observed. Better characterizations of prey fields both in- and outside of areas of repeated exposures would help elucidate whether movements to other areas truly represents lost or reduced foraging opportunities or could simply find whales competing for resources in a crowded prey field. Additional physiological studies in beaked whales and other deep-diving odontocetes that investigate how behavioral responses and stress hormones may impact or mediate gas exchange and nitrogen uptake is critical in furthering our understanding of DCS in these species. Collaborations among researchers in different areas of expertise as has been done in many of the above studies is the best way to continue moving the needle forward on our understanding of the impacts of MFAS on beaked whales.

**Acknowledgments** This review captures the work of a large number of researchers around the world doing this important work, and I would like to thank them all for their efforts. All cited work was done under scientific research permits if needed; permit information for the research is cited in the original literature. I would like to specifically thank Julie Rivers and Jay Barlow for their reviews of this manuscript.

**Abstract**

Increasing evidence documents effects of impulsive underwater noise on hearing and behavior of marine mammals, but knowledge about the impacts of extensive or chronic exposure of cetaceans to continuous noise from shipping is still scarce. The distribution of harbor porpoises (*Phocoena phocoena*) was analyzed in relation to shipping noise and other environmental variables in an area with intense marine traffic, the Fehmarnbelt in the Baltic Sea. Autonomous noise recorders were deployed at 19 positions within the Fehmarnbelt between September 2009 and November 2010 (bandwidth = 16 Hz–16 kHz). Harbor porpoises were surveyed from March 2009 to October 2010 using aerial visual line transect surveys (altitude = 76 m and 250 m). The acoustic data were analyzed using 10 s intervals (CI = L5, L50 and L95). Noise maps were derived using AIS data for each month in 2010 in a grid of 750 × 750 m cells and applying an empirical geometrical spreading loss model. Ambient noise in the Fehmarnbelt was dominated by shipping noise (median SPL: 109–132 dB re 1μPa), and noise levels found are typical for busy waterways. Distribution modelling was used for analyzing correlations between environmental variables and porpoise densities. The best fitting distribution model included variables characterizing water temperature at the bottom, water depth, and underwater noise; plus, temporal variable as survey year and season were also important. The model shows porpoise densities declining with increasing median sound levels to about 130 dB re 1 μPa. Thus, median shipping noise levels significantly affected the distribution of harbor porpoises in the study area, but little habitat displacement appeared as a result. This finding might reflect habituation and a trade-off, where the benefits for the porpoises to stay in the study area outweigh the disruptions of disturbance due to underwater noise exposure.

## Introduction

Growing awareness about the diverse effects of underwater noise in the world's oceans have stimulated a wealth of studies into assessing and regulating underwater noise in order to mitigate significant environmental impacts (see reviews by, e.g., Hildebrand 2009; OSPAR Commission 2009; Williams et al. 2015). Underwater noise may have harmful impacts on aquatic animals including cetaceans through interfering with their acoustic communication, orientation, and prey capturing abilities, and – at high doses – might even lead to auditory damage (Richardson et al. 1995; Southall et al. 2007; National Marine Fisheries Service 2018). Commercial shipping is a very widespread and important source of anthropogenic underwater noise. Noise propagates well under water and the noise emissions of a vessel may exceed ambient noise levels at distances of several 10 km. Although ships are not the loudest sources of underwater noise, their

sheer abundance makes shipping noise a very important source of anthropogenic noise in the oceans (Hildebrand 2009; OSPAR Commission 2009; United Nations 2018). Ambient noise levels have been rising in some regions along with an increase in shipping activity (Anderson et al. 2008; Andrew et al. 2011; Miksis-Olds et al. 2013; Kaplan and Solomon 2016). In some areas, cetaceans are frequently exposed to noise levels, which may elicit behavioral responses (see reviews by Clark et al. 2009; Hildebrand 2009; OSPAR Commission 2009; Erbe et al. 2012, 2019).

The concerns of potential ecosystem implications of rising levels of ambient noise due to shipping have found its way into regulation with the EU Marine Strategy Framework Directive (MFSD) (European Commission 2008, 2010; Tasker et al. 2010). The MSFD requires each EU member state to achieve "Good Environmental Status" (GES) in their marine waters by 2020. Trends in continuous low frequency noise as emitted by shipping is one of the indicators used to assess the GES and as of 2010, all member states have to systematically monitor this type of anthropogenic noise to assess GES and then, based on the initial assessment, define and decide on principles and objectives for GES. In the same context, the International Maritime Organization (IMO) has issued guidelines for the reduction of underwater noise from commercial shipping (International Maritime Organisation 2014). The IMO guidelines are non-mandatory but will likely influence regulation in the future (see United Nations 2018).

Disturbance from underwater noise may have complex direct and indirect effects on marine mammals, ranging from stress (e.g., Rolland et al. 2012) to habitat displacement (Rako et al. 2013). There is growing interest in analyzing how and under which circumstances this might affect their abundance (Bejder et al. 2006; Lusseau and Bejder 2007; Senigaglia et al. 2016) and cause impacts on population level (Nabe-Nielsen et al. 2018; Pirotta et al. 2018; Mortensen et al. 2021). It is an implicit assumption that increasing ship traffic and the resulting noise beyond a certain level and intensity creates conditions that could lead to population consequences. However, as even very busy waterways may still be of high importance for cetaceans (McClellan et al. 2014), there is likely no simple relationship between noise levels and cetacean abundance, distribution, and population level effects. Behavioral reactions of cetaceans to anthropogenic underwater noise are highly variable, ranging from attraction and indifference through short-term changes in behavior to short- or long-term avoidance, which could lead to long-term habitat displacement (Richardson and Würsig 1997; Nowacek et al. 2007; Senigaglia et al. 2016). Rather than simply loudness, further characteristics of a noise signal, such as its duration, its abruptness, its frequency spectrum, and the signal-to-noise ratio play an important role in stimulating an animal's response (Southall et al. 2007).

For harbor porpoises (*Phocoena phocoena*), the onset of individual responses to various noise sources was shown at widely different broadband noise levels: While harbor porpoises responded to low-frequency pile driving at sound exposure levels of 143 dB re 1 $\mu Pa^2$ s (Brandt et al. 2016), a much lower threshold of 119 dB re 1 $\mu Pa^2$ s was found when studying seal scarer noise (Brandt et al. 2013). Even lower response thresholds were shown for the reaction of captive porpoises to stimuli in their best hearing ranges (Kastelein et al. 2017; Kok et al. 2018). Tougaard et al. (2015) conclude that responses to underwater noise relate to frequency-specific

hearing abilities of cetaceans and predict a response when noise levels exceed the hearing threshold by about 45 dB. Similarly, Dyndo et al. (2015) emphasized the importance of the high-frequency components of vessel noise in eliciting avoidance reactions in harbor porpoises.

Avoidance reactions of cetaceans to shipping noise have been demonstrated mainly in relation to relatively small vessels such as whale-watching boats (Erbe 2002; Bejder et al. 2006; Gervaise et al. 2012), leisure crafts (Piwetz et al. 2012; Rako et al. 2013), and speed boats (Ng and Leung 2003; Li et al. 2015). Avoidance reactions of marine mammals to ship noise were found to increase with vessel speed (Richardson et al. 1995; Oakley et al. 2017; Wisniewska et al. 2018). While vessel speed usually correlates with increasing noise level, the movements of the ships and the perceived abruptness of the noise also seem to play a role in eliciting avoidance responses (Ellison et al. 2018). The types of observed responses range from rather subtle behavioral changes to long-term avoidance of disturbed areas.

Most studies conducted so far have looked at direct responses and short-term effects of anthropogenic noise on marine mammals (but see Bejder et al. 2006; Lusseau and Bejder 2007), and modern biologging techniques provide detailed insights into individual responses to underwater sound (van Beest et al. 2018; Wisniewska et al. 2018; Mikkelsen et al. 2019; Martin et al. 2021). Recent studies indicate that shipping noise may affect physiological status (Dey et al. 2019), habitat choice (Lin et al. 2020), and populations (Wang et al. 2020) of cetaceans in estuarine habitats, where animals are more directly exposed to commercial shipping, but still very little is known on the impacts of extensive or chronic exposure of cetaceans to underwater noise from commercial shipping in the sea. The noise emissions from commercial vessels are more intense than those of whale-watching and leisure boats, but of lower frequencies (Richardson et al. 1995; McKenna et al. 2012; Southall et al. 2017). The course of commercial vessels might be more predictable for cetaceans as compared to leisure crafts. Assessing the impact of commercial shipping on cetacean abundance needs to analyze cetacean abundance and their exposure to shipping noise on larger scales and cannot rely only on direct observations (Merchant et al. 2017). The exposure of cetaceans to shipping noise can be assessed by relating cetacean abundance and distribution to underwater noise maps. The global AIS system provides detailed online data on shipping and allows generating noise maps accounting for transmission loss in relation to environmental parameters such as bathymetry, sediment, temperature, and salinity (Maglio et al. 2016; Neenan et al. 2016; Sigray et al. 2016; Bagočius and Narščius 2018; Sertlek et al. 2019; Farcas et al. 2020). It is thus intriguing to use such noise maps, which can be easily produced – even in real time (Nehls et al. 2022) – for the assessment of potential noise impacts on marine mammals (Erbe et al. 2012; Merchant et al. 2014). However, while the exposure of cetaceans to extensive or chronic shipping noise has been mapped in different attempts (e.g., Erbe et al. 2012; Redfern et al. 2017), there is very little knowledge on how mapping of noise levels can be used to predict effects on distribution and abundance of cetaceans. In order to understand the consequences of globally increasing ship noise, this knowledge is an essential step.

The harbor porpoise is a small cetacean species, which is widely distributed and by far the most abundant cetacean in European waters. Recent numbers for the North

Sea have been estimated at about 345,000 (CV = 0.18, Hammond et al. 2017) with no changes in abundance since 1994 (289,000, CV = 0.14, Hammond et al. 2002) and 2005 (355,000, CV = 0.22 (Hammond et al. 2013). The harbor porpoises occurring in the study area Fehmarnbelt belong to the Inner Western Baltic population, which comprises about 23,000 individuals and has been stable over the last two decades (Hammond et al. 2013). The Fehmarnbelt is a relatively shallow area between the islands Lolland (Denmark) and Fehmarn (Germany), showing water depths up to ca. 35 m. At its narrowest part between the islands, it has a width of about 20 km. The Fehmarnbelt is an area with high levels of marine traffic used by ships travelling from the North Sea through the Kiel Canal and the Great Belt to and from the eastern Baltic Sea. Parts of the Fehmarnbelt have been assessed as being of ecological importance, and several marine protected areas have been included in the European network Natura 2000, including the Special Area for Conservation (SAC) "Fehmarnbelt." This SAC covers 280 $km^2$ in the middle of the Fehmarnbelt, and it overlaps with the east-west going main shipping lane and is crossed by high frequent ferry routes between Germany and Denmark (FEMM 2013).

In the present study, the distribution and the total abundance of harbor porpoises (*Phocoena phocoena*) are analyzed in relation to underwater noise levels in the Fehmarnbelt. As the response of marine mammals to acoustic signals may not be uniform but likely depending on the context of noise exposures (Ellison et al. 2011; Lin et al. 2020), habitat quality is considered as an important factor to be considered, as the extent of a response may differ in relation to habitat quality. Therefore, the distribution of harbor porpoises was modelled accounting for environmental variables including underwater noise levels derived from a simple empirical model.

## Methods

### Characterization of Ship Traffic Through Fehmarnbelt

Ship traffic in the Fehmarnbelt is characterized by mainly two sources: (1) cargo vessels and tankers moving longer distances through the Baltic Sea and (2) passenger ships sailing on two routes between Germany and Denmark.

The most frequented routes are the T-route with 35,000–45,000 (Rambøll 2011) movements annually, mostly comprised of cargo ships, and the ferry route Rødby-Puttgarden with about 35,000 movements annually, which crosses the T-route in the Fehmarnbelt. At the crossing of these two main routes, shipping intensity reaches eight passages per hour. These two routes form by far the most important part of shipping in the Fehmarnbelt study area, although ship traffic additionally occurs along some other minor routes, and the T-route splits to the east and the west of the Fehmarnbelt diverting traffic to different destinations (Fig. 1). Vessel speed in the T-route is mostly between 10 and 20 knots with container vessels usually travelling at 15–20 knots and a substantial portion (41%) of the passenger vessels travelling faster than 20 knots (Rambøll 2011). Within the focal area of this study, the main shipping lanes are situated at water depths of 20–30 m.

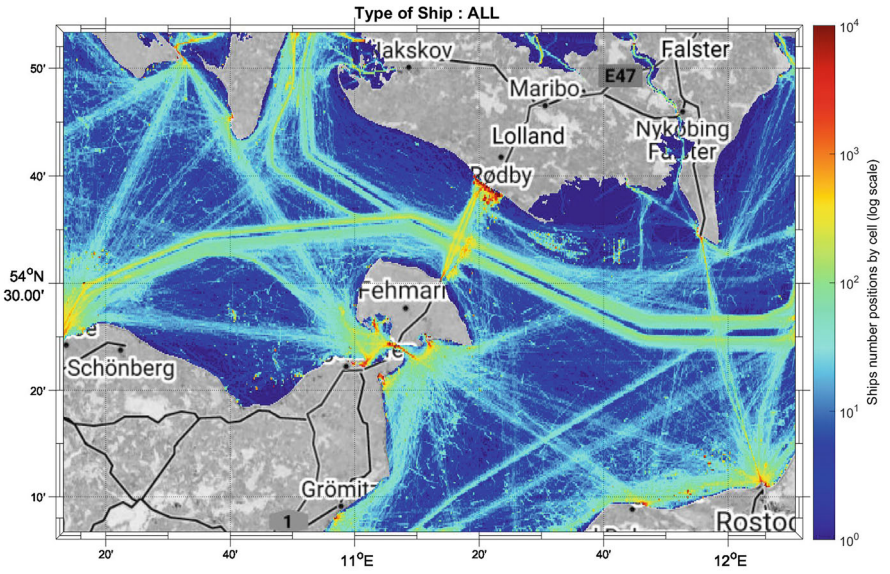

**Fig. 1** Marine traffic lanes in the Fehmarnbelt study area identified from AIS signals

## Noise Measurements

To measure underwater noise, autonomous measurement buoys, capable of recording sound for up to 4 weeks, were deployed at different locations in the Fehmarnbelt.

They were equipped with low-noise hydrophones of type B&K 8106 with built-in preamplifier. Hydrophone receiving sensitivity is nominally −173 dB re 1 V/μPa. Noise recordings cover the bandwidth range from 16 Hz to 16 kHz.

Nineteen buoys were deployed in the Fehmarnbelt (Fig. 2) from September 2009 to November 2010. With the help of a flotation body, the hydrophone was kept approximately 1.8 m above the seabed. Noise measurements were conducted with three buoys at a time. Stations were changed at monthly intervals, but one location (A6) was kept permanently throughout the study period.

Additional noise measurements were carried out during the service trips from aboard the service ship. A portable AIS receiver (automatic identification system) served to record the AIS-telegrams from all ships crossing the Fehmarnbelt. Additionally, sound speed profiles were calculated based on CTD measurements.

The AIS recordings were used to identify ships passing near the measurement buoys (Fig. 3). The combination of this data together with the recorded sound pressure allowed to evaluate the apparent transmission loss for individual ships. Apparent transmission loss is the reduction of ship sound pressure level with increasing distance from the noise source. This experimentally estimated transmission loss served to model the noise propagation and was used to compute noise maps.

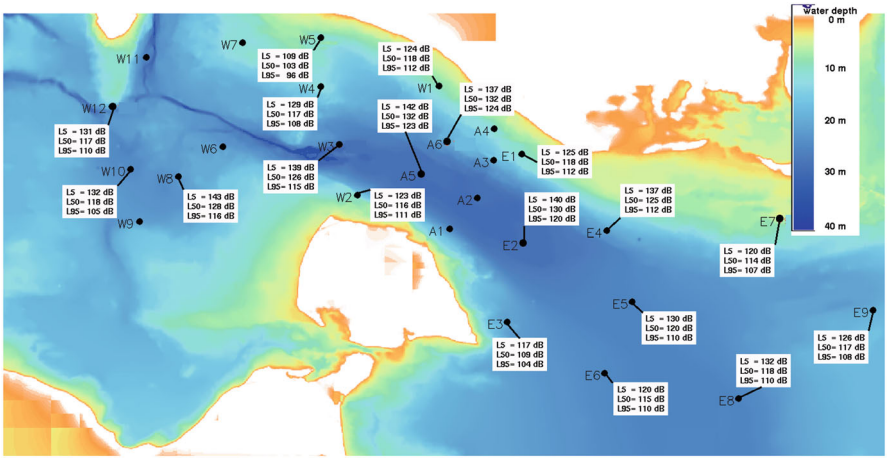

**Fig. 2** Map of the Fehmarnbelt area with color-coded water depths. Noise measurements were conducted periodically, associated to a longer-term C-POD measurement program marked by black dots (FEMM 2013). Noise measurements are labelled with their corresponding percentile levels L5, L50, and L95

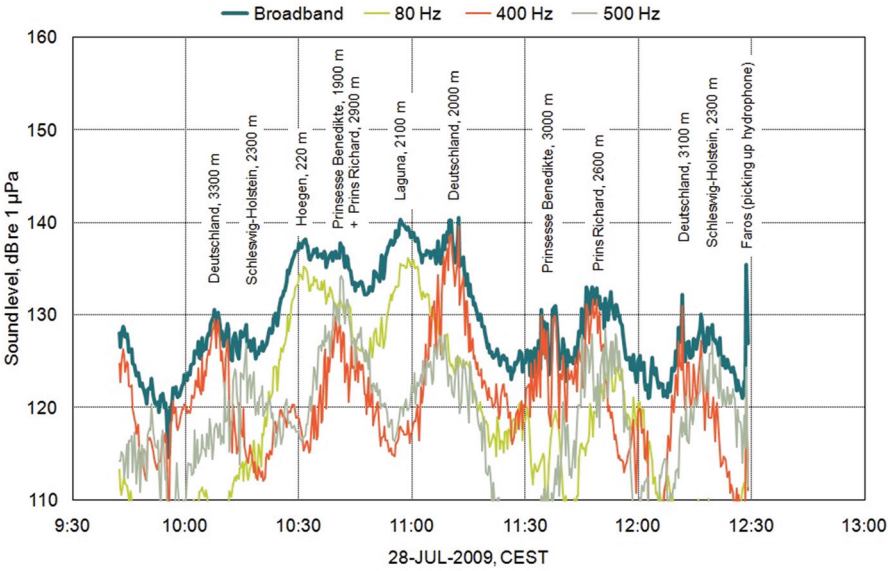

**Fig. 3** Measured sound pressure levels at a central position in the Fehmarnbelt near the ferry route. The name of the ship passing nearest as well as the distance to the hydrophone is given. Levels are given as broadband SPL, and in 1/3-octave bands for 80 Hz, 400 Hz, and 500 Hz, illustrating a variable spectrum of sound frequencies among passing ships

## Data Analysis

First, each recording was subjected to a quality control. Using a calibration signal at the beginning of each recording, the sound pressure level SPL was calculated at intervals of 10 s. After passing the quality check, the data were analyzed in terms of their percentile values (exceedance levels). Calculations were carried out for the median L50 as well as values for L95 and L5. The median sound pressure level is statistically more robust than the mean sound pressure level because the latter is dominated by the loudest period during the measurement and can therefore give a false picture of the overall noise situation. For example, the close passage of a single ship during the 30-day measurement interval may result in a very high mean SPL that does not adequately describe the overall noise situation. The L95 level is the sound pressure level that is exceeded 95% of the time.

It can be interpreted as the lower limit of the permanent ambient noise level during the measurement period at this location. Accordingly, L5 is the sound pressure level that is exceeded during 5% of the measurement time and thus contains information about the highest levels occurring. The difference between L5 and L95 thus characterizes the overall variability of the noise situation. Figure 3 shows the deployment positions for the noise data loggers together with the exceedance levels evaluated there.

A spectral analysis of the recorded ambient noise at position A6 in the loudest part of the Fehmarnbelt is shown in Fig. 4. The form of the 1/3-octave spectrum between 300 Hz and 16 kHz is very similar to the noise radiated by typical merchant ships as given by Wales and Heitmeyer (2002). It can be seen that below 300 Hz, the spectrum of the typical ship noise is higher than that of the measured median ambient noise. Measured spectral components below 100 Hz show the typical drop towards lower frequencies due to the cutoff frequency resulting from the water depth (see Urick 1983). Also shown in Fig. 4 is the hearing threshold of harbor porpoises as given by Kastelein et al. (2002). Extrapolating this threshold towards lower frequencies shows that the ambient noise, i.e., shipping noise, is below the detection threshold at about 250 Hz. Although frequency components below 250 Hz contribute significantly to the broadband level, they are not audible to harbor porpoises.

## Modelling Noise Maps

A noise map was created by relating shipping frequency to measured noise levels for the study area. AIS data for the Fehmarnbelt region were taken from Ramböll (2011) for each month in 2010. The grid for the shipping density consists of 750 × 750 m cells. Only cells containing at least 30 ships passing through per month were included for analyses and were treated as sound sources for the other cells. The source level of those sound emitting cells was computed as a fixed level + 10*lg (No. of ships). Ship type and speed was neglected in this simple model as this was already integrated in the noise measurements. The constant part (fixed level) of this source level was evaluated by comparison of the sound measured at a suitable

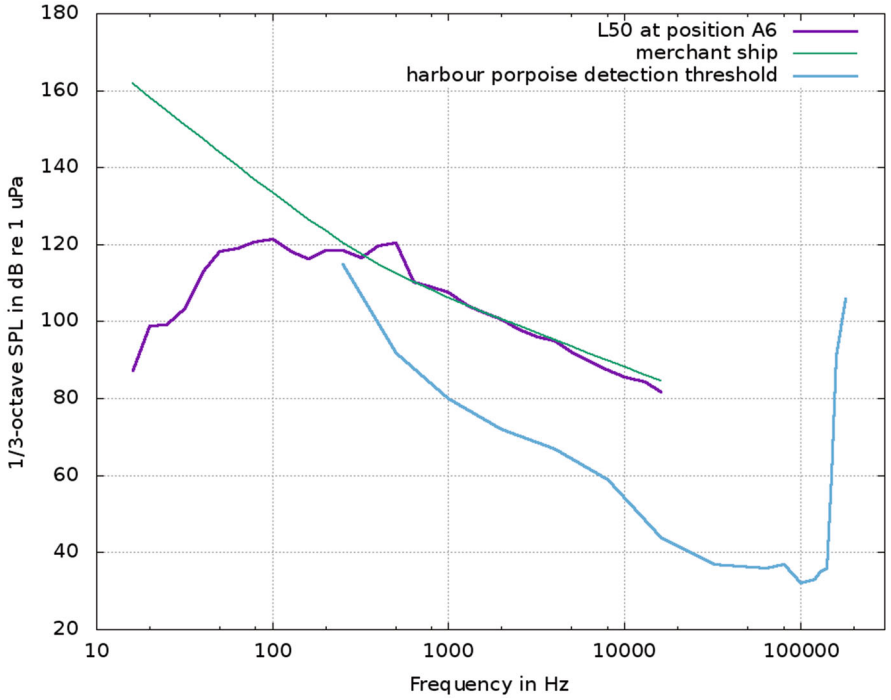

**Fig. 4** Typical 1/3-octave spectrum in the noisiest part of the Fehmarnbelt. A typical merchant ship spectrum as given by Wales and Heitmeyer (2002) shows good qualitative similarity above 350 Hz. Extrapolation of the harbor porpoise detection threshold given by Kastelein et al. (2002) towards lower frequencies will cross the ambient noise spectrum at about 250 Hz

reference station and the modelled sound pressure at this position in an iterative procedure. Station A6 was chosen for reference, as it is located directly in the shipping lane and showed the highest noise levels with L50 equal to 132 dB re 1 μPa. The constant source level per ship was evaluated to 164 dB re 1 μPa. Since no AIS data on ship type, length, or speed was available, this source level entered the model independent of those parameters. Omitting cells with less than one ship per day leads to a slight underestimation of the noise levels, but this is about 30 dB below the source levels neglected.

The decrease of the noise level as a function of distance r to the source gives the transmission loss (TL). The transmission loss usually is of the form TL(r) in dB = k * log(r/r0). Here, k is the propagation constant. Analysis of noise recordings of individual ship passages that were identified by AIS messages yielded a propagation constant of k = 22 for the model. This is similar to results obtained by van der Schaar et al. (2017).

For sound propagation in very shallow areas with 10 m water depth or less, a value of 25 was chosen for the propagation constant. This takes into account that the so-called cutoff frequency, below which sound propagation strongly diminishes,

rises with decreasing water depth. Moreover, there is a higher propagation loss because of the increase in reflections from the sediment and the water surfaces.

The influence of the sediment type on sound propagation was considered as well. Sediment data (grain size) was provided by Ramböll (2011) with the same resolution as the AIS data. The propagation loss due to absorption of sound in the seabed, especially in muddy regions is not negligible (see for example Urick 1983). This effect was incorporated in the noise maps. Bottom attenuation in dependence of grain size was modelled using data for the attenuation from Kibblewhite (1989). In summary, the model is based on the shipping density, the water depth of the source and immission cells, and the grain size of the seabed materials along the propagation path. This yields effective propagation constants k between 14 and 16 depending on the environmental conditions.

## Porpoise Surveys

Harbor porpoises were surveyed from March 2009 to October 2010 using visual aerial surveys of two designs: mammal-only survey flights (flown at 250 m altitude) and bird/mammal survey flights (flown at 76 m altitude). Each dataset was treated separately, and porpoise sightings were adjusted for availability and detection biases (see details in Grünkorn et al. 2005). After correcting for uncertain detection (availability bias and perception bias) and calculating porpoise densities, both datasets were combined, and survey effort data were prepared by splitting transects into approximately 1 km segments. Each transect segment was associated with temporally and spatially matching environmental variables. For detailed description of data collection and treatment, see FEMM (2013).

Porpoise observations were numerous in summer months and few in winter, therefore two seasons were defined in the data: summer (April to August) and winter (remaining months). Also, survey year was used as another temporal factor variable.

## Modelling Porpoise Distribution

Distribution modelling was used for analyzing correlations between environmental variables and porpoise densities. A number of environmental variables characterizing the general water environment and specific anthropogenic pressures were considered in the model. Hydrodynamic variables were derived from a hydrodynamic model developed by DHI specifically for the study area and the study period (FEHY 2013). While the number of variables that can be derived from the hydrodynamic model is very large ($>100$), we focused on the most feasible parameters: current flow describing variables (U, V, and W components of current velocity), frontal characteristics (pycnocline strength, frontal strength, and eddy activity), and water mass patterns (salinity, temperature, and density). Two sets of hydrodynamic data were considered: variables characterizing water environment near the bottom and at the surface. Water depth and seabed sediment grain size were included as static habitat

characterizing variables. Finally, four variables were used describing anthropogenic pressures: distance to land, distance to wind farms, distance to shipping lanes, and underwater sound. Estimated numbers of harbor porpoises were used as a response variable and environmental variables were used as predictors.

Generalized additive modelling (GAM) with a log link and Tweedie error distribution was used in order to account for overdispersion in the data (Candy 2004; Shono 2008). Initially, all candidate variables were fitted in single variable models and only those that were significant were further included in the full model. Further, variables were eliminated from the full model in a stepwise manner based on their significance: nonsignificant variables were excluded. A priori, decision was made to keep an interaction term between coordinates (Easting, Northing) and factor variables identifying year (2009 or 2010) and season (winter or summer) in the model. The permitted degrees of freedom were restricted to maximum 5 ($k = 5$) for continuous variables and 20 ($k = 20$) for the interaction term between coordinates. Fitting the Tweedie distribution, modelling requires selection of an index parameter determining the type of the distribution. Values between 1 and 2 were used as they fit a Poisson-gamma distribution. The value was chosen by changing it and refitting the models in order to find the index maximizing the deviance explained by the model. Predictor variables entering the final model were checked for collinearity in order to make sure that model results are not distorted by highly correlating variables (Dormann et al. 2013). Potential residual autocorrelation in the final model was tested using a correlogram. The generalized additive model (GAM) was fitted using the "mgcv" package (Wood 2015) in R v.3.4.3 (R Core Team 2017).

The fit of the final model was assessed by the deviance explained and used for creating porpoise distribution map. For mapping, the prediction grid with a resolution of 750 × 750 m grid cells was generated. The central point of each cell was associated with values of each variable averaged for the summer 2010 season. The final model was used to predict porpoise density values for each grid cell.

## Results

### Noise Maps

The exploratory analysis (see Fig. 3) showed that shipping noise dominates ambient noise levels in the Fehmarnbelt. Natural sources of sound like wind, breaking waves, and rain did not contribute much to the overall measured broadband noise levels. The noise map in Fig. 5 illustrates how noise propagations varies within the study area and provides a snapshot of the sound field produced by 19 ships based on a real AIS snapshot. All vessels were assigned a source level of 164 dB.

This simulation was carried out to illustrate how the noise maps were created. The noise sources (ships) are clearly delineated as hot spots (red). However, the resulting noise levels do not only decrease on concentric circles around the ships. Due to the different bathymetry and bottom structure, the transmission loss is strongly

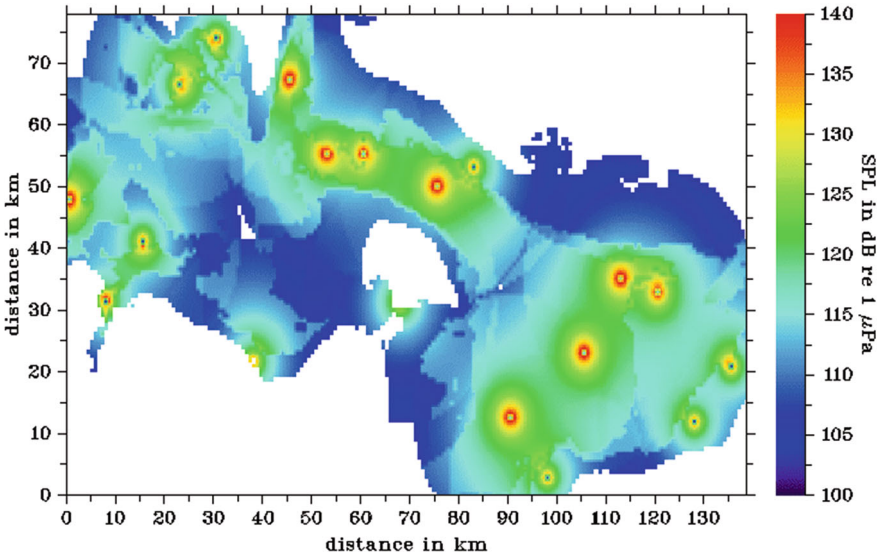

**Fig. 5** Snapshot noise map of the underwater broadband levels generated by 19 ships in the Fehmarnbelt area where high noise levels are shown in red and low noise levels in blue

dependent on the propagation path. As a result, regions with very shallow water and regions with muddy seabed sediments have lower sound levels.

The pixels where the ships are located are not part of the color code since the source level of 164 dB inside those cells clearly exceed 140 dB. Color coding starts at neighboring cells only. Their bathymetry and sediment play a crucial role in the appearance and size of the ships noise footprints.

A summarized median noise map of the mean shipping density for the summer of the year 2010 is shown in Fig. 6. For the reasons given above on sound propagation, this map is not just a reflection of the shipping density. There are areas west and east of Fehmarn with highly absorbing seabed sediments, which lead to lower sound pressure levels in the water column. Especially along the Kiel-Baltic Sea route, the model predicts variations of sound levels of 10 dB and more, primarily due to variable seabed conditions.

The quietest areas appear as the very shallow waters of the Rødsand lagoon, the coast east of Falster, and the German waters close to the island of Fehmarn and the mainland.

The modelled median noise levels show a close correlation to the noise levels measured at 19 locations at monthly intervals (Fig. 7). The deviation from measured noise levels probably arises from some temporal variation and a spatial mismatch of the model grid and the measurement locations. While the measurements at location A6 were conducted throughout a full year, and these measurements were taken as basis for the modelling, all other measurements were conducted for 1 month. There is likely some uncertainty arising from the fact that modelling is based on AIS data

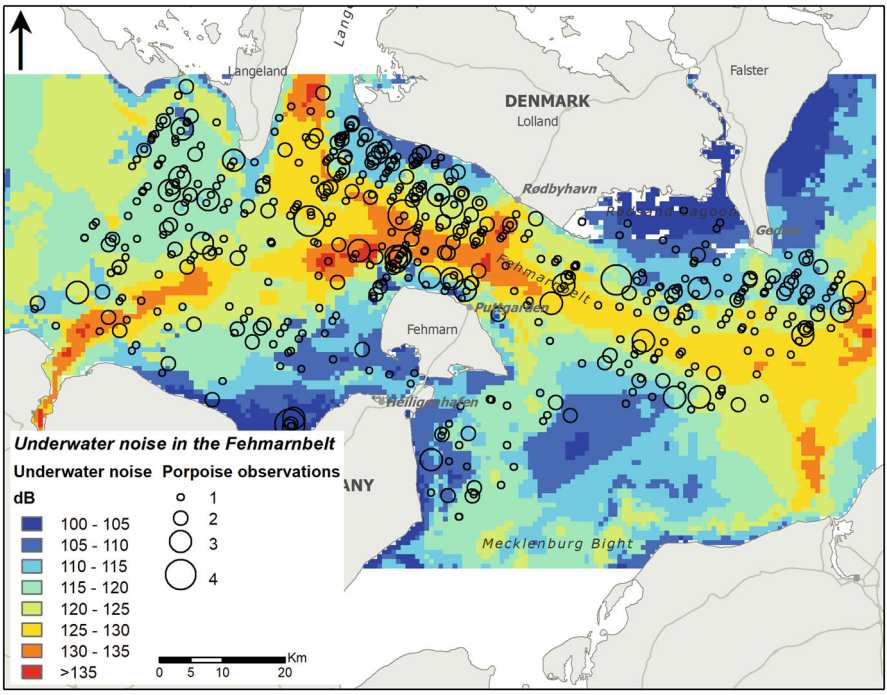

**Fig. 6** Underwater median noise map (L50) of the Fehmarnbelt with porpoise sightings during aerial surveys conducted in 2009 and 2010

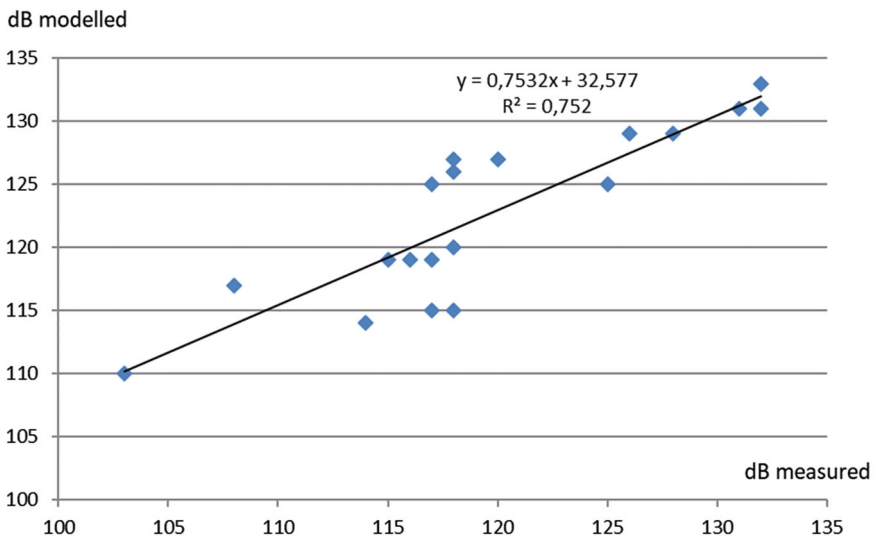

**Fig. 7** Correlation of modelled noise levels versus measured noise levels

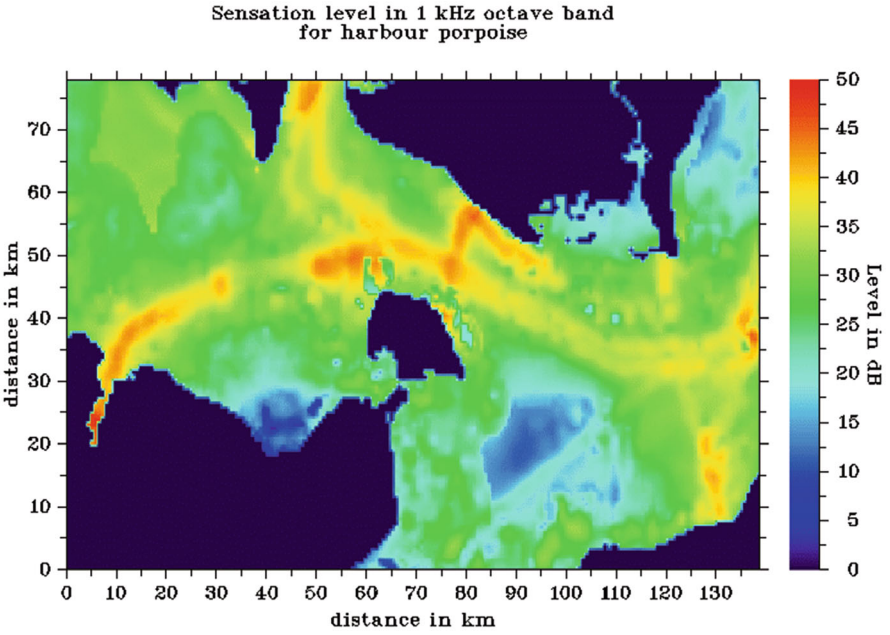

**Fig. 8** Noise map of harbor porpoise sensation level (L05) for the 1 kHz octave band for the year 2010

and thus excludes smaller leisure crafts, which have no obligation for AIS recordings. However, noise measurements indicated little seasonal variation, and as noise emission from smaller crafts are much lower as compared to commercial shipping, the overall contribution to the noise budget in the Fehmarnbelt is considered as low.

In order to highlight areas of noise levels, which might elicit disturbance responses from harbor porpoises, model noise levels for the octave band 1 kHz were calculated based on the measured 1/3-octave percentile spectra and the broadband noise propagation. For 1 kHz, the algorithm had to be modified since this frequency corresponds to a wavelength of roughly 1.5 m. At such a short wavelength, the influence of water depth on sound propagation can be neglected. The L05 noise levels for the 1 kHz octave band forms the basis for the calculation of a harbor porpoise sensation level map at this frequency (Fig. 8). Sensation level means the difference between the determined noise level in a certain frequency band and the hearing threshold of cetaceans in that band, which is set to 80 dB re 1 µPa at 1 kHz (Kastelein et al. 2002). Tougaard et al. (2015) hypothesized that noise levels exceeding the hearing threshold of cetaceans by 40 dB to 50 dB would elicit an avoidance reaction. While median noise levels do not exceed this value even at the loudest station A6 (Fig. 4), the orange to red areas of the sensation level noise map (Fig. 8) indicate those parts of the Fehmarnbelt, where such levels are exceeded in 5% of the time, so that frequent disturbance of harbor porpoise might be expected.

## Harbor Porpoise Distribution Modelling

Plotting sightings of porpoises over the noise map of the Fehmarnbelt area indicates that porpoises occur in areas distinguished by generally high underwater noise levels as well as in more silent areas. However, there was a tendency that porpoises were less abundant in the noisiest zones (Fig. 6).

Following the model selection procedure, the best fitting model included variables characterizing water temperature at the bottom, water depth, and underwater sound in addition to variables that were forced into the model: coordinates, survey year, and survey season (Table 1). All these variables were highly significant and deviance explained by the model was 10.3%. Autocorrelation function showed that no systematic correlation was left in the model residuals.

Variable response curves showed that harbor porpoises preferred water temperatures between 5 °C and 15 °C, water depth below 10 m, were more abundant in 2010, and animal numbers were higher in summer season as compared to winter. The shape of the response curve representing underwater sound indicated that porpoises generally occur in noisy environments and their density does not seem to be affected by noise up to levels of about 110 dB. At louder noise levels, the response curve decreases, indicating that porpoise densities decline with increasing sound levels starting from 115 to 130 dB (Fig. 9).

The map of predicted harbor porpoise densities created using the best fitting model shows that harbor porpoises were most abundant in the northwestern corner of the study area around southern Langeland and in the western part of the Fehmarnbelt between Fehmarn Island and the coast of Lolland, Denmark, except for the deepest part (Fig. 10).

To further evaluate possible effects of median noise levels on harbor porpoise abundance, we tested whether harbor porpoises seem to deselect noisy areas relative to their proportional extension. Application of the Jacob's selectivity index (Fig. 11) indicates that areas with median noise levels below 110 dB were strongly deselected, while areas with median noise levels between 110 dB and 125 dB were selected. Areas with relatively high median noise levels between 125 dB and 130 dB were

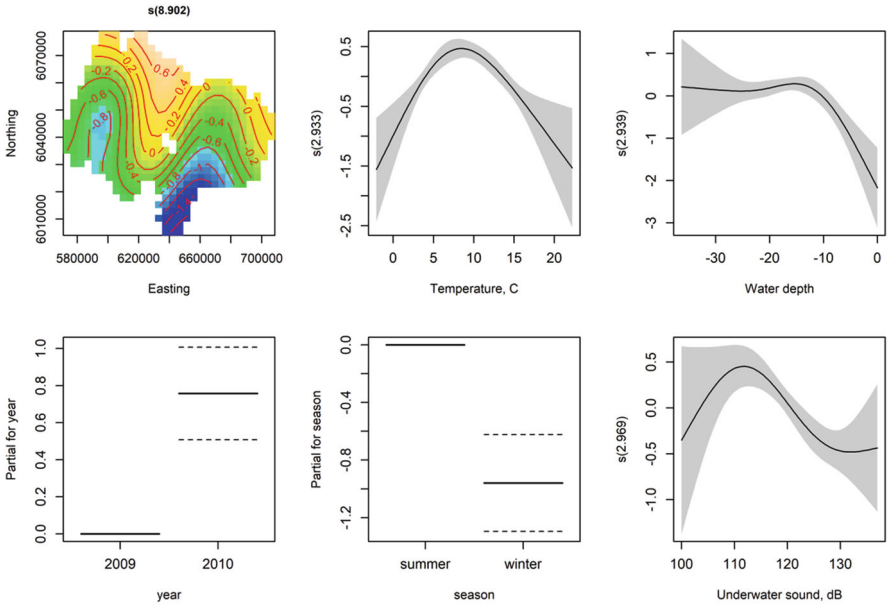

**Fig. 9** GAM response curves for the model of harbor porpoise distribution in Fehmarn Belt. The degree of smoothing is indicated in the legend of the Y-axis and for the interaction terms (Easting, Northing) in the heading. The gray-shaded areas and the dotted lines (for factor variables) show the 95% confidence intervals

deselected but no deselection signal occurred at highest levels of 130 dB to 135 dB, which are found in the main shipping lanes (see Fig. 6).

## Discussion

The results of this chapter show relatively high median noise levels within the Fehmarnbelt, which are typical for busy waterways across Europe and elsewhere. Median sound pressure levels fell between 103 dB and 132 dB re µPa with highest levels found where the main shipping lane T-route crosses the ferry route between the islands of Lolland, Denmark, and Fehmarn, Germany. Median noise levels along the shipping lanes were about 30 dB higher compared to areas at further distance to the shipping lanes. Noise levels similar to those observed in the Fehmarnbelt are found all along the main shipping routes in the Baltic Sea between Russia and Kiel Canal (Folegot et al. 2016). Measurements in the German Baltic Sea for the EC-Life + project BIAS showed average 1/3 octave sound pressure levels between 97 dB and 129 dB re 1 µPa at center frequencies of 63 and 125 Hz (Folegot et al. 2016) with highest levels close to main shipping routes. These results are in the same range compared to those presented here. The differences between methodologies (i.e., 1/3 octave band levels at certain center frequencies vs. median broadband) would in any

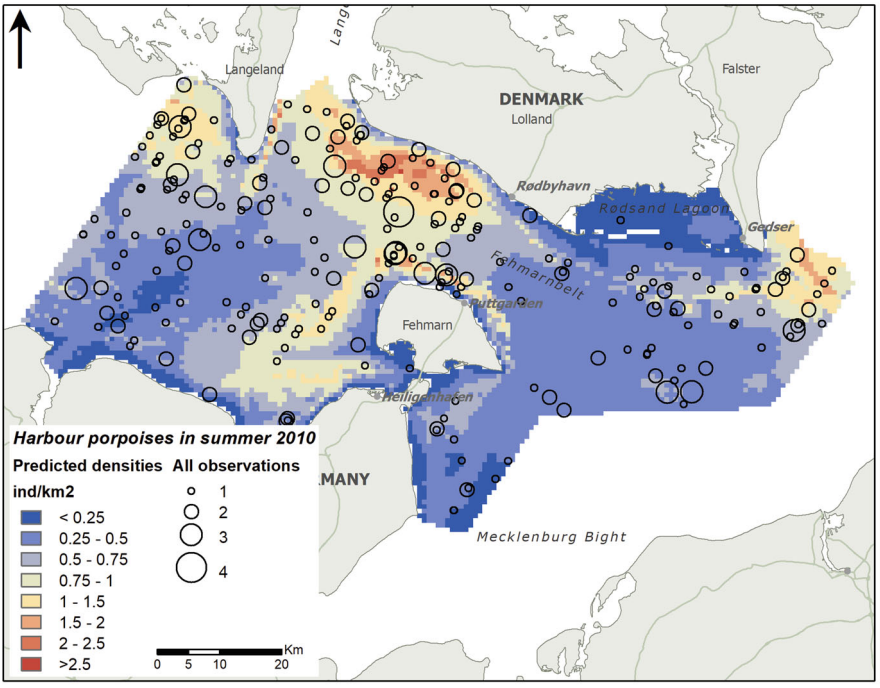

**Fig. 10** Predicted harbor porpoise density distribution in the Fehmarnbelt in summer 2010 with overlaid all porpoise observations recorded during aerial surveys

case result in values of the present study to be slightly higher compared to BIAS data, which is the case. Even considering methodological differences, the sound levels recorded in the Fehmarnbelt are similar to those reported from other areas with similar shipping activity. For example, Bailey et al. (2010) noted mean background noise levels between 104 and 119 dB re 1 μPa in a marine protected area off the coast of Scotland, rising to 138 dB re 1 μPa during times of high shipping activity (30 s average, recorded frequency range: 10 Hz–120 KHz). Nedwell et al. (2007) measured ambient noise at five offshore wind farm locations off the UK East and West Coast. They found levels to be as high as 132 dB re 1 μPa (recording range: 10 Hz–120 kHz; see also Merchant et al. 2017). The higher recording bandwidth in these latter two investigations probably resulted in broadband levels being somewhat higher compared to those of the Fehmarnbelt.

Porpoise density ranges in the Fehmarnbelt correspond well with those observed in areas of the Belt Sea population in general, although species abundance decreases along a north-south gradient leading to low densities towards the southeast. The predicted porpoise distribution map corresponds well with observations of harbor porpoises during the surveys and matches the hotspot area for the species identified by Sveegaard et al. (2011, 2018). Similar to other investigations, it was found that porpoise occurrence relates to habitat parameters. Harbor porpoise did not distribute

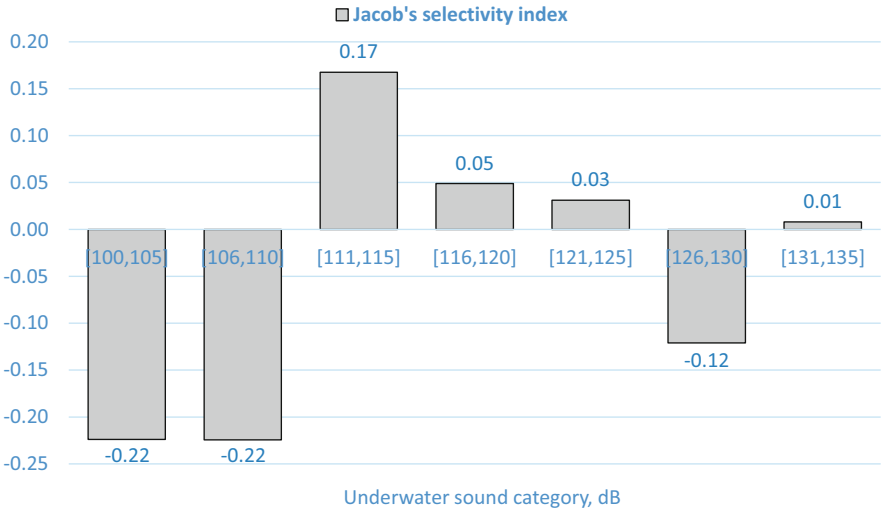

**Fig. 11** Harbor porpoise selectivity indices in the Fehmarnbelt for areas related to median noise level (Jacob's selectivity index)

evenly within the study area, and mean summer densities varied from below 0.1 to about 2 harbor porpoise/km$^2$ indicating substantial differences in habitat preferences within the area. The best fitting model describing harbor porpoise distribution in the Fehmarnbelt included parameters describing bottom current component U (though not significant as single factor), water temperature at the bottom, water depth, and underwater sound, and furthermore coordinate variables, which were forced into the model. The importance of depth and water temperature in the porpoise distribution model is consistent with results of other authors, who also found these variables to be significant (Hammond et al. 2002; Isojunno et al. 2012; Gilles et al. 2016; Lambert et al. 2016). These variables generally indicate similar patterns, suggesting that porpoises in the Fehmarn Belt areas prefer relatively shallow waters, but deeper than 10 m, and coincide in higher presences with water temperatures between 5 °C and 15 °C. In the context of this study, temperature also describes the seasonal pattern of porpoise abundance, as many animals leave the area during winter, and does not only reflect spatial variation within the area. Some authors found porpoises preferring deeper places, e.g., in Scotland, where preferred depth range was between 50 and 150 m (Booth et al. 2013). Other studies conducted over a larger spatial scale (Embling et al. 2010; Lambert et al. 2016) and/or in areas where tides and currents are pronounced (Johnston et al. 2005; Skov and Thomsen 2008; Booth et al. 2013; Jones et al. 2014) found hydrographic parameters such as current strength significantly influencing porpoise distribution. This was also the case in this study, although not very pronounced. This may be due to less variance in hydrodynamic parameters and stronger variance of other parameter in the Fehmarnbelt study area. Furthermore, the scale of the analyses certainly determines what patterns may be

found and what effects can be detected. The relatively low temporal resolution of porpoise abundance data in the present study, when compared to, e.g., continuous acoustic recordings of porpoises, means that it is somewhat limited in detecting effects of hydrodynamic variables, which show high temporal variability. To investigate effects of these hydrodynamic variables, passive acoustic monitoring is therefore more powerful, because of its better temporal resolution due to continuous recording and such investigations in the Fehmarn Belt indeed found a stronger correlation between hydrodynamic parameters and porpoise activity (FEMM 2013).

Harbor porpoises require a frequent and high-energy input due to their small size, limited body fats, and high-energy expenditure (Wisniewska et al. 2016; Rojano-Doñate et al. 2018), and environmental variables explaining porpoise distribution probably only partly reflect animal physiological needs and more likely are proxies of temporal and spatial dynamics in prey distribution. Thus, it can be assumed that their distribution follows the distribution of the most abundant prey species, and when direct information is available on food resources, they are often identified as being an important predictor of harbor porpoise abundance. Gilles et al. (2016) found porpoise density to decrease with distance to fishing hotspots for sand eel, which serves as an important food source in the North Sea. Main food sources for the Baltic porpoises are herring and cod (Sveegaard et al. 2012; Andreasen et al. 2017), and accordingly, porpoise distribution was shown to reflect herring distribution on a larger scale in the northern Baltic Sea, Skagerrak, and Kattegat (Sveegaard et al. 2012). However, for none of the fish species that form the main prey species of harbor porpoise there are data available at a sufficiently high resolution for meaningful analyses, and no clear connections of temporally and spatially variable prey occurrences with any hydrodynamic variables have been described.

With respect to underwater noise, it is demonstrated that, concerning the emitted frequencies, a large part of the shipping noise in the Fehmarnbelt is clearly audible to harbor porpoises. Though shipping noise is mainly of low frequency, the analysis shows that the higher frequency components are likely of sufficient level to elicit temporary avoidance responses in substantial parts of the Fehmarnbelt, most pronounced in the main shipping route to and from Kiel Canal and in the ferry route between the island of Fehmarn and Lolland (Fig. 8). For the assessment of significant avoidance responses, it has been assumed that a response of harbor porpoises to broad band ship noise is elicited at noise levels above 144 dB (FEMM 2013) corresponding to response distances of up to 1 km for larger vessels and ferries. Recent studies of Dyndo et al. (2015) and Wisniewska et al. (2018) also found that harbor porpoises may show initial responses at considerable distances to ship noise, likely responding to noise characteristics rather than just noise levels. Similarly, during a study on wind farm construction effects on porpoise occurrence, Benhemma-Le Gall et al. (2021) found porpoise detections to decrease with shipping intensity within a 5 km radius, depending on the mean distance of the ships to the POD. They also found porpoise detections outside piling activities to decrease by 17% as the mean SPL increased from 102 to 159 dB (Benhemma-Le Gall et al. 2021).

It appears that noise significantly influenced the distribution of harbor porpoise in the Fehmarnbelt. According to the multivariable habitat distribution model, a decrease in porpoise densities was found above received median sound pressure levels of 117 dB re1 μPa and up to median sound pressure levels of 130 dB re 1 μPa. At levels below 117 dB and above 130 dB, the model could not detect a clear response, as uncertainty at these noise levels was high, partly due to limited observations at these noise levels. Comparing the results of the distribution model with the selectivity index reveals further insight into the interaction among basic habitat features and anthropogenic pressures. While the multivariable distribution model indicates a negative impact of median noise levels from about 117 dB to 130 dB, the Jacob's selectivity index indicates a positive selection of harbor porpoises for areas exposed to median noise levels between 115 dB and 125 dB followed by a deselection only for noise levels of 125–130 dB. The finding that porpoises are more abundant than average in areas of elevated noise levels does, however, not contradict the finding that underwater noise affects the presence of harbor porpoises in such areas. Abundance in good quality habitat (based on prey abundance or abiotic habitat features) may be lower with increasing noise when compared to a baseline situation, but it may still be higher than average abundance or when compared to areas of differing habitat characteristics. The findings simply highlight the importance of including habitat parameters when analyzing the significance of impacts of underwater noise on marine mammals in the absence of a baseline situation; a simple comparison of abundance may not allow detecting the significance of noise impacts.

Despite the high frequency of ships passing through the Fehmarnbelt, showing subareas experiencing up to about eight ship passages per hour and rather high noise levels, the survey data show that harbor porpoises occur frequently in the shipping lanes and in areas where noise levels are highest. Concurrent with the aerial surveys, direct observations from ferryboats servicing between Rødby and Puttgarden provided frequent sightings of harbor porpoises at relatively close distance and expected high noise levels of more than 150 dB. During 1 day sailing back and forth with the ferry, up to 53 sightings were obtained (FEMM 2013) giving evidence of frequent porpoise occurrence within the most busiest and noisiest shipping lane. In a parallel study using passive acoustic monitoring (FEMM 2013), "distance to shipping lane" was a significant parameter for modelling overall porpoise presence up to a distance of about 1 km, indicating that shipping has a small-scale effect on the presence of harbor porpoises. However, when analyzing porpoise abundance from aerial survey data, "distance to shipping lane" was not significant. If avoidance responses of harbor porpoise – and in the same way of other marine mammals – entail effects of significance from a habitat use and fitness perspective, it depends not only on the range of a disturbance effect but also on the frequency of disturbance and the subsequent relocation time, i.e., the time it takes for a disturbed individual to return to its original location. We consider it as a fair assumption that the distance of avoidance and relocation time will depend on both the status of the individual and the habitat quality, thus the context of the disturbance (Ellison et al. 2011). In the case of the Fehmarnbelt, there is evidence for habitat preference of harbor porpoise

clearly overlapping areas affected by high median underwater noise levels from shipping. Observations and modelling show that areas at water depths of 15–25 m, which are preferred by harbor porpoise in the study area, over large parts coincide with the main shipping lanes in the shallow waters of the Fehmarnbelt. This makes disturbance effects less visible.

Furthermore, it has to be kept in mind that the modelled distribution of harbor porpoise was obtained from aerial surveys conducted under relatively calm weather conditions, usually at wind speeds not exceeding 3 Bft. At such low wind speed, ship noise is the dominating noise source in the underwater soundscape. Higher wind speed will not only increase ambient noise and thus decrease the signal to noise ratio, but it will also lead to a decrease in sound propagation of anthropogenic noise due to more scattering at a rougher sea surface and higher sound absorption by air bubbles in the upper water layer (Thiele and Schellstede 1980; Jones et al. 2009; Dragon et al. 2016). The distribution of harbor porpoises as derived from aerial survey data during calm weather conditions thus accentuates conditions favorable for detecting effects of anthropogenic noise.

The available data thus indicate that shipping noise affects the distribution of harbor porpoise in a busy shipping area, though animals remain abundant even within the busiest areas. This highlights an apparent trade-off between individual costs (e.g., reduced feeding time, reduced short-term well-being) and benefits (e.g., value of the habitat) of an avoidance response. In other words, anthropogenic sound might be unwanted, principally disturbing, and/or initially unpleasant, but the rewards from staying in or returning to the habitat may under some circumstances and for some individuals outweigh the costs of avoiding it (McGregor 2007).

## Conclusion

The results show noise levels within the Fehmarnbelt that are typical for busy waterways in Europe and elsewhere. The findings of the distribution modelling lead to the conclusion that porpoise distribution within the study area relates to a number of specific habitat parameter, such as those reflecting the chance to encounter prey as also shown in other investigations. However, complete habitat displacement did not occur and most likely, harbor porpoise behavior in the Fehmarnbelt represents a trade-off where the benefits to stay in the overall area outweigh the costs due to anthropogenic pressures such as shipping noise.

The present study demonstrates how shipping noise in an area of variable and intense ship traffic affects the distribution of a cetacean species in relation to their habitat choice (Simard et al. 2008; Campana et al. 2015). While modern biologging techniques more recently allow studying individual instantaneous responses of marine mammals to anthropogenic noise in more detail (e.g., van Beest et al. 2018; Wisniewska et al. 2018; Mikkelsen et al. 2019), noise and density mapping provide essential information to assessing the significance of responses on a larger scale. Both approaches are considered as important for comprehensively analyzing

possible significant population effects of increasing anthropogenic ocean noise on marine mammals.

So far, no conclusions can be drawn as to the extent of a potential reduction in porpoise numbers in the area nor about potential population level consequences; however, the data point at noise impacts that reach well beyond the core areas of the shipping lanes. Considering that substantial parts of the western Baltic Sea are exposed to shipping noise at similar levels as those in the Fehmarnbelt (Folegot et al. 2016), it is of high interest to further analyze possible impacts on numbers, distribution, and habitat use of the subpopulation of harbor porpoises in this area. Further investigations following the approach of this study are thus recommended to disentangle the complicated relationship between human pressures and cetacean distribution and habitat use. It is proposed to apply the method used in this investigation to a larger area where more diverse conditions of preferred habitats exposed to different noise levels should provide more insight into how shipping noise affects numbers and distribution of harbor porpoise, which, as being a rather abundant cetacean, are considered as a useful model species for cetaceans in general.

**Abstract**

Anthropogenic noise has been shown to impair hearing and elicit behavioral changes among marine animals. Humpback whales are known for their complex vocal displays (i.e., song) which can be masked by vessel noise. In the Gulf of Tribugá, a part of the breeding grounds for humpback whale Stock G, a marine port construction project was proposed, and, if constructed, underwater noise levels in the Gulf would significantly increase.

To better understand how humpback whales cope acoustically with increases in vessel noise, humpback whales in the Gulf of Tribugá were studied to examine changes in the high and low frequencies of their song units *during* and/or *after* boat noise compared to *before* it was present.

Out of 38 high- and low-frequency comparisons, the same song units had frequencies that were significantly different *during* boat noise 5 times and *after* boat noise 4 times (as compared to *before* boat noise). Out of 20 bandwidth comparisons, the overall bandwidth of the units narrowed 11 times, broadened 9 times, shifted higher 6 times, and shifted lower 2 times. These results give insight into how humpback whales are capable of altering their song structure when they may be responding to small boat noise.

**Keywords**

Acoustic communication · Anthropogenic noise · Vessel noise · Vocal response · Humpback whale song · Noise pollution

## Introduction

Underwater noise encompasses a variety of different sources such as biological, geological, and anthropogenic ones. At present, significant changes in the underwater acoustic environment are occurring at a fast rate due to increases in anthrophony sources and correlated changes in biophony. Since the Industrial Revolution, increases in shipping and infrastructure development have contributed a great deal to overall anthropogenic noise level increases in the ocean while contributing to reduced levels in sound-emitting animals (Duarte et al. 2021). One pervasive way that anthropogenic noise can affect marine mammals is through auditory masking. Masking refers to when noise in the environment reduces an animal's communication space which interferes with an animal's ability to detect and perceive a sound of interest (Erbe et al. 2016). Therefore, with the overall increase in anthropogenic noise in our oceans and since many marine animals rely on sound for survival, understanding anthropogenic noise impacts on them is important for management efforts. While increases in large-scale anthropogenic activity have worldwide implications, small boat activity has implications on a more local scale. This chapter aims to outline the current impacts of small boat noise on humpback whales in an area

with low levels of anthropogenic noise before a potential large-scale anthropogenic activity occurs in this breeding ground – the building of a marine port.

Acoustic communication serves as a critical role in the social behavior of marine mammals. Many of these animals have evolved to use sound as the primary modality by which to communicate in their aquatic environment. During crucial social interactions, the animal emitting acoustic signals relies on having optimal detection and perception by their targeted receiver (Dunlop 2016). Therefore, the ability to successfully send and receive acoustic signals is vital to critical life functions for marine animals (Cholewiak et al. 2018). When sending acoustic signals in the ocean, the signal experiences propagation loss underwater, and the sender must compete with that attenuation, as well as background noise, along the paths the sound waves take. One persistent contributor to background noise is from anthropogenic sources. This includes a wide variety of sources that extend over a broad range of frequencies (1–100,000 Hz) (Frisk 2012). Most notably, the number and density of large ships in the ocean have increased globally, thus contributing to an overall increase in low-frequency background noise levels in the ocean (Frisk 2012; Tournadre 2014).

As anthropogenic noise continues to increase in our oceans, studies continue to show that this noise negatively impacts marine animal communication by compromising hearing ability and eliciting physiological and behavioral changes in marine animals (Duarte et al. 2021). Some animals have been shown to change the frequencies and source levels of their vocalizations to shift away from the potential effects of masking (Rey-Baquero et al. 2021). Humpback whales are vulnerable to low-frequency shipping noise due to their characteristic vocalizations (called song) having fundamental frequencies concentrated at lower to moderate ranges between 0.03 and 8 kHz (Perazio and Mercado 2018). Their songs are sung by males predominantly in winter breeding grounds, but are also heard along spring/summer feeding grounds and migration routes (Mattila et al. 1987; Clapham and Mattila 1990; McSweeney et al. 1989; Vu et al. 2012). The function of these songs, while debated, is commonly hypothesized to be related to mating behavior – attracting females or mediating male-male interactions (Herman 2017). The Gulf of Tribugá, located in the northern Colombian Pacific in the Chocó Department, is a part of the breeding grounds for humpback whales of Stock G from May through December (Avila et al. 2020).

Chocó, Colombia, consists of roughly a dozen afro-indigenous fishing villages, each consisting of about 50–8000 people along 200 km of coastline. The main form of transit between villages is by boat due to few existing paved roads. When traveling between villages, performing SCUBA, fishing, and/or providing whale watching tours, families use dug-out canoes or small fiberglass boats with outboard motors. Additionally, larger supply vessels (~20 m in length) bring fuel and cargo roughly every week and harvest shrimp during the spring and summer months. Because of this, the Gulf currently possesses a relatively pristine soundscape compared to other gulfs across the globe because it contains a small variety and low density of motorized vessels. However, a large infrastructure concern to local conservation groups in 2020 was the major marine port construction project that

was proposed in the Gulf. Although permits for the port have been denied, it has been an ongoing but fluctuating effort by the Colombian government since the 1990s to build the port. If ever approved in the future, underwater noise would significantly increase due to both construction and operational shipping lanes, and the acoustic environment would permanently be altered.

When both vessel traffic noise and humpback whale song are primary contributors to the soundscape, like in the Colombian Pacific during breeding season, overlap in time and frequency exists between the two sound sources (Rey-Baquero et al. 2021). This overlap likely leads to masking of the whale song which could potentially lead to behavioral changes. Additionally, humpback whales in this breeding area are historically exposed to lower background noise levels and wider communication spaces compared to other studied breeding grounds (Duennebier et al. 2012; Bejder et al. 2019). Thus, new and increased vessel noise, which would come with the establishment of shipping lanes from a marine port, could have a more sudden impact on them compared to the whales in other areas that are more habituated to vessel noise. This is why it is especially important to monitor humpback whales' potential acoustic behavioral changes in the Gulf of Tribugá's current soundscape which has relatively low levels of noise by today's standards.

A before-after control-impact (BACI) study design was implemented to measure the acoustic behavior of humpback whales to better understand how they may cope with a transient increase in vessel noise that they could adapt to spontaneously. The typical BACI framework involves the measurement of an ecological variable of interest at a site that is expected to be affected by an anthropogenic, management, or other assumedly disturbing activity before and after the presence of the activity (Kerr et al. 2019). The BACI framework was implemented to identify potential changes in song units in response to noise disturbance from small boats.

However, noise from boats does not usually have sudden onset and offset. Rather, a passing boat will be heard at low levels from a distance, increase to highest levels at the closest point of approach to the receiver, and then have decreasing noise levels as it fades away into the distance. Therefore, an amount of time exists when the song of a whale could overlap in time and space with the fluctuating noise levels of the passing boat. Instead of assigning before and after times of the BACI as delineated by the closest point of approach, the BACI framework was adjusted to include samples of humpback whale song units sung during the active presence of boat noise. This framework has been named a BA(D)CI study where D stands for "during." The before time range ends the moment a boat engine was detectable in a spectrogram, at which time the time range became the during range. Once the boat engine either turned off or disappeared from detectability in the spectrogram, the during time range changed to the after time range. This adjustment was implemented to observe the possibility that rapid responses in humpback whale song could occur upon the immediate presence of boat noise (*during*) as opposed to slower responses that may be observed in the units sung at various time lags after boat noise has subsided (*after*). This may give important information regarding how quickly a whale is able to make crucial song adjustments if trying to avoid masking in real time.

## Metrics

Frequency measurements of the song units sung *before* boat noise that were detected on the passive acoustic monitoring device were classified as the "Control" part of the BA(D)CI framework, while frequency measurements of the song units sung *after* and *during* boat noise were both classified as the "Impact." In addition, to consider any natural variability in the whale's song units between different whales, songs that were recorded without coincident recording of boat noise present were analyzed to serve as an additional Control variable. These non-boat Control (NBC) song units were recorded from different hours and days as the songs that were interrupted by boat noise, so it should be noted that comparing the *NBC* song units to *after*-boat Impacted units would most likely be comparing two different whales and are not an appropriate comparison for determining a response to boat noise. Comparing the *NBC* song units to the *before*-boat Control song units, though, can provide insight into how much variability exists between individuals. Then the amount of variability in an individual without boat noise present can be compared to the amount of variability in an individual singer while reacting to boat noise.

## Hydrophone Deployment

Acoustic data were collected at Morro Mico from October 22 to November 28, 2018, at the coordinates 5°52.101′N, 77°19.007′W using an ecological acoustic recorder (EAR) on loan from Oceanwide Science Institute. Morro Mico is a small rock island located just north of all the coastal villages in the Gulf of Tribugá and is just south of a national marine sanctuary (Utría National Natural Park), so it experiences less boat traffic than areas between villages where people are transiting more often. The EAR was deployed at 25 m depth at high tide by SCUBA divers attaching it to an anchor. It recorded at a 15.625 kHz sampling rate for a duty cycle of 33.3% (recording occurred for 10 min every half an hour). Data was provided by the PHySIColombia Project database (Fig. 1).

## Before, During, and After Comparisons

Acoustic data from the EAR was downloaded and converted to .wav files using custom MATLAB code (L. Munger). For a more comprehensive look into the data analysis, please refer to the sister study (Rey-Baquero et al. 2021).

Data were analyzed in a total of 29 10 min audio files using Raven Lite to annotate humpback whale song units on a spectrogram. This was to measure the high and low frequencies, and thus shifts in bandwidth, for each song unit type. Since frequency is a parameter that can be affected by propagation, faint songs (roughly $<6$ dB above background noise levels) were not analyzed to reduce the possibility that a shift in high-frequency elements of the song was affected by attenuation and not the animal's behavioral change. Each audio file analyzed was considered one part of a song from one individual whale.

**Fig. 1** A map of the field site (Map was created in R using "ggmap" package (Kahle & Wickman 2013)) and location of the hydrophone deployment. The hydrophone was deployed at Morro Mico into the Gulf of Tribugá in the Chocó region of Colombia in October to November, 2018

Of the 29 audio files analyzed, 20 had boat and whale presence, and 9 had only whale presence. For each audio file, song units were characterized based on their contours and then classified into one of the ten different unit types (see Table 1 for a list of all unit types) regardless of the min, peak, or max frequencies or length. Specifically, for audio files containing both boat and whale presence, the contours of the song units were required to remain the same *before* vs. *during* or *before* vs. *after* boat noise (Fig. 2) to be considered comparable. Due to the timing of when boat noise was interrupting the song in the 20 audio files with boats, 20 *before* vs. *during* comparisons and 18 *before* vs. *after* comparisons were collected. That is to say, if boat noise was at the beginning or end of an audio file, no *before* or *after* time range, respectively, was available. In the 9 audio files containing only whales, 20 *before* vs. *NBC* comparisons were characterized (Table 1).

The null hypothesis stated that no significant structural changes in the song units occurred *during* nor *after* exposure to boat noise compared to song units *before* exposure. The first alternative hypothesis stated that the high, low, or both the high and low frequencies in song units were sung significantly differently *during* boat noise compared to *before* it was present. The second alternative hypothesis stated that the high, the low, or both frequencies in song units were sung significantly differently *after* boat noise compared to *before* it was present.

## Frequency and Bandwidth Analysis

The high and low frequencies, duration, and annotated labels for each song unit were extracted from Raven Lite and opened with Excel for statistical analysis. In Excel,

**Table 1** The results of the Kruskal-Wallis significance tests displaying the low frequency (LF) and high frequency (HF), sample size, and p-value for each unit type. Each of the three temporal classes (*during*, *after*, and non-boat Control (NBC)) was compared to the units *before* the boat noise. The shaded boxes represent *p*-values that are significant ($p < 0.05$). NA represents samples that were not present so could not be compared

the Kruskal-Wallis test was used to calculate the significance level ($p$-value $<0.05$) for each of the comparisons between unit types (Fig. 1). Shifts in the bandwidths of each unit were analyzed by:

1) Overall bandwidth: comparing the difference in the high and low frequencies between *before* vs. *during* and *before* vs. *after* for each song unit type.

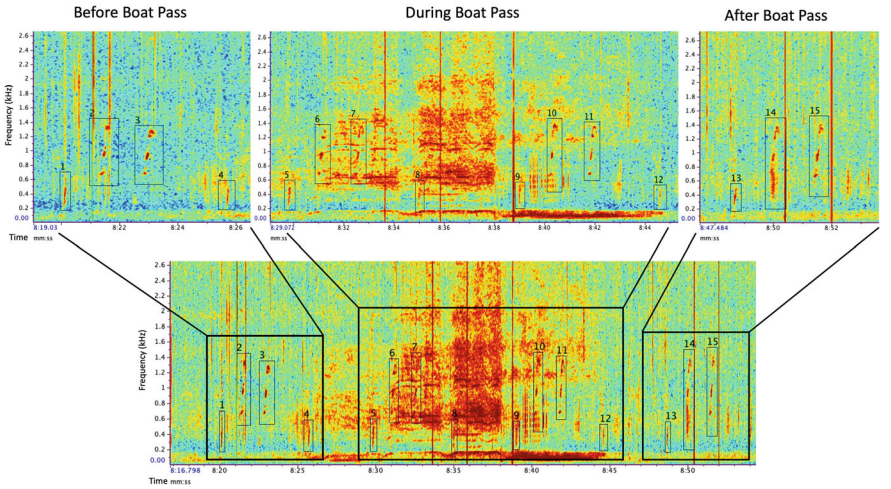

**Fig. 2** An example of the same song units *before*, *during*, and *after* a boat pass from one individual singer. Each box and subsequent number represent an individual song unit. Units with the same contours were classified into a unit type based on their contours (e.g., unit type B1 and unit type D1)

2) Narrowing/broadening of bandwidth: comparing the median frequencies of all samples (both high and low collectively) for during and after boat noise and then comparing these to the *before* samples.

## Noise Effects on Humpback Whale Song

### Effects of Noise on High and Low Frequencies of Humpback Whale Song

Out of the 19 audio files containing both boat activity and whales, there were 18 comparisons of *before* vs. *after* boat noise and 20 comparisons of *before* vs. *during* boat noise. Out of these comparisons, the high and low frequencies of song units were significantly different *before* boat noise compared to after it was present 4 of the 18 times. For the *during* comparisons, the high and low frequencies of song units were significantly different *during* boat noise compared to *before* it was present 5 of the 20 times. When song units from *before* boat noise were compared to the same unit type from audio files without any boats present (a.k.a. comparisons between different whales), they were significantly different 11 times of 20.

### Effects of Noise on Overall Bandwidth of Humpback Whale Song

Bandwidth results were acquired for each of the ten-unit types due to the shifts in the high and low frequencies of song units. For bandwidth, there were ten *before*

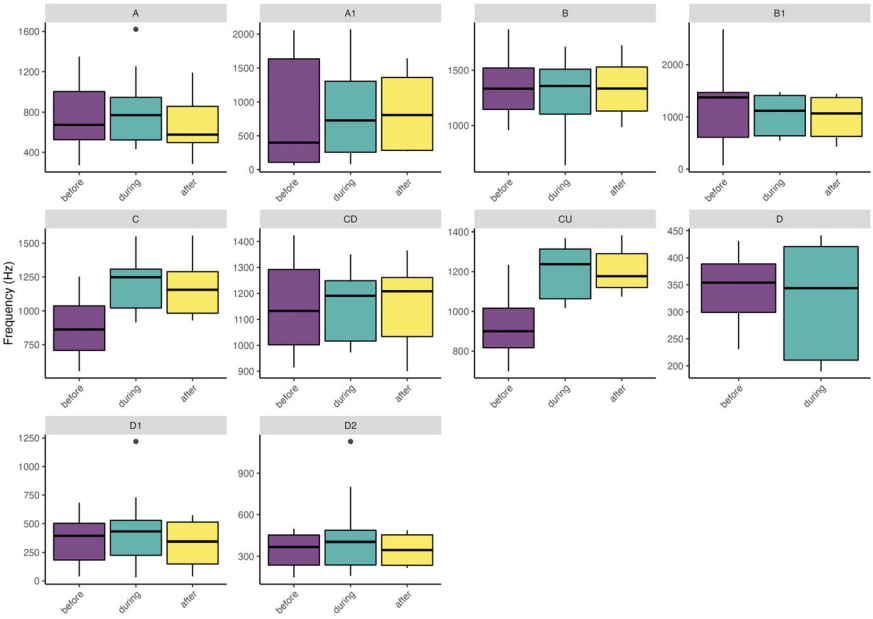

**Fig. 3** Box and whisker plots (displaying the median, minimum, and maximum values, the first and third quartiles, and the extreme singular outliers) of the frequency changes of song units in the presence of boat noise. *Before* represents units that have yet to be exposed to boat noise in the audio file; *during* and *after* represent units in the presence of or following boat noise in the audio file. Units were identified from individual singers and compiled based on unit type for analysis

vs. *during* comparisons, nine *before* vs. *after*, and nine *before* vs. *NBC* comparisons. Among the *during* comparisons, the bandwidth narrowed five times, broadened five times, shifted higher seven times, and shifted lower three times. Among the *after* comparisons, the bandwidth narrowed five times, broadened four times, shifted higher four times, and shifted lower five times. Among the *NBC* comparisons, from the files with boats, the bandwidths were narrower four times, broader five times, higher seven times, and lower two times (Fig. 3).

## Assessing Song Unit Adjustments

In the Gulf of Tribugá, whale watching is an important seasonal livelihood for local fishermen who rely on the high tourism demand during the winter breeding season. Although humpback whales are exposed to less vessel noise in this area than others studied in the Pacific, humpback whales are still annually exposed to whale watching vessel noise where their acoustic field is masked when in close proximity with these vessels (Rey-Baquero et al. 2021). Considering this, adjusting song unit structure, as seen in other marine mammals, could help to avoid the most prevalent effects of masking.

## Variations in Song Units

Some humpback whales showed changes in the spectral structure of their song units when assumed to be in audible proximity to boat noise. The high and low frequencies from the song units *before* boat noise from one singer were significantly different than the high and low frequencies of song units from another singer when no boat noise was detected (*NBC*) in an audio file 11 of 20 times. For example, the high and low frequencies from song unit type A in sound file 00000727 were compared to the high and low frequencies from the same song unit type (unit type A) in sound file 00001207. These comparisons are assumed to be comparisons between two different whales singing the same unit type (further explanation provided in methods) due to the mobility behavior of whales. Additionally, song unit frequencies in the same song from the same individual (the song analyzed in 1 audio file) significantly changed 9 times between *during* and *after* comparisons in the 20 files with boats analyzed. Of these nine significant changes, four were *during* and five were *after* boat noise presence. Therefore, significant frequency differences between whales existed more times than significant frequency changes in the same whale's song.

Although it is common to see conformity to a single song type within a population, it is also typical to observe variations in the same song sung between different individuals as seen in the results of Garland et al. (2013) and Payne and McVay (1971). Therefore, the 11 of 20 (about half of the time) significant differences observed between the *NBC* units and the *before* units are likely representative of individual variation between different whales and not of any response to boat noise. Comparatively, the changes in the same unit type from the same singer (potentially in response to boat noise) were also significantly different about half of the time. This demonstrates that humpback whales exhibit variability in their songs between one another and that they are capable of individual elasticity, changing the frequencies of their song units if needed.

Since the changes in the *during* and *after* cases as compared to *before* cases were temporally around the presence of boat noise, it is reasonable to assume that the significant variations observed were correlated to the boat noise. A study by Thomas F. Norris (1995) found that humpback whales changed their unit and phrase structure in response to boat noise. He found that phrases were shorter in the presence of boat noise and that frequencies of some units were altered with the occurrence of large vessel noise (Norris 1995). Similarly, fin whales have been shown to alter the frequencies of their songs in response to vessel noise. Fin whales lowered the bandwidth, peak frequency, and center frequency of their sounds in response to increased background noise from large vessels (Castellote et al. 2012). Like the frequency shifts observed in the two studies just mentioned, the humpback whales currently being studied may have intentionally shifted the frequencies of their song units when exposed to boat noise. Further, these changes could in fact be a causal result of the humpback whales using their flexible voices in an attempt to shift away from the effects of masking.

## Changes in Bandwidth

Humpback whales were observed changing the frequencies, and thus the bandwidth of their vocalizations, both *during* and *after* the presence of boat noise as compared to *before* it. One such bandwidth shift was to higher bandwidths which could help to avoid the loudest part of the boat because boat noise is concentrated at lower frequencies. A second shift was to lower bands which may help those units propagate further (especially if they are below the main boat noise frequencies) as lower frequencies propagate further underwater than higher frequencies. A third shift was narrowing the bandwidth which may help to focus more acoustic energy into one section of the spectrum and increase the source level of the peak frequency of a unit. Finally, broadening the bandwidth allows songs to contain a wider frequency range. With this wider range, hopefully more of the song's frequencies will transmit sufficiently enough, or be masked less, than more narrow-banded songs so that any vital information contained within can reach its intended target. As these interpretations illustrate, it is possible that any bandwidth shift could yield a benefit to the singing whale. Since humpback whales have also been previously observed increasing the source levels of their vocalizations in response to background noise levels (Dunlop et al. 2015; Fournet et al. 2018), they may employ multiple strategies to reduce masking effects, with frequency changes being one of them.

## Variations in Song Units with Exposure to Varying Noise Levels

A study by Tsujii et al. (2018) found that humpback whales off the coast of Japan altered part of their singing behavior due to large shipping vessel noise. The whales studied reduced their sound production or stopped singing temporarily in response to the noise (Tsujii et al. 2018). In contrast, the humpback whales currently being studied showed that they often continue to sing throughout small boat noise. One potential explanation for this difference could be that Tsujii et al.'s study site had large cargo ships and most likely higher noise levels compared to the Gulf of Tribugá which is currently void of shipping lanes. This may indicate that humpback whales lack the necessary adaptations to cope with louder vessel noise that comes with increases in shipping lanes and rather than attempt to adjust their song units, they rely on temporal masking release or saving their energy to strategically sing only when the surrounding noise seems low enough to be worth the communication effort. If there is a gradation of responses for adapting to increasing levels of vessel noise from sometimes adjusting frequency to reducing singing until only the most opportune times, this would be especially concerning in areas that are more heavily trafficked. Whale song being increasingly masked by escalating anthropogenic noise levels could correlate with more extreme, different, or more various acoustic behavioral changes.

## Conclusions

A variation of the BACI study design was implemented in order to quantify humpback whale acoustic behavioral reactivity to small boat noise in a gulf currently void of noise from shipping lanes. Significant changes in song unit structure were found between different individuals and in a single individual's song in the presence of boat noise from small vessels.

A study conducted by Maria Paula Rey-Baquero and Laura Valentina Huertas-Amaya analyzed how whale watching boat noise effects humpback whale song in the Gulf of Tribugá (Rey-Baquero et al. 2021). Their study found temporal aspects of singing activity were significantly different when boat noise was present compared to when it was absent. There were fewer numbers of longer units sung in the presence of boats and longer inter-unit intervals (the time between units) which they hypothesized could be a strategy to escape the masking (Rey-Baquero et al. 2021). The combination of these two studies contributes to our understanding of how humpback whales may attempt to cope with anthropogenic noise sources in a relatively low-disturbance region. This is especially important to document the current behavioral reactivity of humpback whales to present noise conditions and aim to describe these behaviors prior to the potential increase in noise levels caused if the port is ultimately constructed in the Gulf of Tribugá. Further, both studies contribute to a larger effort to record the baseline soundscape in a place with relatively less coastal infrastructure than many parts of the world. In this form, the Gulf of Tribugá can serve as a reference point for what louder marine soundscapes may have sounded like before their primary disturbance was developed.

**Abstract**

The Gulf of Tribugá is a relatively pristine acoustic environment in the Colombian north Pacific. Since the 1990s, many administrations have tried to build a deepwater port in Tribugá. While the construction permits were most recently denied in September 2020, they could be applied for again in the future. If built, the Gulf's terrestrial and marine environments would change forever. One strategy to promote the conservation of these marine and coastal habitats is to visually illustrate how much ocean space that ship noise could occupy if a seaport were built. Thus, noise footprints of possible configurations of shipping lanes were simulated. Acoustic propagation models were made for a "control" shipping lane configuration and two predictive lane configurations to compare the spatial coverage of their noise footprints that had levels above the threshold of humpback whale audibility. Differences in the spatial extent of these configurations were found, with the deepwater trench and the random configurations more similar to each other than the control configuration, and both non-control ones had noise occupying more space than the control configuration.

## Introduction

The humpback whale (*Megaptera novaeangliae*) is a cosmopolitan species, migrating long distances between feeding grounds at high latitudes and breeding grounds in tropical waters. Humpback whales are grouped into 14 distinct population segments (DSPs) worldwide (Fisheries 2020, 2022). The Southeast Pacific DPS is also called "breeding Stock G" and is the focus of this research. Stock G breeds along the southwestern Pacific (Peru, Ecuador, Colombia, Panama, Costa Rica) during the austral winter (June–October) and feeds in southern Chile and the Antarctic Peninsula during the austral summer (December–April) (Acevedo et al. 2017; Avila et al. 2021).

Both sexes of this species and all age classes are documented to communicate with acoustic signals or "social calls" (Mattila et al. 1987; McSweeney et al. 1989; Norris et al. 1999; Dunlop et al. 2008; Stimpert et al. 2012; Seger et al. 2015; Rey-Baquero et al. 2021; Gascón 2021) to facilitate life functions such as foraging, courtship, communication, reproduction, and calf protection (Richardson et al. 1995; Merchant

et al. 2015; Haver et al. 2019). In addition to social calls, humpback whales have two other types of vocalizations, including songs and repetitive tones (Payne and McVay 1971; Norris et al. 1999; Rey-Baquero et al. 2021; Gascón 2021). Song refers to a series of "units," which are structured vocalizations, that create increasingly complex combinations known as "phrases," "themes," "songs," and "singing sessions." These songs are only produced by males, mostly during the breeding season (Payne and McVay 1971; Clapham 1996; Clapham 2000; Darling and Berube 2001; Mercado et al. 2005; Au et al. 2006; Stimpert et al. 2012). Repetitive tones have only yet been documented off the coast of Colombia (Gascón 2021).

All of these vocalizations propagate through the ocean to reach conspecifics and facilitate communication. But they compete with other sounds, particularly noise from vessels, in the environment to propagate effectively. For the remainder of this chapter, the biological sounds of interest are vocalizations by humpback whales, meaning they are the "signals" referred to in this work. Furthermore, any sound source that is not a biological signal will be referred to as "noise." particularly the sounds produced by vessels.

Noise from vessels and animal vocalizations are subject to the same physical limitations in how they propagate underwater. Oceanographic variables like bathymetry, sediment type, water temperature, and salinity have an influence on the propagation, dispersion, attenuation, and absorption of sound in the water column (McKenna et al. 2012). Additionally, the source characteristics of a sound also affects how it will travel. For vessels, traffic density, propeller type, length, and speed all affect their source characteristics. Even though noise is a by-product of vessels traveling at sea, it can impact the acoustic environment around it and affect the communication strategies of marine mammals that inhabit it. Too much noise could disrupt the signal transmission of humpback whales and thereby affect a population's viability (Cholewiak et al. 2018; Rey-Baquero et al. 2021). When noisy zones intersect with critical habitat areas (i.e. areas occupied by species with physical and biological characteristics essential to the ecosystem or at risk and requiring conservation or protection (Fisheries 2022), the effects of the noise on the vital functions of the animals must be a focus of analysis to promote conservation goals.

In 2002, the U.S. National Marine Fisheries Service (NMFS) Ocean Acoustics Program compiled data and developed methods to assess and quantify noise exposure levels for different anthropogenic sources, including Temporary Threshold Shift (TTS) and Permanent Threshold Shift (PTS) and incorporating the auditory exposure criteria described in Southall et al. (2008). Threshold shifts that recover within hours, days, or weeks after exposure are called a TTS. A TTS occurs when the cells of the inner ear become fatigued, making it difficult to detect and interpret sounds. The probability of a temporary threshold shift occurring increases proportionally with sound level and duration of exposure (Weilgart 2007). A permanent threshold shift (PTS) occurs when hearing does not completely normalize after noise exposure and the ability to hear has been permanently altered or lost (Ryan et al. 2016; Putland et al. 2018). In general, fish and marine mammals tend to be affected by permanent threshold shifts when exposed to particularly high levels of anthropogenic noise (Putland et al. 2018).

A third category of exposure criteria pertains to behavioral changes, which are assumed to be more common than PTS and TTS (Southall et al. 2015). The sound level that is expected to elicit a behavioral change in marine mammals is 160 dBrms (Ainslie 2010; Heaney and Seger 2020). If noises above 160 dB elicit a behavioral change often enough to interrupt vital functions, it can lead to deleterious effects such as reduced foraging, difficulty maintaining cohesion, difficulty navigation, and increased stress (Ainslie 2010; Rolland et al. 2012; Heaney and Seger 2020).

A sound that reaches a minimum sensitivity or is loud enough for an average individual of a certain species to hear it is an audible sound (Erbe 2002). Audibility is a fourth category in how animals receive sound pressure and the main category of focus for this study. For humpback whales, no studies have been conducted that measure audibility levels directly because such research is commonly conducted with smaller species and in confined spaces. There are studies, however, that extrapolated audiograms from other species to estimate a humpback whale audiogram (Houser et al. 2001; Erbe et al. 2014). These audiograms provide a description of hearing capabilities of humpback whales at various frequencies. It is reasonable to assume that if an animal can hear a sound, it is likely to generate a reaction if that sound is deemed threatening. Because ship noise is neither impulsive nor as loud as some noises (e.g. pile driving), its audibility level and what spatial scales different shipping lanes create above this level is a focus of this research.

A fifth and final category discussed here is a combination of audibility and the received level of a noise source, called the masking threshold. Masking is when the sound pressure level of a sound necessary to be audible is drowned out by a different and unwanted sound source, a.k.a. "noise." If a noise is easily detected by an animal, it is possible that it has the capacity to superimpose itself on the animal's signal and interrupt it to such an extent that it is more difficult to detect and interpret by a conspecific. When experiencing masking, it is likely that an animal may suspend emitting its signals to avoid being interrupted, could change key signal characteristics, or could attempt to increase its vocal effort to improve its audibility (Lombard effect) so it can be heard by the intended receiver (Knowlton 2017). These and other masking release strategies could carry an energetic cost to the species (Noren et al. 2012). While many vessels do not reach source levels high enough to exceed the TTS and PTS thresholds, and few even exceed the behavioral change threshold, they can reach marine species' audibility thresholds. Therefore, this study focuses on received levels from shipping traffic above published audibility thresholds for humpback whales (Houser et al. 2001; Erbe 2002) and assumes that any audible sound may have the potential to do some masking on humpback whale signals and/or elicit a behavioral response from some individuals.

Globally, several studies have used acoustical models to better understand the effects and/or impacts caused by increased noise produced by different types of vessels (McDonald et al. 2006; Hildebrand 2009; Aulanier et al. 2017). One such study was conducted in the Canadian Arctic, where shipping as a dominant noise source (SNL = Shipping Noise Level) of high traffic density (>110 dB re 1μPa$^2$) was observed to cause a transformation of soundscapes, masking marine mammal signals and triggering behavioral responses (Aulanier et al. 2017). Similarly, in the

Celtic Sea, ship and seal tracks were coupled with an acoustic modeling system to assess noise exposure level. It was found that the animals which experienced steep changes in sound levels up to ~20 dB at a frequency of 125 Hz and ~10 dB on average over 10–1000 Hz would dive through the thermocline, particularly during the summer months (Chen et al. 2017). An additional study, conducted in the Dutch North Sea, used sound maps averaged over time and frequency to reveal that most of the human noise in the soundscape came from ships, followed by seismic sources and, lastly, by seismic explosions (Sertlek et al. 2019). Most of the anthropogenic sound energy from all three sources was concentrated between 100 Hz and 1 kHz, which are frequencies important to many marine mammal species. Therefore, this research is also using models to determine how much space is occupied by ship-specific noise frequencies that overlap with peak frequencies in humpback whale song. The models are based on current types of large ships transiting through the waters off western Colombia to understand where in this space the noise levels are or could be high enough to be heard by a humpback whale from Stock G.

For comparison to the current noise footprints off the Colombian coast, this research has also made predictive scenarios of likely shipping lanes to understand how much more space the shipping noise could occupy should human infrastructure increase in the location of the Gulf of Tribugá where conservation goals have recently collided with large-scale construction goals.

The Gulf of Tribugá is located in the northern region of the Pacific coast of Colombia, specifically on the western side of the department of Chocó. Its southern limit is Cabo Corrientes at 5°53′N, 77°28′W, while its northern end is at 6°11′N, 77°09′W. Its approximate area is 103,110 ha (Díaz et al. 2016). This Gulf contains a series of geographic features such as the coves of Arusí, Coquí, Tribugá, and Utría – all of which are framed by the Serranía del Baudó, which is a mountain range parallel to the westernmost mountain range of the Andes and the coastline (Díaz et al. 2016). The eastern foothills of the Serranía del Baudó correspond to a tertiary formation of unconsolidated marine sediments that are located at great depths and have thicknesses of ~4000 m (Díaz et al. 2016). Average annual sea surface temperatures (SSTs) in the Gulf of Tribugá can range spatially from 24.5 °C to 28 °C, and the largest variance for any given month is in March, from 24.79 °C to 28.68 °C. This temperature range is ideal for supporting coral reef patches, especially in the Utría Cove. Salinity in the Gulf is rather consistently 33.2 ppm (INVEMAR 2007; Díaz et al. 2016) throughout the year. An important fact to consider in this study is that salinity and temperature are both quite uniform over depth, leading to a high likelihood of many areas having isovelocity sound speed profiles, at least near the surface.

Most of the human population along the coast of the Gulf of Tribugá are Afro-Colombian and Indigenous people living in several villages. The total number of municipalities that surround the Gulf of Tribugá have a population of 127,633 inhabitants (ANLA 2020). The municipality of Nuquí has few roads as a method of access. Its main accessibility is by a small airport connected with Medellín, Bogotá, and Quibdó. Another option to reach Nuquí is through maritime transportation, by taking an overnight trip on small fuel or goods shipment boats that

connect with Buenaventura, or by paying for a taxi-style boat from Bahía Solano. Due to the lack of roads, it is not possible to drive between the villages, which is why navigation by residents is primarily done by river and sea. This lack of connection is why Nuquí tends to have problems with high costs of food products and sometimes shortages in many types of supplies and medical care. Therefore, the Gulf has developed and relies heavily on an economic infrastructure revolving around ecotourism, artisanal fishing, small-scale cattle ranching, and agriculture (Díaz et al. 2016).

The study area has a wide diversity of flora and fauna. Specifically, in terms of marine fauna, the Pacific shelf has a great variety of species such as sharks, fish, coral formations, and baleen and toothed whales (Díaz et al. 2016). It is one of the most important fishing reserves in the eastern tropical Pacific for local Colombian economies (Díaz et al. 2016). The Gulf of Tribugá is an essential ecosystem for humpback whales since it is one of Stock G's primary breeding grounds. Currently, it preserves great biodiversity of both marine and terrestrial species as it is a place less affected by human infrastructure on land and in the sea compared to more commercial coastlines in other countries. Thus, underwater noise pollution in Tribugá, as compared to other baleen breeding grounds in North and South America (Rey-Baquero et al. 2021), is thought to be relatively lower. As a result, many conservation groups consider it essential to protect this ecosystem from further human encroachment (DMRI 2020), and efforts like naming it a Hope Spot in 2020 are trying to foster its protection.

Recent research supports the assumption that boat noise in the Gulf of Tribugá, despite it being at lower levels than many places around the globe, still evokes behavioral responses from humpback whales. For example, Rey-Baquero et al. (2021) reported temporal differences in song units produced by humpback whales in the Gulf of Tribugá before as compared to after boat noise occurred. Additionally, a study that used the Gulf of Tribugá's passive acoustic monitoring dataset at the Morro Mico site found that humpback whales changed high and low frequencies of their songs about half the time after a boat pass occurred (Brown et al. 2021). Ethogram studies have also documented behavioral changes, like in Bahía Málaga where 44% of the humpback whales sighted in the area were approached by ships and subsequently modified their behavior, displaying faster travel speed and decreasing resting time (Avila et al. 2015). Such foundational research highlights the variety of reactions of different individuals in Stock G responding to vessel presence, acoustic or otherwise. Much of the acoustic energy from ships is concentrated at low frequencies, which increases the likelihood of masking acoustic signals from marine species that communicate in the same low-frequency range, such as humpback whales. Considering that songs are characterized by source levels reaching 151 dB re 1μPa$^2$ in Tribugá Rey-Baquero et al. 2021), and ships transiting between ports can have source levels higher than this (MacGillivray and Jong 2021), masking of large-scale merchant traffic could have negative implica-

tions on the communication of marine species in the aquatic ecosystem along shipping routes and for many kilometers around them (McKenna et al. 2012).

The construction of a multipurpose seaport in the area has been on the Colombian government's agenda since the 1950s. Construction and operation of this port would introduce all levels (PTS, TTS, behavioral, and masking) of noise exposure to the Gulf of Tribugá (Barrios and Plazas 2015). If built, the port would be similar in size to the port of Buenaventura, but smaller than the port of Long Beach, CA, USA. It would be intended to transport goods to other national and international ports (Colombia port of Buenaventura 2019; Port of Los Angeles 2020). Such characteristics typical of other similar-sized ports, as well as plans of the Tribugá port released by Arquímedes, were considered for the predictive modeling of this research.

Understanding the impact of the Tribugá Port, if it were constructed, is the major reason for doing this study. While the Gulf itself would see a lot of additional noise from ships coming in and out of the port, the larger ocean area along the Pacific coast of Colombia, Ecuador, and Panama would also be affected by the new shipping lanes. Therefore, the study area for this project not only considers the Pacific Coast of Colombia, but a larger portion of the Southeastern Pacific along much of the northwest corner of South America that overlaps with a larger portion of Stock G's migration and breeding grounds.

## Research Objectives

The current work (1) used acoustic propagation modeling to calculate how much area off the West Coast of Colombia is currently ensonified by large vessel traffic for a single "control" scenario, (2) simulated two possible shipping lane configurations and used acoustic propagation modeling to estimate the area that noise from each configuration could ensonify off the West coast of Colombia, (3) compared the increase in noise area between the current scenario and the future simulations, and (4) calculated how much area that boat noise could be audible to humpback whales in each configuration. Typical databases for the oceanic variables were used in the acoustic propagation modeling. General characteristics of the vessels that transit from the port of Buenaventura were used to predict the types of ships that could be transiting from the Port of Tribugá, if it were to be built. The JOMOPANS-ECHO model (MacGillivray and Jong 2021) was used to calculate the source levels of the ships given these general characteristics. The best possible current audiograms for humpback whales (Houser et al. 2001; Erbe 2002) were used to set audibility thresholds. Combining these factors allowed for the calculation of the area of the ocean over humpback whale audibility levels so that if there exists a more optimal navigation route, i.e. the one that would affect the communication space of humpback whales the least, it could be determined.

## Construction of Control Map and Predictive Configurations

The construction of the shipping lane configurations was based on a number of assumptions. First, there is currently only one shipping route, as shown on MarineTraffic.com (Fig. 1), several hundred kilometers off the coast of Colombia. With a new port based in Tribugá, it is assumed that this route would become more densely transited and that more routes would need to be created. Where those new routes are placed could have various effects on the underwater soundscape since sound waves propagate so differently depending upon the temperature, salinity, and depth of the water column they are traveling over. Therefore, the larger oceanic area of the NW coast of South America was considered in this acoustic propagation project, including the Gulf of Tribugá out to and beyond the current shipping route, up to the Panama Canal, and down to the Port of Buenaventura. Since sound travels hundreds of miles in the ocean, the study area is larger than just the coastal waters of Colombia. Instead, boundaries were selected to include as much sound as possible from ships traveling from the Panama Canal to the Port of Buenaventura.

The four corners of the study area are, beginning at the northwest corner and going clockwise, NW (7.879604°, −83.054129°), NE (8.986911°, −77.639609°), SW (0.982849°, −81.979942°), and SE (1.935371°, −76.528972°) (Fig. 2). The present work considered three configurations: the "control map" (the current ships from MarineTraffic.com on May 15, 2021), additional ships organized into a "random map," and additional ships organized to travel over the "deepwater trenches."

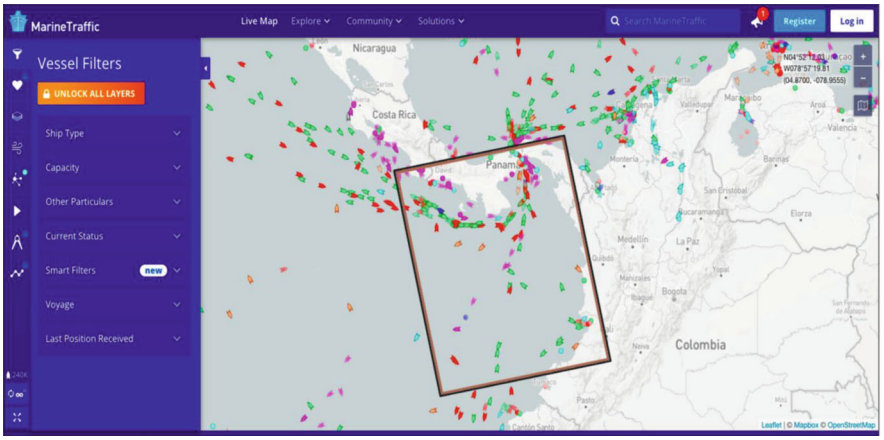

**Fig. 1** Automatic Identification System (AIS), geographic coordinates, information and/or variables for each vessel for May 15, 2021. (Source: MarineTraffic – Global Ship Tracking Intelligence (www.marinetraffic.com))

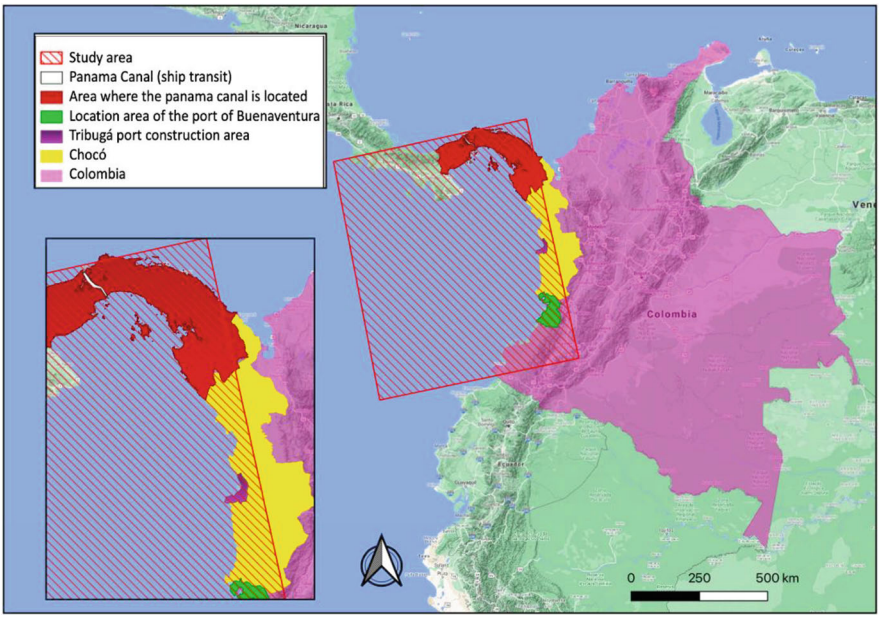

**Fig. 2** The study area is centered in the Colombian North Pacific, reaching from the Southern border of Colombia to the Panama Canal. The current main shipping lane cuts largely through the middle of this area

## Control Map

The following information was collected from MarineTraffic.com from ships within the study area on May 15, 2021: name/number, type, length, draft, location, and speed. Not all of this information was readily available, so if the vessel had only a name listed, further information about it was searched online. Several vessels were only assigned numbers, types, and locations. For these cases, data were interpolated from known vessel parameters. Distributions of lengths, drafts, and speeds of each ship type were generated. Then, the standard deviations of these distributions were used as limits in a random number generator (Thijssen 2013) to fill in the needed parameters for each vessel lacking such information. In this way, all variables needed for the JOMOPANS-ECHO model (MacGillivray and Jong 2021) could later be calculated from a range of realistic values.

## Construction of Predictive Maps

For the random and deepwater maps, new shipping lanes were drawn and ships were placed along these routes. The new hypothetical shipping lanes were assumed to have destinations that would serve the largest and closest international ports of surrounding countries and continents. These five destinations

included: the Panama Canal, the Port of Long Beach (California, United States), Chinese ports like Shanghai or Shenzhen, the Port of Buenaventura (Colombia), and the Port of Buenos Aires (Argentina).

To estimate the number of ships that could be leaving and entering the hypothetical Port of Tribugá, the LCA (Logistics Capacity Assessment) tool was used to obtain the count of ships entering the port of Buenaventura in 2019 (the last year in which the count was estimated), giving a total of 1458 entrances. This total, when divided by the 365 days of the year, gives a maximum total of 4 ships per day entering the port of Buenaventura (Colombia port of Buenaventura 2019). In comparison, the Port of Long Beach in 2019 had a total of 1867 vessel arrivals, so 5.11 boats per day (Port of Los Angeles 2020).

The Port of Tribugá is estimated to handle roughly an average amount of ship arrivals ranging between those at the ports of Buenaventura and Long Beach. Therefore, it was assumed that over 5 days, approximately 5 boats per day would enter and 5 would exit Tribugá. The total number of ship entrances and exits over each 5-day span was actually set at 47 ("almost" 5 per day) with the following weightings: 10 ships would be in transit to/from China, Long Beach, and South America (30 ships in total); 9 ships would be in transit to/from the Panama Canal (since there is a limit to how many ships can pass through the Panama Canal), and 8 ships would be in transit to/from Buenaventura (based on the Colombia port of Buenaventura 2019).

Because sound waves travel well in deepwaters, especially if they can enter the SOFAR channel, a deepwater map was drawn to route vessels over the deepwater trenches that spread out from the Gulf of Tribugá. The rhetoric around the port consistently cited the deepwater trenches being a reason for building the port so that the area would not need to be dredged as commonly as the Port of Buenaventura does (Barrios and Plazas 2015). For this reason, the deepwater shipping lanes may be a more reasonable hypothetical map than the random map's shipping lanes. To do this, ships were placed into lanes over the deepwater trenches in route to the aforementioned five destinations until they had to shift out from over a trench to a more direct path. The spacing between ships was evenly drawn between ports of call and was similar to the current spacing of ships along the route from the Panama Canal to the Port of Buenaventura using marinetraffic.com. However, spacing between ships over the deepwater trenches was also shortened as compared to the control map to account for the higher density of ships given the additional 47 in this scenario.

As described above, it was assumed during the construction of the random map configuration that roughly 5 vessels would depart and arrive each day, with roughly one going to/coming from each of the 5 assumed destinations. The same additional 47 ships were added to the study area, starting with the deepwater configuration. Nonetheless, to increase the sense of randomness with the random map, several ships were moved from a shipping lane and placed in other areas of the study area. For example, one of these may be a supply ship diverting to the Galapagos.

The randomization decisions were made intentionally to move ships into areas of the ocean that might be void of large ship noise between the deepwater model lanes to make it as different as possible to that scenario. Finally, the locations of

every ship in each map were downloaded as three .kmz files for later ingestion into the acoustic propagation model and GIS software.

## Calculating Source Level for All Ships in All Maps

Once all variables were obtained for use in Eqs. (1) and (2) of the JOMOPANS-ECHO (J-E) model of MacGillivray and Jong (2021), source levels were calculated. The J-E model uses a reference speed per vessel class measured in knots ($V_c$) so our maps used only vessels in these classes.

Equation (1) in the J-E model solves for source level:

$$LS_f\ \ J-E(f,\ \ V,\ \ l\ \ ,C) = Ls_{f,0}(f,C) + 60\log_{10}(V/V_c)\,dB + 20\ \ \log_{10}(l/l_0)dB \tag{1}$$

where $LS_f$ refers to the spectral density of the source level, $f$ represents frequency in Hz, $V$ indicates velocity in knots, $l$ refers to the length of the ship in ft. (feet), $l_0$ equals 300 ft., $C$ represents ship class, and $V_c$ indicates reference speed (MacGillivray and Jong 2021).

However, to solve Eq. (1) one must first calculate $LS_{f,0}(\hat{f}, C)$, using Eq. 2. Eq. 2 states that $\hat{f} = f/f_{\text{ref}}, \hat{f} = 480$ Hz * $(V_{\text{ref}}/V_c)$, $f_{\text{ref}} = 1$ Hz, $V_{\text{ref}} = 1$ kn, $K = 191$ dB, and $D = 3$ for all classes except $D_{\text{cruise vessel}} = 4$. Considering the above values, proceeded to solve Eq. (2):

$$Ls_{f,0}\left(\widehat{f,C}\right) = K - 20\ \log_{10}\left(\hat{f}_1\right)\,dB - 10\log_{10}\left(\left(1-\frac{\hat{f}}{\hat{f}_1}\right)^2 + D^2\right)\,dB \tag{2}$$

where $K$ stands for the average sound level of a ship and $D$ stands for ship class (MacGillivray and Jong 2021). In other words, $K$ is a typical source level (SL) for many ships and the rest of the equation is a large extension of "20 $\log_{10}$ ($\hat{f}_1$)," which represents spherical spreading. Then, with the result of the calculation for $LS_{f,0}(\hat{f},\text{C})$ from Eq. (2), it leads to the calculation of Eq. (1) and thus to the generation of the source level of each ship based on aspects unique to each ship. The $f$ (or frequency of choice) that we used was 350 Hz because this is a known peak frequency used in common song units of Stock G (Perazio and Mercado III 2018), and since it's also a common harmonic in ship noise, masking could occur in this band.

## Calculating the Acoustic Propagation Models

With source level (SL) calculated for each ship in each map using the J-E model, we could use maps of transmission loss (TL) for each to make maps of received levels (RLs) at each point in the study area. It is of note that the additional 47 ships in the deepwater map are the same as the additional 47 ships in the random map so that

differences in noise area were not a result of varying ship types, but only a result of ship locations in the study area. RLs were calculated to be the sound levels from combined ambient and ship noise that humpback whales would be experiencing if they were located in a particular spot in the study area grid. The TL fields were computed with the acoustic propagation model "Seahawk," a split-step Padé parabolic eq. (PE) model (Heaney and Campbell 2016) developed by Applied Ocean Sciences.

The PE model requires ingestion of the following variables: water column temperature and salinity (taken from a CTD cast or from World Ocean Atlas (Boyer et al. 2018), the latter of which was used in these models) (Locarnini et al. 2018), bathymetry, sediment type, depth of cargo vessels in the water, average humpback whale swimming depth, a frequency band of interest, and locations of sound sources (taken from marinetraffic.com) (Rey-Baquero et al. 2021; Soares et al. 2015; McKenna et al. 2012).

This study used the following values for these variables:

Because it is assumed that other marine mammals are like humans and sense acoustic energy in a logarithmic way, the frequencies between 300 and 400 Hz that were incoherently summed together to represent this audible band of boat noise were not linearly spaced; rather they were the decidecade bands that are non-linearly spaced (Miksis-Olds et al. 2021). The exact central frequencies of the decidecade bands that acoustic transmission loss was calculated and incoherently summed for were 300, 308, 317, 327, 336, 346, 356, 366, 377, 388, and 400 Hz. The noise from the boats was modeled to be emitted at a depth of the hauls from each vessel that had such information in the MarineTraffic.com database or were determined by random draw from a realistic distribution of haul depths. Finally, because the part of the water column where humpback whales are usually found singing and breathing is near the surface (Pack et al. 2017), the received levels at depths of the receivers in the model were incoherently summed every 10 m from 0 to 30 m.

These boat-specific, whale-specific, and environmental parameters from Table 1 were fed into the parabolic equation model (Applied Ocean Sciences) for each ship. The transmission loss fields of noise from all ships were then incoherently summed across the entire study area. The form of the SONAR equation used was:

$$\mathrm{SL} - \mathrm{TL} + \mathrm{NL} = \mathrm{RL}$$

where SL is the Source Level of the boats, TL is the Transmission Loss of each boats' noise, NL is the Noise Level of the ambient acoustic environment, and RL is the resulting Received Level field of acoustic energy across the study area. For NL, the value from a 2018 passive acoustic monitoring study in the Gulf of Tribugá that measured median ambient noise levels (NL) was used: 48 dB re 1 $\mu Pa^2$ (Rey-Baquero et al. 2021). This uniform background level was applied to the calculations after the TL was calculated for each ship's SL and incoherently summed to create a single TL field of all the ships combined.

This resulted in a single field of RL values across the study area. The RL field can be interpreted as the amount of sound that a given humpback whale within the top

**Table 1** Variables used in the acoustic propagation model

| Variable | Value | Rationale |
|---|---|---|
| Frequency | 300–400 Hz | Peak song frequency is 350 Hz; a band avoids pure tone so is more realistic |
| Humpback whale depth | 0–30 m | Typical part of the water column occupied by humpback whales (Pack et al. 2017) |
| Bathymetry | GEBCO 2019 | Best bathymetry map available for the region |
| Sound velocity profiles (water column temperature and salinity) | World Ocean Atlas | Best available database of sound velocity profiles |
| Sediment grain size | $\phi = -2$ (Wentworth table) | Value representing an average of sand/stony bottom, known as common bottom type from SCUBA surveys in Tribugá |
| Propagation range | 400 km | Likely range to capture most of the TL for a SLs of the ships |
| Ambient wind noise | 48 dB re 1 $\mu Pa^2$ | Average ambient wind noise for the Gulf of Tribugá recorded in Tribugá in 2018 (Rey-Baquero et al. 2021) |
| Receiver depths | 0–30 m every 10 m | Pack et al. (2017) |

30 m could receive from the collection of ships within a detectable range around it in the study area for a particular shipping lane configuration. Finally, this gridded RL field, a.k.a. a georeferenced matrix representing the amount of sound (in dBs) from a combination of ship noise and ambient sound levels, was exported as a NetCDF file to be ingested into GIS software.

## Determining the Audibility Threshold

It is important to note that in the gridded map of RLs, not every pixel in the map would have levels high enough to be heard by a humpback whale because they ranged down to 48 dB (baseline ambient noise but below the audibility threshold). For that reason, the pixels in the maps were color-coded as either "inaudible" or "audible" (depending on the audiogram) to best interpret how much area in which a humpback whale could detect ship + ambient noise. Published audiograms of humpback whales were used to establish these audibility thresholds to delineate audible vs inaudible (Houser et al. 2001; Erbe 2002). While 300–400 Hz was the bandwidth used in the PE model and considered in the audiograms, it was not completely compatible with the two humpback audiograms (Fig. 3). Therefore, this study considered two humpback whale audibility thresholds (51 dB and 80 dB) to add nuance to the interpretation of the maps. The 51 dB threshold is more conservative (because it is a lower threshold of audibility) and would assume that more whales would have better hearing and be more capable of detecting lower levels of ship noise. The 81 dB threshold is less

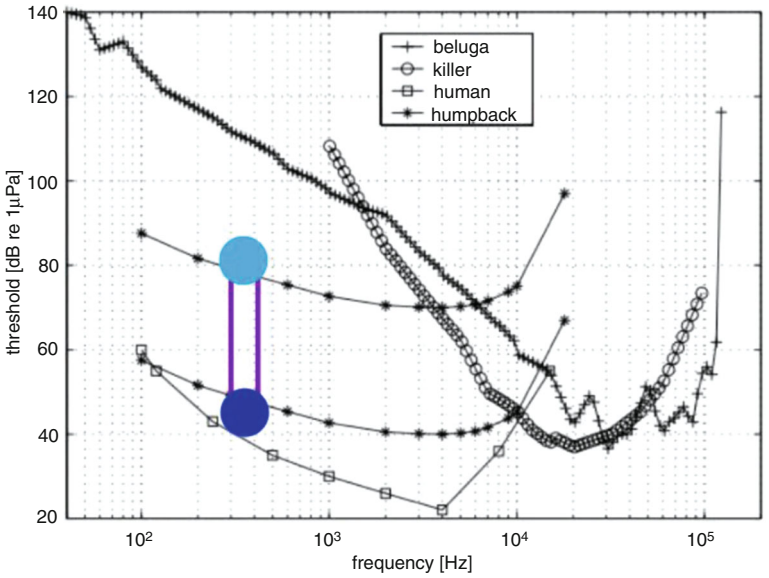

**Fig. 3** The humpback whale audiograms (asterisk lines) from Erbe (2002) based on humpback whale anatomical data and predictive models. The purple box indicates the thresholds that were considered for the 300–400 Hz frequency band under consideration. Shared with permission of Cristine Erbe

conservative. At this higher audibility threshold, it would assume an average whale had less sensitive hearing and therefore would be less likely to hear lower levels of ship noise. It is likely that the actual average audibility threshold of humpback whales lies somewhere between these two values.

## Evaluating Received Level Maps in ArcGIS

ArcGIS was used to ingest the results from the PE models and to calculate spatial parameters of the study area. ArcGIS is a geographical information system (GIS) that allows for handling and visualizing geographical statistics through layer-building maps (Shaktawat 2020). This tool was necessary to visualize and to calculate the audibility range category for each configuration. First, conversions were made to ensure accurate calculations. To calculate distance, bearing, and to convert the grid pixels to square area, the Movable Type Scripts (MTL) website was used, taking specific latitude and longitude points. According to MTL, the distance between the northern and southern edges of the study area was 1541 km, and the distance between the eastern and western edges was 1188 km (Chris 2022). Using these geographic reference points, it was possible to determine how many kilometers from N-S and E-W each pixel represented throughout the study area.

To convert .nc files to raster .tiff files, Qgis was used. Then, the coordinate system was defined in the "Transverse Mercator" projection. By using this coordinate system projection on a georeferenced NetCDF file, it was possible to calculate how many square kilometers each pixel represented. All .tiff files were uploaded to ArcGIS to find the unique values (pixel count per value) for the three selected audibility ranges (48–50.9 dB, 51–80 dB, and 80.1–123.4 dB) for each .tiff file. A spatial analysis reclassification was then carried out to vectorize the raster files into polygons. Each pixel in the raster file did not represent the same spatial area, but the conversion from pixel to square kilometers, as described in the previous paragraph, was done to accurately calculate the total area of the audibility ranges in each map so they were comparable to each other. Then, the pixels in each audibility range category were summed to calculate the total area occupied by each audibility category. These final spatial areas in each audibility class were then compared across the three maps.

## Maps of TL and RLs of Shipping Lane Configurations

A total of 79 vessels transited inside the study area on May 15, 2021. Of all 79 ships, the ship that produced the highest intensity source level was a merchant ship named Tianjin with 162.1 dB re 1 μPa @ 1 m, followed by a natural gas tanker (LNG) with an SL of 157 dB re 1 μPa @ 1 m. In third place was Conti Contessa, a merchant ship with an SL of 156 dB re 1 μPa @ 1 m. The ship with the least intense SL was number 42 with 122 dB re 1 μPa @ 1 m. The only merchant ship with (barely) enough energy to pass the "behavioral change" threshold (160 $dB_{rms}$) in marine mammals was "Tianjin," whose SL at 162 dB would have attenuated below 160 dB rather quickly.

The spatial area of noise from all of these 79 ships was depicted in planview (bird's eye view) maps. The .nc files from the RL matrices were projected in Google Earth to visualize the area that each boat's noise occupied and how noise from nearby boats combined. Notably, the control map showed a more pronounced accumulation of sound energy near the coastline. Sound energy was represented on a jet color scale with warm colors such as red, orange, and yellow representing relatively louder zones, while areas with cool colors such as dark blue and light blue represented less acoustic energy and therefore being relatively quieter. Additionally, the dark blue tones were placed in the matrix for <48 dB (or average ambient noise levels). These dark blue areas are all far away from any sound sources, since they are the portions of the study area where energy from the ships had significantly attenuated. Dark blue areas or rings close to the ships were likely over deepwaters as they are places where sound waves were not in the top 30 m of the water column, but rather were traveling in deeper waters until reflected off the bottom or other bathymetric feature to return again to the surface. It is this reflection of sound waves between the surface and bottom that creates the rings of sound energy in our planview maps, since only acoustic energy in the top 30 m of the water column is shown. The reflection paths, however, can be seen in

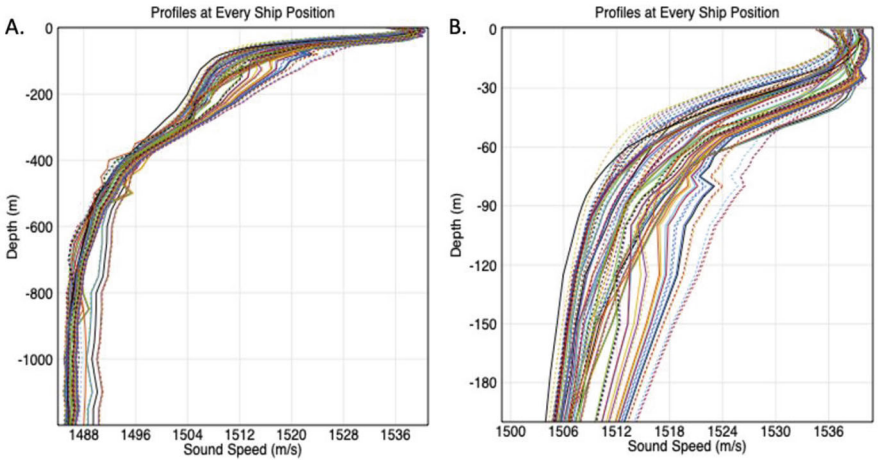

**Fig. 4** Sound speed profiles (SSPs) from World Ocean Atlas for vessel positions taken from marinetraffic.com from the surface until (**a**) 1200 m depth and (**b**) until 200 m depth. (Courtesy of John Boyle)

the slice view figures, such as Fig. 7b. In order to compare sound propagation patterns between ships, the sound speed profiles at the location of each vessel were plotted (Fig. 4). The sound speed profiles plotted on top of one another show not only the range in profiles across all 79 vessels, but also a clear pattern of how sound travels as the water column deepens over the study area. In general, the sound speed is about 1544 m/s at the surface and reaches a sound speed minimum of about 1482 m/s around 800 meters that stabilizes until the ocean bottom. When looking closely at the top 30 m, there is a sound speed maximum of about 1538 m/s near 15 m deep, but then sound speed quickly slows down until 90 m deep. It is between 90 and 200 m that the most variability in sound speed occurs over the study area. This 30 m sound speed maximum is interestingly the layer where humpback whales tend to sing between breaths (Pack et al. 2017). This layer of the ocean, in the study area, where sound travels the fastest, possibly creates a slight surface duct. This means that humpback whale songs could travel most effectively at the depth at which males sing. Ship noise, however, also travels effectively in the same layer, meaning masking in this layer could be particularly problematic.

## Predictive Maps

For the two simulated maps (random and deepwater) the highest and lowest source level of any simulated ship was 161.3 dB re 1 μPa @ 1 m and 122 dB re 1 μPa @ 1 m, respectively. Furthermore, while the source levels of the simulated set of boats were the same, their positions changed. The two configurations are shown as

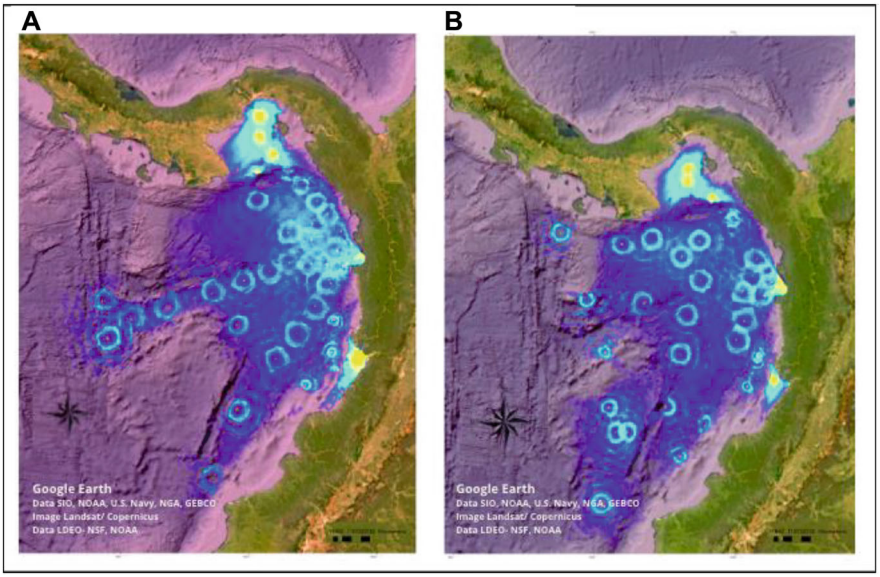

**Fig. 5** Predictive maps of the planview modeling results of two simulated shipping lane configurations: deepwater (left) and random (right). The colors represent the relative intensity of the sound around each ship. Both maps only represent frequencies at 300 Hz at 30 m depth and are without the effect of the wind to create a better visualization of the distribution of the ships. (Background image source modified from Google Earth)

planviews in Fig. 5. Recall that the 47 simulated ships in these two predicted shipping lane configurations were added to the 79 original ships from the control map. As the results will show, the addition of this many ships makes the overall noise area significantly larger in both simulated configurations as compared to the control. This increase is realistically what could happen if a port were ever built, so the comparison of more future ships to fewer current ships is a valid concern for conservation groups, management groups, policymakers, and the like.

## Interpreting Transmission Loss Figures

The three following figures show the main ways that transmission loss (TL) occurred from various ships with different source levels (SLs) in different spots along the shipping routes. The scale is in decibels lost during transmission, thus the negative values. Warm colors(−40 dB to −60 dB) represent sound levels with higher intensity because they have traveled less distance and/or attenuated less, therefore have experienced less transmission loss. Each figure represents a different TL planview (left-side subplots) and sliceview (right-side subplots) to exemplify some interesting examples of how bathymetry, temperature, and pressure combine to propagate or attenuate sound in various locations across the study area. The three

chosen TL planview and sliceview figures illustrate how sound can accumulate in shallow areas closer to the coast compared to the greater dissipation of sound as it travels to the depths in areas farther from the coast. While bottom sediment can rapidly absorb sound waves, shallow waters can also reflect sound waves between the bottom and surface more often, further ensonifying the water column over shorter distances until the absorption into the bottom wins out.

Because sound waves from Ship 30 went into the depths and were entrapped in the SOFAR channel quickly, its TL planview does not exhibit a typical concentric ring structure as many planviews of ships do (like Fig. 7a). Rather, Ship 30's emitted sound meets the seamounts, which have depths exceeding a little more than 2900 meters (Fig. 6b). The sound waves being mostly blue in color by 40 m from Ship 30's location show about 80 dB of TL or a rather rapid attenuation of the emitted energy with distance compared to ships in shallower waters of the study area. Even after 5 km from the point of emission, at a depth of 400 m, the noise has attenuated by 42 dB (warm colors), and by 15 km from the point of emission, TL is 77 dB (cold colors). Reasons for this could be (1) the amount of distance sound waves are traveling to reach the ocean bottom create space over with to be attenuated, (2) the type of sediment found at depth could be highly absorptive, and/or (3) temperature below about 400 m is colder than at the surface so sound travels slower and has more time to dissipate its energy.

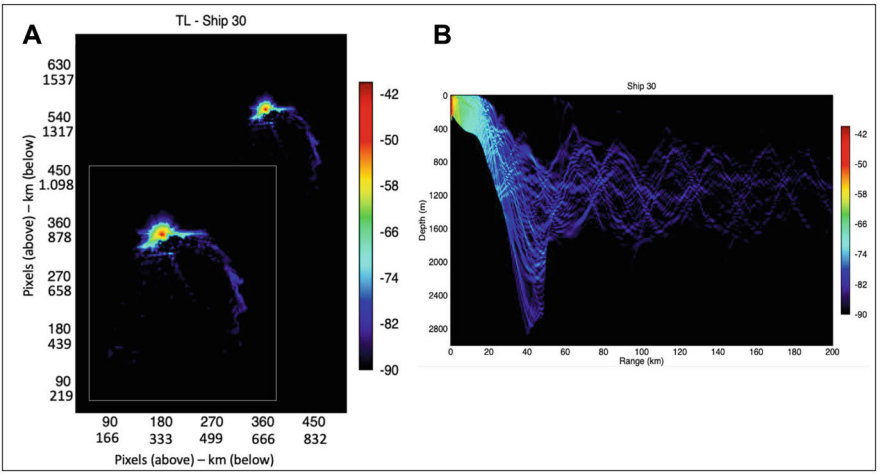

**Fig. 6** A deepwater subsurface duct example from Ship 30 as an incoherent average of the TL in the 300–400 Hz band. TL planview (A-left; zoomed out and zoomed in) that displays the top 30 m of these oscillating reflections, and the TL slice (B-right) that runs 180 degrees from the vessel position (north to south). Note the reflection off of the ocean bottom (blue rays in the sliceview) that bounce off the black bathymetry contour and then become entrapped in the SOFAR channel about 1 km deep. The blue tail in the planview is likely rays reflecting off the bottom that do not become entrained in the SOFAR channel and reach the top 30 m of the water column throughout their reflections. Units in the color bar are transmission loss (TL) in dB re 1μPa$^2$ where warmer is less TL and cooler is more TL

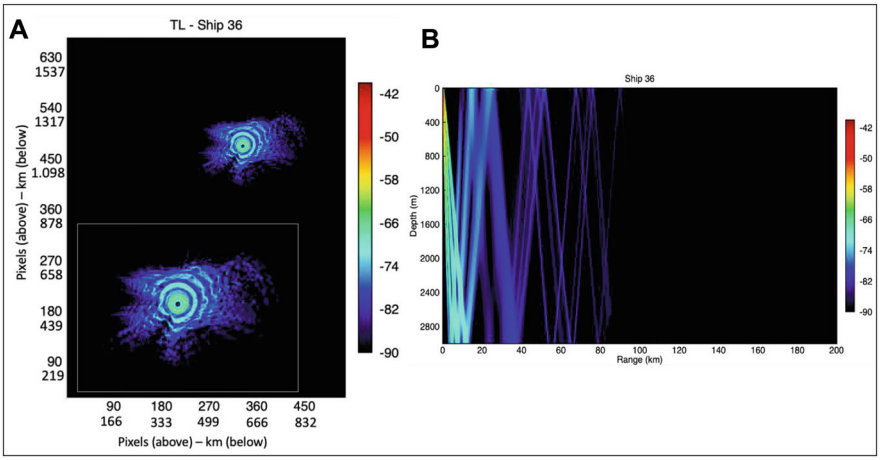

**Fig. 7** A deepwater bottom-to-surface reflection path example from Ship 36 as an incoherent average of the TL in the 300–400 Hz band. TL planview (A-left; zoomed out and zoomed in) displaying the top 30 m of the water column, and TL sliceview (B-right) going south from the ship's location. Note the propagation of sound around the boat is similar in many directions (sound propagation rings in the planview). Also, note the reflection of sound waves as they strike the surface and bottom of the ocean (blue rays in the sliceview). Units in the color bar are transmission loss (TL) in dB where warmer is less TL (less negative values) and cooler is more TL (more negative values)

Figure 7 illustrates how the sound waves of a ship at Ship 36's location propagate from the surface immediately to the sea floor at 3 km deep. Over these 3 km, from the first surface to bottom transit, about 70 dB are attenuated. When reflecting off the bottom, it is noted that another few dB are lost, and depending on the type of bottom sediment at different locations, this absorption of sound energy could be more or less, causing sound energy to dissipate faster or slower. Over the next four reflections against the surface and bottom, the TL is only about another 10 dB, so more attenuation is occurring at the beginning near the ship and less attenuation is occurring at the end of the sound wave's path, farther away from the ship.

Acoustic propagation from most of the ships followed either of these two examples (Figs. 6 and 7): getting entrained in a subsurface duct or reflecting between the surface and bottom. The final way sound propagated from ships across the study area was in shallower waters (Fig. 8). Figure 8 illustrates how the sound waves of a ship at Ship 04's location propagated from the surface immediately to the sea floor at 50 m deep.

## Final Maps of Transmission Loss (TL) and Received Levels (RLs) from Control and Simulated Shipping Lane Configurations

The final maps of the random and deepwater simulated configurations (Figs. 10 and 11) show the positions of the ships and their noise prints in TL (A-left subplots) and in RLs with the 48 dB NL included (B-right subplots). The map

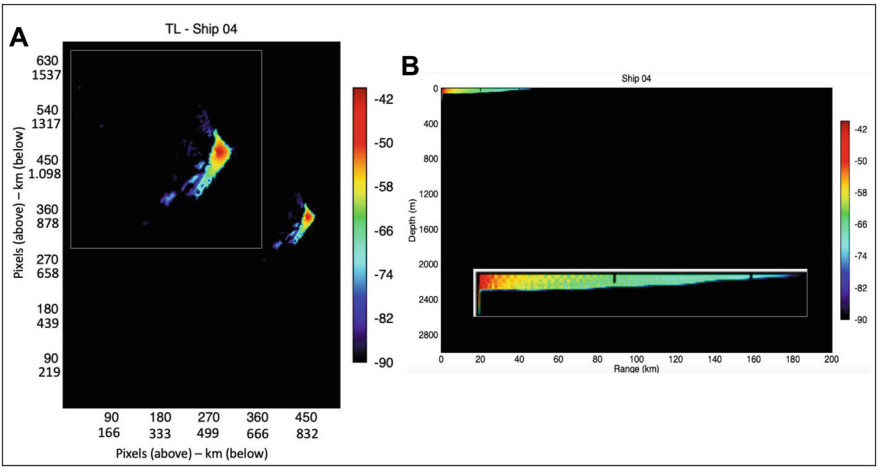

**Fig. 8** A deepwater bottom-to-surface reflection path example from Ship 04 as an incoherent average of the TL in the 300–400 Hz band. TL planview (A-left; zoomed out and zoomed in) displaying the top 30 m of the water column, and TL sliceview (B-right) going south from the ship's location. Note the propagation of sound fills up the shallow water column completely from surface to bottom (**b**) and toward the east until the coastline, but sound waves likely drop below 30 m and continue toward the west (**a**). Units in the color bar are transmission loss (TL) in dB where warmer is less TL (less negative values) and cooler is more TL (more negative values)

format makes it easy to see how ship noise propagates throughout the study areas in the Colombian Pacific Ocean. In the TL maps (A-left), the red color(−30 dB to −45 dB) represents the levels with less loss (i.e., they are more audible), while the blue color(−85 dB to −90 dB) represents the levels with more loss (i.e., they are less audible). In other words, the areas with blue shades(−85 dB to −90 dB) represent areas where the whales would likely be unaffected by the noise emitted by the ships because the received levels are below their audibility threshold. It is in these blue areas that we can assume they may communicate more effectively, assuming no other sources of interruption exist.

To determine exactly which colors represent sound levels that are and are not audible to whales, the SONAR equation must include noise level (NL) to create a more realistic map of RLs. The resulting map of RLs (Fig. 9b) represents the incoherent summation of ship noise with the 48 dB of average ambient sound known to be a typical sound level in the Gulf of Tribugá at Morro Mico (Rey-Baquero et al. 2021). Therefore, this map shows the total modeled sound energy from ships and ambient noise levels that the whales could receive at each point in the study area. In some places, the ambient sound is louder than the attenuated noise that traveled long distances from the ships. Nonetheless, over a large portion of the map, the ship noise is louder than (or in excess of) the ambient noise (MacGillivray and Jong 2021). It is important to say while there may be a significant amount of sound energy at depth, it is not represented in these maps, so the concentration of sound energy along

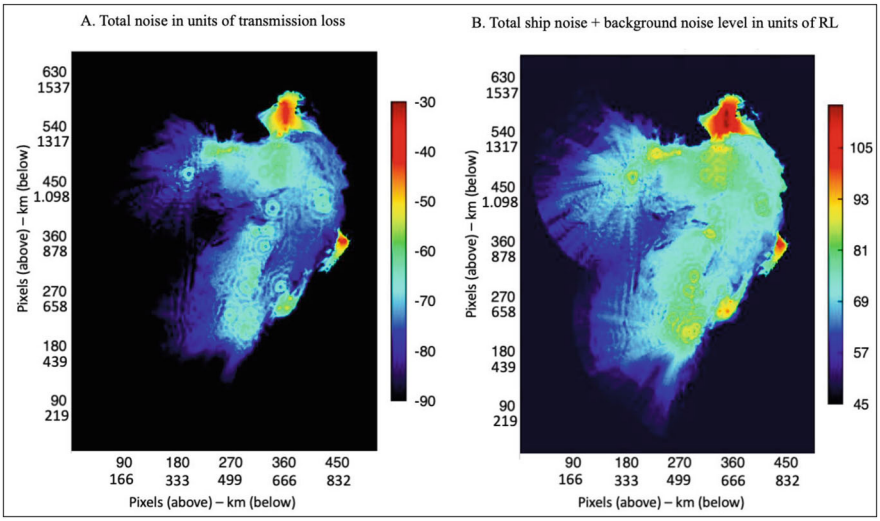

**Fig. 9** Planview maps for TL in dB re 1 μPa$^2$ (left) and RL in dB re 1 μPa$^2$ (right) of noise emitted by 47 ships of the control map in the Colombian Pacific Ocean study area

the coastlines is only in the area of the water column that literature shows humpback whales tend to swim and sing in (0–30 m in this study).

Warmer colors represent less transmission loss and higher intensity sound, while cooler colors represent more transmission loss and less intense sound. Figures made in the parabolic equation modeling software owned by Applied Ocean Sciences. The color scale used in the subplot (Fig. 9b) is 45–110 dB, so places without any noise from the ships in our models will appear black, making them easier to see. Capping the range at 110 dB allows the noise level of 124.5 dB to be dark red, making the highest ship noise levels more visually obvious. Maps are of the full 30 m surface summation and integrated over 300–400 Hz bandwidth. The same TL and RL planview maps (an integration of sound levels only in the top 30 m of the water column) were made for the deepwater trench configuration and the RL noise field can be seen in next Fig. 10. The most intense noise levels (91–123.4 dB) in the deepwater maps were found along coastal areas such as Buenaventura and the coastal strip near the Panama Canal (Fig. 10c). The central area of the study area tended to have more intermediate noise levels (73–90 dB) in yellow and greenish hues, while the areas farthest away from the coasts held the lowest noise levels (45–72 dB), shown in dark blue and light blue hues (Fig. 10c).

The second hypothetical configuration was the "random map" (Fig. 11b), which adjusted the 47 additional ships from the deepwater configuration to be more randomly arranged within the study area. As before, the control map (Fig. 11a) was combined with the additional 47 ships of the simulated random configuration (Fig. 11b) and a flat ambient noise level to create the combined total noise field of the projected random configuration (Fig. 11c). Ships in this

configuration tended to be closer to the coast (Fig. 11b). In this random configuration, the highest noise levels (91–123.4 dB) accumulated in areas closer to the shores (Fig. 11c). The central area of the study area tended to have more intermediate noise levels (73–90 dB) in yellow and greenish hues, while the areas farthest away from the coasts held the lowest noise levels (45–72 dB), shown in dark blue and light blue hues (Fig. 11c).

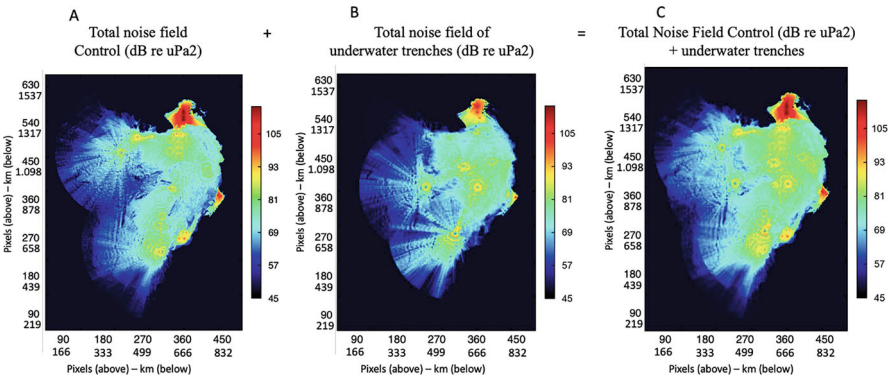

**Fig. 10** Total noise field of deepwater and control configuration. (**a**) The control configuration in RL (dB re 1 μPa$^2$), (**b**) total noise of 47 ships in the deepwater simulated configuration, and (**c**) the incoherent sum of the noise from the ships in the control map plus the noise from the 47 additional ships. **Fig. 11** Total noise field of random and control configuration. (**a**) The control configuration in RL (dB re 1 μPa$^2$), (**b**) Noise map of 47 ships randomly arranged around the Colombian Pacific Ocean, and (**c**) the incoherent sum of the noise from the ships in the control map plus the noise from the 47 additional ships of the random configuration. Figures made in AOS' PE software. Color scale in dB of RL and include NL = 48 dB re 1 μPa$^2$

The main visual difference between subplots A and B in Fig. 9 is that the circles do not appear as clearly in Fig. 9b. This is because the ambient sound contribution at all locations has a received level of 48 dB, so the RL map has a more diffuse effect that is more realistic as it includes an average amount of ambient noise throughout the environment. On the other hand, the primary spatial comparison between the control map and the deepwater and random maps come from the fact that the control map (Fig. 10a) is added to both (Figs. 10b and 11b) to simulate current shipping traffic plus future projected traffic if there was a port (Figs. 10c and 11c).

## Scenario of Audibility Zones

Before comparing the spatial extent of all noise levels in the three maps, audibility ranges were delineated. Figures 12 and 13 are visual representations of the audibility ranges with color indicating audibility zones considering the humpback whale audiograms from the literature (Houser et al. 2001; Erbe 2002). Red represents the portions of the study area with the highest audibility (80.1–123.2 dB) where the possibility that whales can detect ship noise is high. Dark blue indicates portions of the study area that contain noise levels between the two published audiograms for the bandwidth in question (51–80 dB). This is an audibility range where humpback

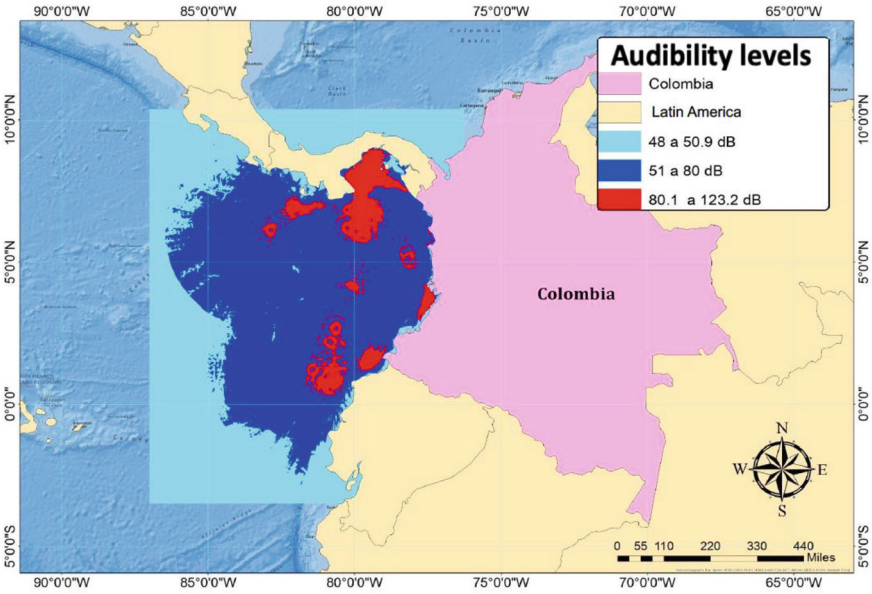

**Fig. 12** Map of received levels grouped by audibility ranges in the study area for the control map configuration. Minimum audibility/lowest sensitivity threshold (80.1–123.2 dB) in red, intermediate audibility/medium sensitivity threshold (51–80 dB) in dark blue, and maximum audibility (48–50.9 dB)/highest sensitivity threshold in light blue

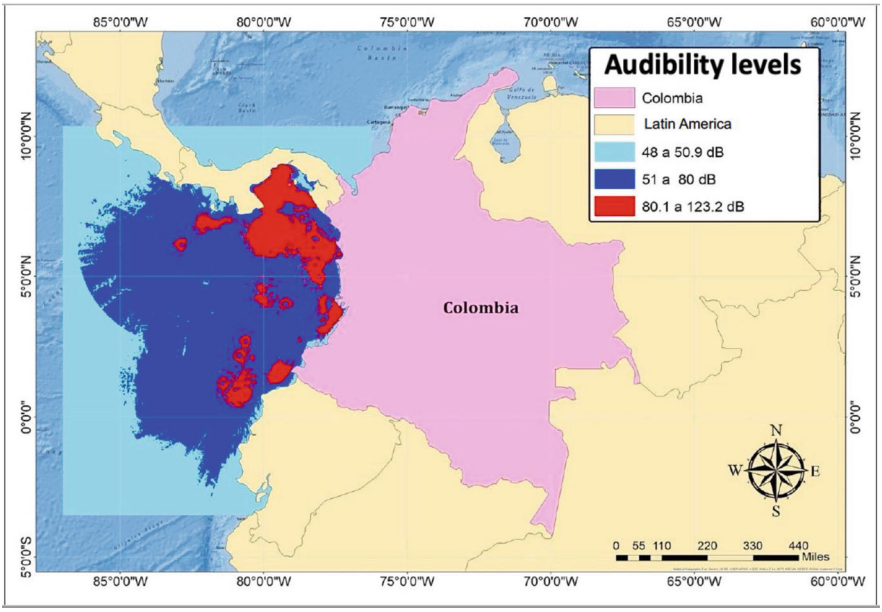

**Fig. 13** Map of received levels grouped by audibility ranges in the study area for the random map configuration. Minimum audibility/lowest sensitivity threshold (80.1–123.2 dB) in red, intermediate audibility/medium sensitivity threshold (51–80 dB) in dark blue, and maximum audibility (48–50.9 dB)/highest sensitivity threshold in light blue

whales could still hear the ship noise, but less certainly so, or where fewer could. This is also the portion of the study area that is very susceptible to change, as ship noise could easily shift to higher audibility levels with the addition of just a few more ships, ships with louder source levels than considered in this study, or from slightly different routing over areas with more effective propagation. The portions of the study area in light blue correspond to the most sensitive audibility threshold (48–50.9 dB) for humpback whales. It is possible that some whales could still hear the shipping lane traffic noise in these portions of the study area, but only those individuals with particularly sensitive hearing.

Similar to the noise field planview for the random configuration, the red areas that fall within the highest audibility range (the areas where humpback whales with even low hearing sensitivity could probably detect boat noise) are closer to the coasts with an accumulation of noise in areas closer to the Panama Canal, the port of Buenaventura, and southern coastal areas (like Tumaco and Ecuadorian coastal areas) (Fig. 13).

The deepwater configuration, as predicted from the planview noise field (Fig. 14), has portions of the study area that surpass the highest audibility threshold (reddish colors from 80.1 to 123.2 dB), particularly toward the center. The central portion of the study area actually tends to have a noisy channel that is mostly filled in between the Port of Buenaventura and the Panama Canal.

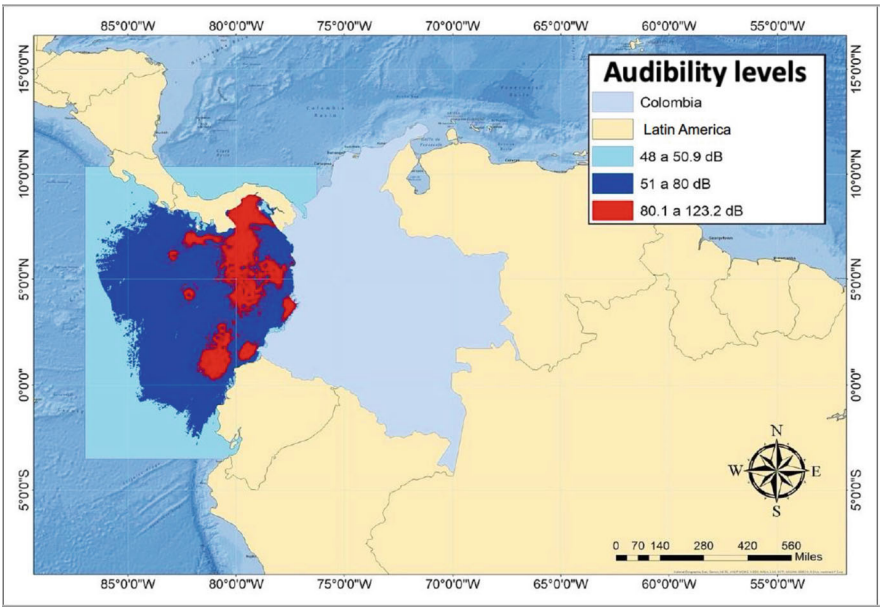

**Fig. 14** Map of received levels grouped by audibility ranges in the study area for the deepwater trenches map configuration. Minimum audibility/lowest sensitivity threshold (80.1–123.2 dB) in red, intermediate audibility/medium sensitivity threshold (51–80 dB) in dark blue, and maximum audibility (48–50.9 dB)/highest sensitivity threshold in light blue

**Table 2** Areas associated with the three audibility ranges of humpback whale hearing for all three map configurations

| | Area in $km^2$ | | |
|---|---|---|---|
| Audibility ranges in RLs (dB re 1 $\mu Pa^2$) | Control | Random | Deepwater trenches |
| 48–50.9 | 1,086,991 | 1,084,276 | 1,070,432 |
| 51–80 | 676,602 | 629,083 | 615,889 |
| 80.1–123.2 | 89,734 | 139,965 | 167,003 |

The calculations for spatial coverage of each colored (each audibility range) polygon in each of the configurations (random, deepwater, and control) are presented in Table 2. The total area for all the configurations was 1,854,500 $km^2$. The control configuration yielded the largest area (1,086,991 $km^2$) for the lowest audibility range (48 at 50.9 dB) which is thought to be a level too low for most humpback whales to detect sounds (Houser et al. 2001). The control configuration also had 676,602 $km^2$ with levels between 51 and 80 dB or where RLs would be relatively average for humpback whales to detect sounds. Finally, the control configuration had the smallest area (89,734 $km^2$) occupied by noise levels between 80.1 and 123.2 dB which are received levels assumed to be sufficiently loud for most humpback whales to detect sounds. The deepwater configuration had the largest area (167,003 $km^2$) within noise levels in the highest audibility range, while the random configuration

**Table 3** Spatial area percentages of audibility ranges in each of the control, random, and deepwater configurations

| | Percent area (%) | | |
|---|---|---|---|
| Audibility ranges in RLs (dB re 1 μPa$^2$) | Control | Random | Deepwater trenches |
| 48–50.9 | 59 | 58.53 | 57.76 |
| 51–80 | 37 | 33.91 | 33.23 |
| 80.1–123.2 | 5 | 7.56 | 9.01 |

had a more moderately sized area (139,965 km$^2$). This moderately sized area, however, is only 27,038 km$^2$ less than the deepwater configuration and 50,231 km$^2$ larger than the control map. Therefore, the random configuration does not maintain the control configuration's less intense noise field: it is actually closer to the more disruptive noise field of the deepwater configuration.

Table 3 shows the percentage of space in the study area occupied by the three audibility ranges of ship noise in each of the configurations. The control configuration had the highest percent area for the 48–50.9 dB audibility range at 59% of the total study area with respect to the other configurations, while the deepwater configuration had the lowest percent area at 57.76%. The control configuration also had the highest percent area for the audibility range of ship noise between 51 and 80 dB at 37%. Similarly, the deepwater configuration had the lowest percent area at 33.23%. Conversely, the deepwater configuration had the highest percent area (9.01%) of the audibility range between 80.1 and 123.2 dB (the noisiest levels), while the control configuration had the lowest at 5%.

The total area and percent of area results show that the control configuration is the most suitable for facilitating humpback whale communication, but that was expected. Intuition would suggest that placing any additional ships in the study area would increase the vessel noise print overall, so the control configuration being the best-case scenario of the three configurations was a good sanity check. However, when more ships were added, the random configuration was more suitable for humpback whale communication than the deepwater configuration, at least for the audibility ranges chosen in this study.

Adding the 47 ships to the study area resulted in a couple of interesting observations. First, for the audibility range of 80.1–123.2 dB, the deepwater configuration had almost twice (9%) the percent area being occupied by noise at these levels than the control configuration (5%). Placing 47 ships over the deepwater trenches nearly doubled the amount of area that noise from the original 79 ships produced. Therefore, a 59% increase in ship traffic led to an 80% increase in the percent area covered by noise in the highest audibility range. For the random configuration with only ~7.5% of the study area instead of 5% occupied by noise levels in the highest audibility range, a roughly linear relationship between additional ships (59% increase) and additional noise (a 50% increase) does exist. This is strong evidence that ships traveling over areas of the ocean with effective propagation input more noise to the near-surface acoustic environment than ships traveling over areas of the ocean with less effective propagation features. Even though deepwater ports

arguably do not need to dredge their shipping lanes as often (meaning less noise in the environment over time from dredging), these results show that having ships travel over the trenches may offset the noise reduction benefits associated with less dredging, as it results in noisier soundscapes.

## Propagation Models Estimations

This study estimated the noiseprints of potential shipping routes that could service the proposed Port of Tribugá if it is ever built. Using parabolic equation propagation models, areas and percent coverage of the study area were calculated for two audibility levels to better understand how increased ship noise could be perceived by humpback whales. Two predictive shipping route configurations were calculated and compared to understand the variability in propagation environments shaped by natural features that exist off the Pacific coast of Colombia. Although the proposed port would undoubtedly increase sound levels, the exact effect of factors such as the location, size, and a number of additional ships on the soundscape remains unknown but were predicted as best as possible. Modeling the noise pollution from various possible shipping lane configurations could help managers mitigate some of the noise that would inevitably result from increased ship traffic. While there is no configuration of additional ships that will prevent further ensonification of the ambient acoustic environment, it could be possible to determine which configurations are relatively less disruptive than others for humpback whales to communicate effectively.

## Understanding the Colombian Pacific Soundscape

Acoustic propagation models are commonly used to determine how sound spreads through a given environment. They can later be used to pinpoint where the noisiest and quietest parts of that area are likely located given a certain configuration of sound sources. When the ships' sound sources in the current models were close to shore, shallow coastal waters commonly became very noisy. This could be the case if the sediment is not very absorptive because sediments more absorptive than the grain size we chose would dampen the noise more quickly. In contrast, when the ship sources were over deepwater, the sound attenuated quickly, as it could dissipate in many directions, so the acoustic energy was spread out over a larger volume of water. If the sound became entrained in a submarine duct, though, it did travel very far distances in some directions from the sources. Overall, the propagation environment depends on parameters such as the sound speed profile and sediment type that allow sound to refract, absorb, scatter, or otherwise dissipate and attenuate slower or faster across the soundscape (Ainslie 2010; Erbe 2011). The results of the present investigation show that sound propagation has little attenuation near the coast of Colombia as compared to its offshore, deeper water areas. This could be because the sediment that predominates in shallow water is known to be sandy or silty from

current knowledge of SCUBA divers ($\Phi = 2$ in the Wentworth table), resulting in waves that reflect off the seafloor more than if the sediments were mud or clay, but absorb better than if the sediments were rock or limestone (Ainslie 2010; Erbe 2011).

The features of the ships also affected propagation. The sound emitted by ships is not isotropic (i.e., it does not scatter equally in all directions (e.g., Arveson and Vendittis 2000)) and not all frequencies emitted by ships are as intense as others. Since propagation depends on the source frequency of the environment in which the ships travel, if the ships' source frequencies match those of the environment, then they would naturally propagate better than others, potentially traveling hundreds of kilometers. In addition, changing speed, cargo type, size, and other ship characteristics affect the dispersal patterns of their noise (e.g., Arveson and Vendittis 2000). These complexities could explain the vertical mode transmission loss figures in the present study where sound radiated with different frequencies and directions, generating a complex and dynamic noise field. Furthermore, in an example transmission loss model, Erbe et al. (2012) also indicated that as a vessel travels over different environments from coastal to offshore waters, its noise field changes. In shallow water, the propagating noise repeatedly interacts with the surface and seafloor where it is reflected, scattered, and partially absorbed (Erbe et al. 2012). The directionality of the noise in deepwater tends to be dipolar and interactions with other sound waves are reduced by coupling quickly to the SOFAR channel, with little energy loss. This entering and propagating of sound through a submarine duct (like the SOFAR channel) was observed for some of the ships in this study. It mainly occurred over deeper waters, illustrating how the paths of the sound waves can change according to the bathymetry. With this, it can be said that humpback whales, independent of where they are, can experience quite different noise fields even at the same distance from the same ship (Erbe et al. 2012).

This discussion also illustrates why changing the position of a ship inherently changes a number of variables that affect acoustic propagation. Variables like sound speed profile, distance to shore, depth, etc. are inherently tied together in the ship position variable and cannot be teased apart without doing an intense Monte Carlo investigation that was beyond the scope of this study. For an example of determining which inherent variable encased in the position of a sound source most affects acoustic propagation within and between sites, see Sect. 6 of Heaney and Seger (2020).

## Determining the Best Potential Shipping Configuration for Humpback Whales

There is a submarine duct in the study area that was a common channel for the modeled sound to become entrained in and spread boat noise effectively at depth. According to the transmission loss propagation models (e.g. Figs. 7 and 8), initially, the direct interaction of the acoustic signal between the bottom and the surface occurred. But after a few reflections, considerable acoustic energy refracted into a subsurface channel. Conduits like these have been hypothesized to allow humpback

whales, which usually occupy shallower waters (<80 meters) (Pack et al. 2017), breathe at the surface, and then submerge and communicate with other individuals over longer distances than if they were to sing at other depths with less propagation potential. However, acoustic propagation does not discriminate between boat noise and animal sounds. The same mechanism that whales can use to project their signals will also allow noise from boats and other manmade sources to propagate far across the oceans. For this reason, the deepwater trenches configuration was included in the set of models to evaluate. It was unknown whether noise emitted by the ships aligning with the trenches would cause more sound energy to enter the deep acoustic channel or not, since depth is not the only nor strongest factor in affecting propagation distance. Therefore, the idea that depth could increase propagation distance needed to be tested against a more random configuration. Also, the deepwater trenches configuration was important to evaluate since one of the reasons that the Colombian government (Arquimedes project S.A 2015) claimed to want to build a port in Tribugá was for its deepwater accessibility (which would reduce the amount of dredging needed for maintenance of the port). Therefore, shipping lanes that followed the paths of the deepwater trenches would be a realistic simulation.

After evaluating three models (control, random, and deepwater), the "control map" configuration (Fig. 12) was the simulation with the smallest audible area covered by boat noise. This is because it was a real-world scenario where only the ships that transited on May 15th over the Colombian Pacific were considered and no simulated additional boats were added. Any port or increase in shipping activity in the area would most likely create a larger area of audible noise, so it was a good sanity check that our control model was the one with the smallest acoustic impact area. This would also be the main reason why there are such noticeable differences in the area occupied by boat noise between this control map and the two other configurations.

The two hypothetical configurations (random and deepwater) showed increases of 50,231 $km^2$ and 77,269 $km^2$ compared to the control occupied by audible boat noise, respectively. Thus, it can be said that in the Colombian Pacific Ocean, if a port were built in Tribugá, there would be an increase in the area where noise would be audible to humpback whales and, therefore, could cause a possible reduction in their communication space. Any spatial increase in boat noise could confound signals more often for a species that, during their reproductive season, rely heavily on acoustic communication. Meaning, larger noiseprints from ships could generate possible degenerative effects in their biological processes and behavior (Ovide 2017).

## Potential Effects on Humpback Whales with Respect to the Models Made

Depending on how much acoustic energy a vessel is emitting, its impact on cetaceans will vary in severity, from PTS to TTS to behavioral and masking effects. Where the noise is traveling also varies and matters. For example, when sound

waves emitted from a ship propagate through the surface or within a subsurface duct, they could be heard by humpback whales, disrupting and masking their calls and/or songs (Erbe 2011). Even if all ship noise became entrained in a deep SOFAR channel like in Fig. 6, that would move the noise out of the water column depths where humpback whales usually swim, but would move the noise into the depths where other species, like sperm whales, vocalize and communicate. Therefore, the interpretation of impacts from noise on marine mammals needs to be species-specific. Since the most common baleen whale species in the Gulf of Tribugá is the humpback whale, it was chosen as the focal species for this project. But it is unknown which other species besides humpback and Bryde's whales might be present and how many of them inhabit the areas far offshore of Colombia's Pacific Coast (Vallejo et al. 2022). Therefore, the results of this study should not be extrapolated to impacts on other species. When considering other species, new acoustic models that are tuned to their diving depths, hunting depths, audiograms, and calling frequencies would need to be made.

A physiological effect on baleen whales as a result of noise is another impact to consider. According to Erbe (2011), stress is a physiological response in which heart rate and gas exchange increase and more blood flows to the brain, thus activating a fight or flight response. It is not well known whether a fight or flight response is activated by ship noise in all whales, but it has been documented in large whales that boat noise can elicit behavioral changes that could be indicators of fight or flight (Avila et al. 2015; Ovide 2017). This work shows that larger areas with audible anthropogenic noise would result if more vessels, regardless of configuration, are added to the waters off the Colombian Pacific. It is therefore reasonable to assume that an increase in the occurrence of stress responses to noise by humpback whales could also increase as the area ensonified by boat noise grows (Fair and Becker 2000). If these humpback whales are in areas with high noise levels for extended periods, this repetitive or prolonged stress exposure could negatively affect their long-term health (Erbe 2011).

Stress response to audible noise and its overlap with a humpback whale's communication space is the most likely effect to occur in the study area. This is because all shipping lane configurations yielded sound levels below the PTS threshold for the low-frequency marine mammal hearing group. In fact, most source levels of ships did not even exceed the TTS threshold. Only in a few rare cases in our models would a humpback whale have experienced TTS conditions, and only then if they were swimming alongside a vessel. Therefore, the interpretation of this work should focus more on constant noise exposure and how it could have long-term effects due to corrosive impacts on whale hearing when noise exposures are experienced over time, thus generating a chronic effect on an individual's health (e.g., Bejder et al. 2006; Clark et al. 2009; Ellison et al. 2012).

For a contrary interpretation, the possible resiliency of the humpback whale to human noise should be considered. Ellison et al. (2012) reported mysticete cetaceans to inhabit or often settle in areas where anthropogenic noise is abundant. This suggests the capacity for behavioral adaptation or plasticity to fluctuating environments when a dose of noise is applied (Ellison et al. 2012). The whales in the Gulf of

Tribugá may be equally as adaptive to added noise in their habitat, so it is not guaranteed that they would be severely impacted by some increase in noise. Instead, the increase in ships could lead to different impacts on the humpback whale population, like more ship strikes, which are fatal. Regardless, due to the paucity of data on stress response and its long-term effect on the immune system, it is reasonable to consider that the area surrounding the Gulf of Tribugá, being that it has little anthropogenic noise currently, could be serving as an acoustic haven for Stock G during their lifespans. Therefore, while science currently cannot document whether ensonifying a breeding ground with human noise could cause irreversible damage or not, it is a worthy research endeavor to understand better in the future and the precautionary principle should be implemented when possible.

## Conclusions

The shipping lane configurations created for the hypothetical mega port in the Gulf of Tribugá resulted in areal noise increases of 50,231 $km^2$ within the study area for the "random" configuration, and 77,269 $km^2$ for the "deepwater trenches" configuration as compared to the control map. Although the random configuration (Fig. 13) moved ship noise sources out from over some deepwater trenches to determine if that was enough to make a significant decrease in the audibility area of the shipping lanes, it did not result in a large difference compared to the deepwater configuration. Specifically, the deepwater configuration had an excess area of 27,038 $km^2$ where boat noise was between 80.1 and 123.2 dB (the area of most audibility). Nevertheless, increases of 13,194 $km^2$ and 13,844 $km^2$ in random configuration were detected for the 50–80 dB and 48–50.9 dB classes, respectively. Therefore, while the random configuration would be the better shipping lane management strategy of the two in terms of audible ship noise area, it is not that much of an improvement, and further exploration into other configurations could yield an even better management option.

If a port were to be built in the Gulf of Tribugá, it is not known exactly what type of vessels would transit, nor what cargo would be transported. Additionally, there is not much information on the potential routes that would be used for merchant shipping. However, the present research showed that the addition of more ships in the ocean would significantly increase noise levels in the water, so there would be potential for more masking of acoustic signals emitted by humpback whales. Studies like this one would allow the government and/or related entities to regulate, mitigate, and take the necessary measures to anticipate a decision that could be detrimental to areas that are highly diverse and therefore must necessarily be conserved.

**Abstract**

The effects of intermittent sound exposures on the hearing of marine mammals are not well understood. This chapter explores a model to predict growth of Temporary Hearing Threshold Shift (TTS) considering level and duration of the sound exposure in harbor porpoises, a species which has vulnerable hearing. This model was evaluated using TTS growth data obtained for harbor porpoises with different sound exposures (intermittent and continuous sonar, and intermittent pile driving and air-gun sound).

An adapted version of a modified-power-law (MPL) model was introduced, which attempted to overcome some shortcomings of the original model, proposed by Humes and Jesteadt (J Acoust Soc Am 85:1285–1294, 1989)) that required growth and recovery from individual exposures to be measurable. Fitting of the data to this model resulted in parameters that could explain TTS growth observed in a wide range of sonar exposure conditions (various sound pressure levels, 1–2 kHz, 10% duty cycle vs continuous exposure, and various exposure durations), but underestimated the TTS growth of exposure to impulse sound (air guns and pile driving) and sonar with higher (6–7 kHz) frequencies. These results suggested that development of a single TTS growth model for different fatiguing sound exposures is promising, but requires further development and validation, as well as additional data on TTS growth and recovery due to different signal parameters of the fatiguing sound.

Temporary threshold shift · Auditory impact · Harbor porpoises · Underwater sound · Modified power law model

## Introduction

Management of man-made underwater noise to protect marine life requires guidelines for predicting risk of hearing damage. Noise exposure criteria have been proposed to predict the onset of auditory effects in various marine mammal species (Southall et al. 2007; Tougaard et al. 2015; Finneran 2016; Southall et al. 2019).

There is a general understanding that impulsive sounds are harmful to the mammalian hearing. Currently different thresholds are applied to pulsed and nonpulsed signals, but especially the effects of intermittent sound exposures on the hearing of marine mammals are not well understood (Finneran 2015).

The sensitivity to hear a sound is typically expressed in terms of the hearing threshold (i.e., the lowest level of sound required to detect the sound with a specified probability). When the hearing system is overexposed to sound, a raising of the hearing threshold is observed, which is called a threshold shift (TS). A threshold shift that recovers to the baseline hearing threshold after some duration is called a "temporary threshold shift" (TTS) and is called "permanent threshold shift" (PTS) when it does not fully recover. Prediction of when PTS is induced in marine mammals relies on the ability to extrapolate from low levels (6 dB) of TTS to high levels (40 dB; Southall et al. 2019).

A recent study carried out explored different approaches to improve predictions of TTS growth in harbor porpoises (*Phocoena phocoena*). First, the literature of mechanisms and models explaining TTS growth and recovery in humans and terrestrial mammals was reviewed to identity promising model approaches. Then two TTS growth models were investigated: a kurtosis-based method and an adapted version of a modified power-law (MPL) model, proposed by Humes and Jesteadt (1989). The MPL model was applied to TTS data collected with harbor porpoises exposed to a range of different sound exposures. The kurtosis-based approach is described in von Benda-Beckmann et al. (2022).

## Literature Review

### TTS Growth Studies in Human and Terrestrial Animals

TTS growth and recovery have been reported for a wide variety of exposure conditions and species. A number of papers provide extensive reviews on these studies (e.g., Melnick 1991; Finneran 2015). TTS growth typically follows an exponential growth with SPL (Finneran 2015), possibly followed by a plateau when the TTS reaches the so-called asymptotic threshold shift (ATS; a maximum induced TTS that does not increase even when exposure duration is increased, Melnick 1991). In some instances, a reduction in TS during the exposure (cochlear toughening) can be observed (Hamernik et al. 2003). The exposure level associated with the turning point where the TTS growth changes from increasing logarithmically with SEL to a linear increase is referred to as the "critical level." It has been argued that this constitutes a point at which mechanical fatiguing processes start to dominate over metabolic processes (Price 1981; Hamernik et al. 1987). For humans, TTS growth and recovery can be predicted well as function of the percentage of the ATS is induced by the exposure (Melnick 1991). However, ATS has not been observed in marine mammals, due to avoiding the long exposure durations employed in terrestrial mammal laboratory studies required to reach an ATS, such

as those on chinchillas and primates (4–36 h) (Bohne and Clark 1982; Clark 1991; Yoshida and Liberman 2000; Finneran 2015).

In laboratory studies, terrestrial mammals have commonly been exposed to fatiguing aerial sounds of 15 mins or longer, often for multiple hours. These sounds, with A-weighted SPLs over 100 dB re 20 μPa, elicited shifts of 40–50 dB with recoveries considered as acceptable after 2 or more days (Miller et al. 1963) and in some cases up to 1 month postexposure. These studies typically induce larger initial TTSs than are reported for marine mammals exposed to underwater sound and, similarly, have complete recovery times that are longer for these larger shifts. It is also noted in Price and Kalb (2018) that at the very highest exposure levels recovery is delayed and often results in PTS (Hamernik et al. 1987; Luz and Hodge 1971; Price 1983).

Key points of consensus that have emerged across experiments in multiple mammal species about the nature of threshold shift risk are as follows:

**Risk of noise-induced hearing loss**: (a) Damage is roughly proportional to total sound energy (duration X intensity); (b) intermittent exposures are less dangerous than continuous; (c) low frequencies are generally less dangerous than higher frequencies at similar sound levels; (d) narrow-band sounds are more dangerous than broad-band; and (e) large inter-subject variability in noise resistance (susceptibility to TTS/PTS).

**Growth, recovery, and pattern**: (a) Hearing loss deteriorates to an asymptote during continued exposure; (b) recovery begins after termination of the exposure; (c) above a certain "critical level," hearing loss grows more rapidly; (d) hearing can recover over long periods (up to 1 month postexposure, possibly even longer); (e) the maximum TS due to narrow-band sound exposure occurs near the exposure center frequency at lower SPLs; (f) the frequency with maximum TS shifts upward in frequency to about 1/2 octave above (and sometimes even higher) the exposure center frequency with increasing SPLs; and (g) the maximum TS due to sound exposure that is broad-band compared to the hearing range occurs at mid frequencies within the hearing range.

## Mechanisms for Hearing Loss and Recovery Due to Impulsive Sound Exposure in Terrestrial and Marine Mammals

Mechanisms for TTS and PTS have been reviewed in several studies (Nordmann et al. 2000; Heinrich and Feltens 2006; Ryan et al. 2016; Kurabi et al. 2017; Liberman and Kujawa 2017). These indicate several key observations: (a) Different mechanisms underlie TTS and PTS; (b) different mechanisms may mediate TTS; (c) hair cells of the organ of Corti are the most vulnerable to permanent noise damage; (d) most PTS (>50 dB loss) is due to damage to the stereocilia of the hair cells; (e) severe TTS causes little overt pathology: changes are submicroscopic; (f) inner-hair cell (IHC) damage results in loss of transduction; outer-hair cells

(OHC) damage raises thresholds; and (g) hair cell loss leads to retrograde neuronal death over time.

Clearly, mechanisms underlying TTS must be to some extent recoverable. Many of these are still being investigated. The majority of the mechanisms that are considered to be related are fatigue, swelling, buckling, or recovery of structures that are submicroscopic, such as the fine hair-like projections atop the hair cells (stereocilia) and strands between them (tip-links) (Heinrich and Feltens 2006; Liberman and Kujawa 2017; Ryan et al. 2016).

Mechanisms that produce PTS related with permanent damage to hair cells, or their afferent neurons, are likely mediated by biochemical processes that occur within the cells themselves (Liberman and Kujawa 2017; Kurabi et al. 2017). One recent hypothesis for noise-induced PTS is that an excess of glutamate in the system produces "excitotoxicity" and an imbalance of calcium ions that are fundamental to degeneration of inner ear structures observed after noise exposure (Kujawa and Liberman 2009; Liberman and Kujawa 2017).

In the case of blast exposures, in addition to the potential for immediate mechanical destruction of some ear structures (dislocation of ossicles, blow-out of inner ear membranes), the exceptional peak levels of the associated sound wave can produce acute damage to inner ear components, such as disruption of hair cells, stereociliary arrays, and supporting cells, with collateral damage to adjacent cells from the flood of intracellular fluids (Liberman and Beil 1979; Slepecky 1986; Patuzzi et al. 1989; Kurabi et al. 2017). These processes all result in PTS.

Sound exposure at levels that are low enough to not cause or contribute to TTS (a concept known as "effective quiet") has been investigated primarily in humans (Ward et al. 1976). Effective quiet has not been measured in marine mammals (Finneran 2015). Due to the lack of data on effective quiet, current models tend to accumulate all exposures over a long period (e.g., 24 h), which may result in an unrealistic high accumulated exposure.

## Self-Suppression of Hearing Sensitivity

Several papers (e.g., Nachtigall and Supin 2013, 2014; Nachtigall et al. 2018; Finneran et al. 2015; Finneran 2018) have reported the ability of trained, captive odontocetes of several species to reduce their auditory brain stem response to loud sounds. These studies have documented the "self-mitigation" response in these species but were not geared to identifying explicit mechanisms resulting in the onset and control involved in diminishing the auditory response.

Any one or a combination of mechanisms (such as an efferent reflex or stapedial reflex), simultaneously or sequentially, are feasible for marine mammals based upon the current knowledge of their highly developed auditory structures that contain all of the components known to be involved in reducing sensitivity to sound in other mammals.

## Models for TS Onset and Growth of Intermittent and Impulsive Sound Exposures

### Equal Energy and Frequency Weighting

In a recent review of TTS studies on marine mammals, Finneran et al. (2015) summarizes the empirical models for predicting the TTS growth of intermittent sound exposures and how these apply to marine mammals. The review discriminates between two types of models: "exposure summation" methods and "TTS summation" methods.

The most common exposure summation method used is the "equal energy" rule in which the TTS-onset is solely dependent on the cumulative (frequency-weighted) sound exposure level (SELcum), regardless of how the exposure is distributed over time. This method does not account for potential recovery between exposures. An equal energy rule is currently used widely to predict noise-induced hearing loss for humans (NIOSH 1998) and forms the basis for marine mammal exposure criteria (Southall et al. 2007; Finneran 2016; Southall et al. 2019). In these cases, to account for differences in the frequency sensitivity of marine species, a frequency weighting is applied to the sound exposure level, which emphasizes the increased risk of hearing loss at the frequencies of best hearing (Finneran 2015; Houser et al. 2017). Frequency weighting was first proposed by Fletcher and Munson (1933) for variations in the perception of loudness of low-level sounds rather than a relation to susceptibility to damage. Over the years, A-weighting (one of five weightings for humans developed for different sources) has become a standard for estimating workplace exposures, with trade-off of time versus intensity. The appropriate use of frequency weighting is still debated for impulse sound (Finneran 2015; Houser et al. 2017) as well as the applicability to nonhumans exposed to a variety of sound sources, although it is lately being applied in marine mammals (Southall et al. 2007, 2019).

### Modified Power Law Growth and Recovery During Intermittent Exposures

For humans, equal energy models do not explain the differences in TTS between continuous and intermittent noise exposures, which is likely because these models fail to account for recovery. The modified-power law (MPL) model has been proposed for predicting TTS growth or over multiple exposures (induced either by sound, or by medicine). This "TTS summation" method has been shown to provide good agreement to experimental data for human and terrestrial mammals after exposure to intermittent sounds (Ward 1973; Humes and Jesteadt 1991; Macrae 1993, 1994). In this model, the TTS from individual exposures is raised to some power, and it also can account for recovery between exposures (Finneran et al. 2010; von Benda-Beckmann et al. 2022). The MPL model proposed by Humes and Jesteadt (1989) is

$$\left(10^{\frac{T_N}{10\ \mathrm{dB}}}\right)^P = \left[\left(10^{\frac{T_1}{10\ \mathrm{dB}}}\right)^P + \left(10^{\frac{(T_{N-1}-T_r)}{10\ \mathrm{dB}}}\right)^P - 1\right], \quad (1)$$

with $T_N$ the amount of TTS induced after $N$ exposures, $T_{N-1}$ the TTS caused by the ($N$-1)-th exposure, and $T_1$ the amount of TTS induced by a single exposure. The recovery term $T_r$ represents the amount of recovery of TTS that occurred since the (N-1)-th exposure (Finneran et al. 2010), and $P$ is a compression term. For humans, the factor $P$ was found to lie in the range of 0.1–0.3 (Humes and Jesteadt 1991).

Finneran et al. (2010) showed that the model can be used to fit TTS growth in dolphins exposed to intermittent tonal noise. They found a best fit of P=2.4 in dolphins (Finneran et al. 2010). In section "Adapted Modified Power Law Model," the possibility is explored of applying the MPL model for predicting growth of TTS in a harbor porpoise due to intermittent exposures, with relatively short intervals (10–20 s), such as those used in air-gun or sonar operations.

### Mechanical Models for Modeling Auditory Injury from Impulse Sounds

Models of the mechanics of the middle and inner ear exist that relate acoustic stimulation to hearing damage in humans and cats (Price 2007a; Zhang and Gan 2011; Zagadou et al. 2016; Walilko et al. 2019). The US Army Auditory Hazard Assessment Algorithm for Humans (AHAAH) model (Price 2007a, b; Price and Kalb 2018) was developed specifically to estimate permanent hearing loss (PTS) from shot noise and blasts in humans (with derivative modeling in cats).

The AHAAH model assumes that the risk from loud impulse sounds is related to the number of upward deflexions of the basilar membrane (which is assumed to put the stereocilia tip links of the hair cells in tension, which Price and Kalb (2018) speculated to be the most likely mechanical failure mode). Frequency-dependent displacement of the basilar membrane is computed using an electric analogy that models the outer ear, middle ear, and inner ear. The model also includes two nonlinear elements: middle ear muscle response (stapedial reflex) and peak-clipping due to the limited dynamic range in displacement allowed in the middle ear (displacement of the annular ligament of the stapes).

The AHAAH model expresses the hazard in terms of Auditory Risk Units (ARU), which are defined as the sum of the maximum amplitude squared of the upward displacement $D$ (in μm) of the basilar membrane for each cycle $\mathrm{ARU} = \sum D^2$, which are summed over all cycles (interval between zero crossings). The maximum ARUs over all frequencies were found to be related to the amount of compound threshold shift (CTS – amount of hearing threshold shift observed which may be combination of TTS and PTS) observed at 30 minutes after exposure in cats by

$$\mathrm{CTS} = 26.6 \ln\left(\frac{\mathrm{ARU}}{1\mu\mathrm{m}^2}\right) - 140.1 \tag{2}$$

For these intense stimuli that result in mechanical damage, the amount of CTS also has a linear relation to the amount of PTS induced and hair cells lost, according to Price (2006), who found that approximately 60–80% of the CTS would become PTS (Price and Kalb 2018). Note that this can be rewritten as

$$\mathrm{CTS} \approx 10 \log_{10} \left( \frac{\sum_{\mathrm{cycles}}^{\square} D^2}{1 \mu \mathrm{m}^2} \frac{1}{10^{\frac{140.1}{60}}} \right)^6 \mathrm{dB}, \tag{3}$$

Hence, the combination of two exposures, causing $\mathrm{CTS}_1$ each, will generate a combined $\mathrm{CTS}_2$ of

$$\left(10^{\frac{\mathrm{CTS}_2}{10\ \mathrm{dB}}}\right)^{\frac{1}{6}} = \left(10^{\frac{\mathrm{CTS}_1}{10\ \mathrm{dB}}}\right)^{\frac{1}{6}} + \left(10^{\frac{\mathrm{CTS}_1}{10\ \mathrm{dB}}}\right)^{\frac{1}{6}}. \tag{4}$$

This equation is therefore essentially a modified power-law relation, with $P = 1/6 \sim 0.16$, which lies well in the range of $P$ values observed in humans (Humes and Jesteadt 1991). This suggests that a MPL model can also apply to impulsive sound exposures. However, the exposures to continuous and impulse sound may have different growth and recovery mechanisms, so the same set of parameters are not expected to explain both TTS growth from exposures with continuous and impulse sounds.

The ARUs have shown to better predict risk of CTS than growth models based on the equal energy rule for frequency-weighted sound exposure level (see Price and Kalb 2018). The AHAAH also accurately predicted the frequency-encoding locations along the basilar membrane that were affected by hair cell loss in cats (Price 2003; Price and Kalb 2018).

A practical drawback of this AHAAH model is that it is complex and consists of 69 parameters and relies heavily on knowledge on middle ear and inner ear properties, which have been well studied in cats and humans, but are currently less well established for many marine mammals (e.g., Miller et al. 2006; Ketten 2000; Tubelli et al. 2012, 2018; Tubelli and Ketten 2019).

## Recovery Models

The form and degree of recovery depends considerably on the underlying mechanism for TTS growth. The dominant mechanism for the observed TS may change according to the type and degree of exposure (differently for SPL or exposure duration). That is, if the TTS is caused by tip-link breakage, it is time for tip-link to regenerate. For longer duration exposures, an alternative recovery mechanism may be the regulation of chemical processes related to excitotoxicity that lead to damage. It is likely that several mechanisms operate simultaneously, with relative importance changing with exposure conditions, making it impractical at this stage to create a bottom-up predictive model for the recovery.

There have been some developments in describing the exponential short-term (timescales of few milliseconds) adaptation of hair cells (Charasse et al. 2003; Zylani et al. 2009), sometimes also power-law relations used for modeling the long-term (timescales of 10s of seconds) adaptation of discharge rates in IHCs (e.g., Zylani et al. 2009). However, so far these recovery models deal with saturation of hair cells

and the resulting forward masking (brief elevation of hearing thresholds after sound stimulation, i.e., Harris and Dallos 1979) and do not incorporate the effects of noise overexposure.

Recovery of TTS is typically measured on timescales of minutes to hours, or even longer (depending on the elicited TS). It is generally found that one or a combination of logarithmic decay functions can properly describe the recovery of TTS with time (Ward 1960; Finneran 2015). Melnick (1991) notes that when expressed in terms of the ATS, the percentual change follows an exponential function, as $TTS(t) = ATS \cdot \exp.(-t/\tau)$. Short-term recoveries of OHC responses on the timescales of hundreds of milliseconds to seconds have been measured indirectly using cochlear microphonics (CM) techniques (Price 1974), suggesting that a logarithmic recovery with time may be appropriate for these small timescales. However, it has been debated to what extent CM techniques directly measure the OHCs activity (e.g., Perez et al. 2007).

### Summary

Figure 1 represents the key mechanisms that are involved in the occurrence and mitigation of hearing loss induced by sound exposure. Mechanisms underlying TTS can affect both the structure and integrity of the inner ear, producing changes in hair cell responsivity, possibly through alterations of the stereocilia (e.g., broken tip-links), through intracellular chemical changes affecting synaptic transmissions at the base of hair cells and alterations in hair cell conformation with swelling and degeneration of synaptic ribbons that transmit electrical signals from the cochlea to the brain.

The summary of mechanisms underlying TTS and PTS presented here served to show the complexity of the mechanisms for TTS growth, and recovery. Although significant advances have been made in the understanding of these processes in humans and terrestrial mammals, the exact functioning is still not well understood. It is likely that several mechanisms are at play with changing importance depending on exposure duration (metabolic exhaustion) and increasing sound pressure (mechanical fatiguing). This makes it not yet feasible to make a direct link to biomechanically motivated growth and recovery functions. For this reason, the next sections explored the MPL model to empirically relate sound levels to TTS growth for different exposure conditions.

## Adapted Modified Power Law Model

### TTS Growth from Individual Exposures, and Timescale for TTS Growth

For the MPL model (Eq. 1) to be useable, the amount of threshold shift caused by a single exposure $T_1$ and the recovery of the threshold shift at the time of the next exposure $T_r$ need to be measured directly (Humes and Jesteadt 1991;

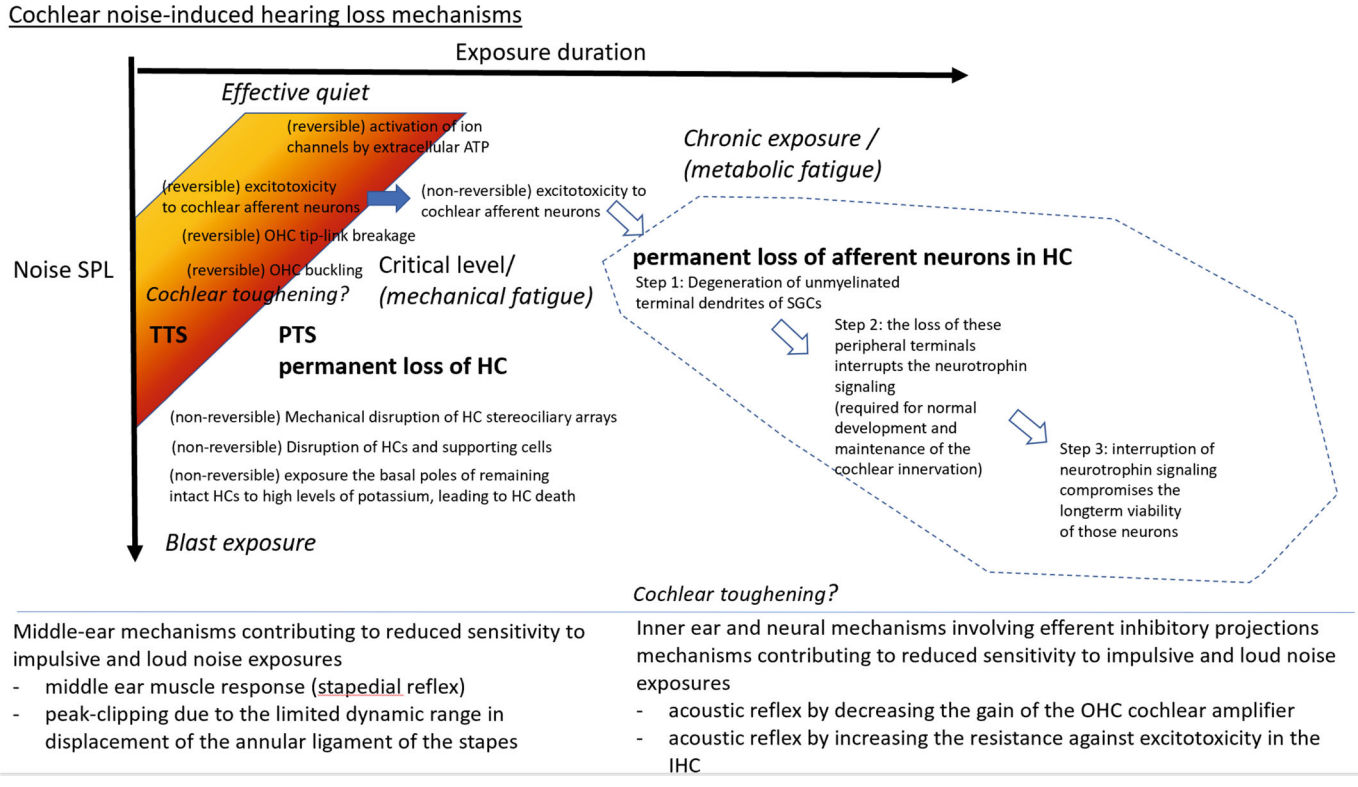

**Fig. 1** Schematic summary of underlying mechanisms causing noise-induced TTS and PTS and their dependencies on the level of the noise and exposure duration, and middle ear and inner ear mechanisms that mediate hearing sensitivity and vulnerability of animals

Finneran et al. 2010). However, in the case of harbor porpoises exposed to repeated, intermittent air-gun and sonar sounds, TTS was only measurable after multiple exposures (Kastelein et al. 2014a, b, 2015, 2017); hence, $T_1$ could not be directly measured. A second challenge was that seismic, piling, and sonar exposures typically have short repetition times, in the order of 5–20 s. Recovery rates at those timescales are hard to measure directly (see section "Recovery Models"). In order to make use of Eq. (1), therefore, variables $T_1$, $T_r$, and $P$ were estimated by fitting the model to data of TTS measured after multiple exposures. To allow such a fit, relationships between exposure conditions and TTS growth and recovery have to be hypothesized.

The MPL model describes how to add the threshold shifts caused by individual exposures, but it does not specify what causes the TTS. Exposure durations differ between the stimuli considered here (few 100 milliseconds to seconds for intermittent air guns and sonar) and become somewhat arbitrary defined for continuous noise exposures. It is therefore not obvious what constitutes the "single exposure" that is added by the MPL model. In this study, harbor porpoise TTS data was used to explore whether the MPL model can be generalized to exposure conditions with arbitrary duty cycles, by representing a continuous sound exposure as a series of consecutive "sub-exposures" with a 100% duty cycle (i.e., no recovery between subexposures).

In the proposed adapted MPL model, the measured exposure is related to its contribution to the TTS growth ($T_1$ in the MPL model) on a chosen unit reference timescale $t_{ref}$ (Fig. 2). In principle, the exposure can be quantified in different ways, e.g., either SEL within this timescale, but other parameters such as the peak sound pressure level or SPL could be used as well. For instance, the AHAAH model (section "Mechanical Models for Modelling Auditory Injury from Impulse Sounds") relates the CTS growth to the maximum displacement of the basilar membrane, which is likely more related to the frequency-weighted sound pressure measured in a smaller frequency band over the relevant timescale of the hearing system.

Several studies showed that the TS typically increases exponentially with SEL (Finneran 2015). Therefore, the amount of additional TTS induced was related to the sound exposure level, $L_{E,p,1}$, measured on a short reference timescale $t_{ref}$ using the following relationship,

$$T_1 = a \log_{10}\left(1 + 10^{\frac{L_{E,p,1}-b}{10\ \mathrm{dB}}}\right), \tag{5}$$

with parameters ($a$, $b$) to be fitted from data.

A time duration for the individual intermittent exposures in the continuous sound needs to be chosen. Possible options would be to use a timescale related to the hearing integration time, or shorter timescales such as the dynamic timescales of neurons (~ 1.4 ms, as in Zylani et al. 2009), or per cycle of the basilar membrane (BM) vibrations as in the AHAAH model (Price 2007a). Here, the integrated energy within the integration time of the mammalian auditory system was considered as the base unit of exposure. For this, an approximate average of the measured integration times for signals below 10 kHz: $t_{ref} = 200$ ms (Kastelein et al. 2010) was adopted.

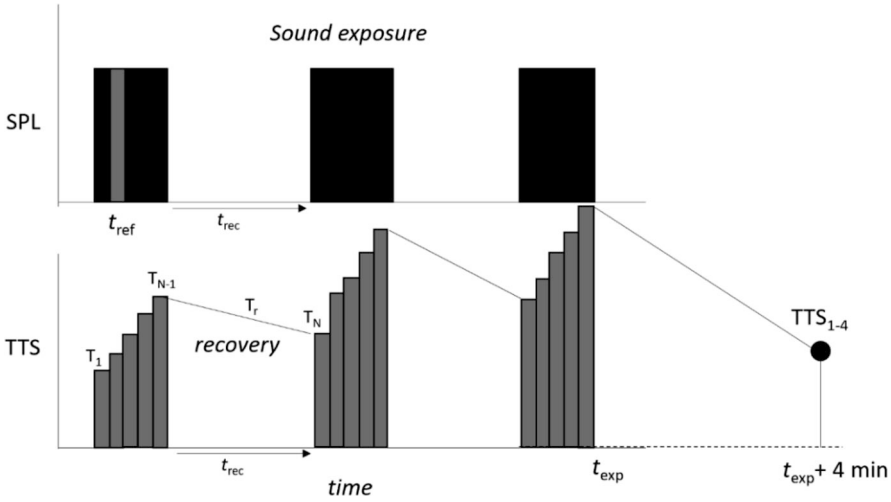

**Fig. 2** Schematic representation of the TTS growth model for an intermittent sound exposure based on the adapted MPL model. The model considers a unit reference time ($t_{ref}$), over which the contribution to TTS is computed, which are summed over multiple time units using the MPL model (Eq. 1) resulting in the measured $TTS_{1-4}$ (black circle). The TTS is assumed to recover during the silence periods of duration $t_{rec}$ between individual exposures

$L_{E,p,1}$ is the sound exposure level within that time window (Fig. 2). The effect of choice of reference timescale is discussed in section "Discussion."

## Compression Factor *P* in the MPL Model

In this analysis, a range of possible compression factors were considered in the range of $P = 0.1$ to 3 (the observed range for human TTS studies, Humes and Jesteadt 1991) and dolphins (Finneran et al. 2010).

## TTS Recovery Between Exposures

For the recovery term between pulses, a single logarithmic decay with time after exposure was assumed, with decay rate $m$ that was dependent on total amount of TTS caused by previous exposures (as generally observed in marine mammals, Finneran 2015):

$$T_r = m \log_{10}\left(\frac{t_{rec}}{t_{ref}}\right) \text{dB}, \qquad \text{for } t_{rec} \geq t_{ref} \tag{6}$$

$$T_r = 0 \text{ dB}, \qquad \text{for } t_{rec} < t_{ref}$$

with $m = c_1 \cdot T_N + c_2$, $t_{ref} = 0.2$ s, and $t_{rec}$ the duration of silence between exposures. It was assumed that no recovery occurred for consecutive exposures periods when signal durations exceeded the integration time of the unit exposure ($T_r = 0$ dB). After the final exposure, $T_r$ was computed for a period of 4 min (up to the point at which TTS was measured) (Fig. 2). Here the parameters ($c_1$ and $c_2$) were obtained from fitting the model to TTS growth data.

### Fitting of the Adapted MPL Model

Statistical model fitting (Eqs. 1–3) was carried out using Bayesian inference, with a Gibbs sampling routine (in JAGS through R), and the model was fitted to the 1–2 kHz exposure data alone. Uniform priors were used for the estimated parameters: P ~ uniform (0.1, 3); a ~ uniform(0.0001, 1); b ~ uniform (140, 180); c1 ~ uniform (0, 0.01); and c2 ~ uniform (0, 0.01). This dataset was used because it had the widest range of exposure conditions at fixed exposure frequencies. The model predictions based on TTS 1–2 kHz exposures were compared to the TTS measurements for exposures to 6–7 kHz sonar, air-gun, and pile-driving sound.

## Results

### Fit of the MPL Model to 1–2 kHz Sonar Data

The fitted MPL model resulted in reasonable predictions of the growth functions for the 100% and 10% duty cycles, and for the varying duty cycle (Fig. 3). The lower growth rates for 10% duty cycle, as well as the similar growth rates for different exposure conditions (combinations of SPL and exposure duration), were predicted with the MPL model. Posterior mean estimates of the MPL model parameters (Fig. 4 and Table 1) resulted in a compression factor $P = 0.31$.

### Comparison with Other Exposure Types

After the model was fitted to the 1–2 kHz sonar data, it was investigated how well it could predict TTS growth induced by different frequency exposures.

#### Sonar Exposure (6–7 kHz) (Kastelein et al. 2015)

Kastelein et al. (2015) showed that the 6–7 kHz sonar signals induced a maximum TTS at 9.3 kHz. When compared to this TTS data (measured at 9.8 kHz; Kastelein et al. 2015), the model predicted lower growth than observed, especially for the continuous sound exposure (Fig. 5).

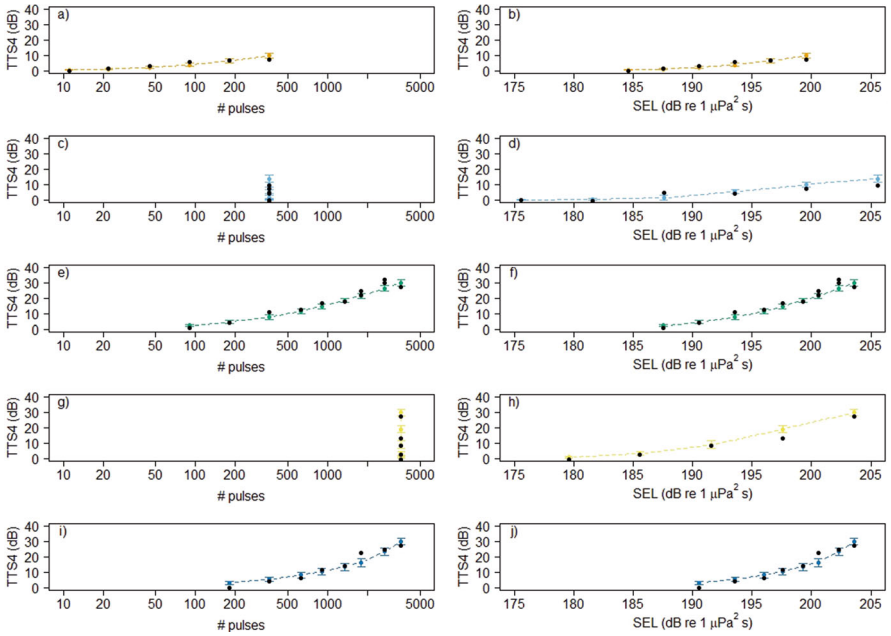

**Fig. 3** Measurements (black) and model predictions (color; posterior mean estimates with 95% credible intervals) of TTS growth as a function of number of pulses (left) and SELcum (right) for various exposure conditions: intermittent (panels a-b, e-f, and i-j) and continuous sonar exposure (panels c-d, g-h) using either fixed SPL (168 or 174 dB re 1 µPa) or varying SPL. Exposure signals were 1-s duration 1–2 kHz HFM down-sweeps, with 5–100% duty cycle). (Data from Kastelein et al. 2014a)

## Impulsive Sound Exposures

The adapted MPL model was applied to TTS growth data obtained for porpoises exposed to piling playback sounds for periods of 15–240 minutes (Kastelein et al. 2016). The low growth with exposure duration as observed in Kastelein et al. (2016) is predicted using the exposure model from Eq. 1, although the predicted TTS levels are somewhat lower (Fig. 6). The MPL model was compared to TTS growth measurements obtained for porpoises exposed to 1–10 air-gun exposures (Kastelein et al. 2017). When comparing the model predictions to the TTS measurements at the frequency with the highest TTS (4 kHz), the model fitted to the 1–2 kHz sonar TTS growth predicted smaller TTS than those observed for air-gun exposures (Fig. 6).

## SEL Predictions at TTS Onset as Function of Exposure Duration

Interestingly, the MPL model predicted that the SEL onset threshold for TTS (6 dB) was dependent on the exposure duration, both for intermittent as well as continuous sound exposure (Fig. 7). This appears similar with an observation for dolphins

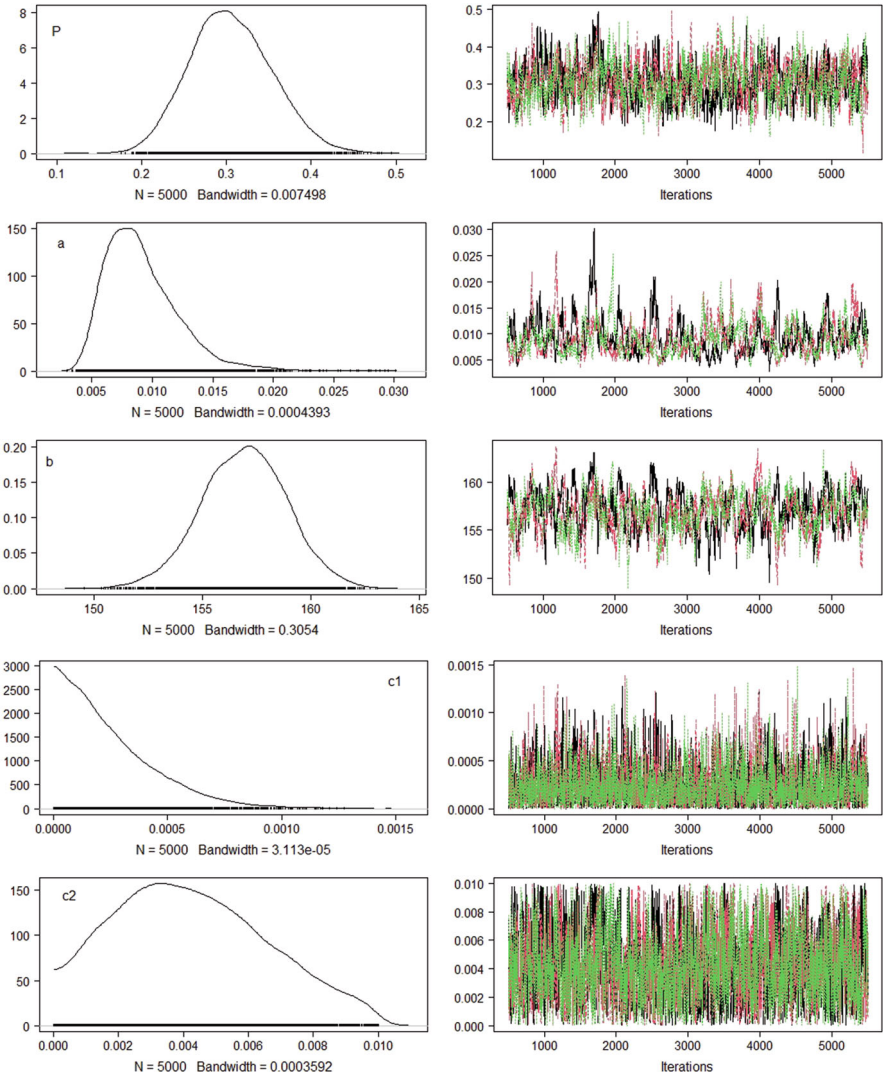

**Fig. 4** Posterior probability distributions (left) and trace plots (right) for parameters in the MPL model fitted to the TTS growth data for 1–2 kHz (LFAS) continuous and intermittent sonar. The model was fitted using Bayesian inference with a Gibbs sampling routine

exposed to sonar sound, where the SEL onset threshold appeared to decrease with increasing exposure duration (Mooney et al. 2009). For shorter duration exposures, thresholds for TTS onset were predicted to be higher, but for longer duration exposures, the model converged to an equal-energy rule (constant SEL, independent on duration over which the SEL was delivered).

**Table 1** Statistics of the estimated posterior probability distributions (mean, standard deviation (SD), and 25 and 75 percentiles) for the parameters of the adapted MPL model fitted to the 1–2 kHz sonar TTS growth data

| Model parameter | Mean | SD | 25% | 75% |
|---|---|---|---|---|
| $P$ | 0.31 | 0.05 | 0.27 | 0.33 |
| $a$ (dB) | $9.1 \times 10^{-3}$ | $3.1 \times 10^{-3}$ | $6.9 \times 10^{-3}$ | $1.1 \times 10^{-2}$ |
| $b$ (dB) | 157 | 2.0 | 156 | 158 |
| $c_1$ | $2.6 \times 10^{-4}$ | $2.1 \times 10^{-4}$ | $8.9 \times 10^{-5}$ | $3.6 \times 10^{-4}$ |
| $c_2$ | $4.3 \times 10^{-3}$ | $2.3 \times 10^{-3}$ | $2.5 \times 10^{-3}$ | $5.9 \times 10^{-3}$ |

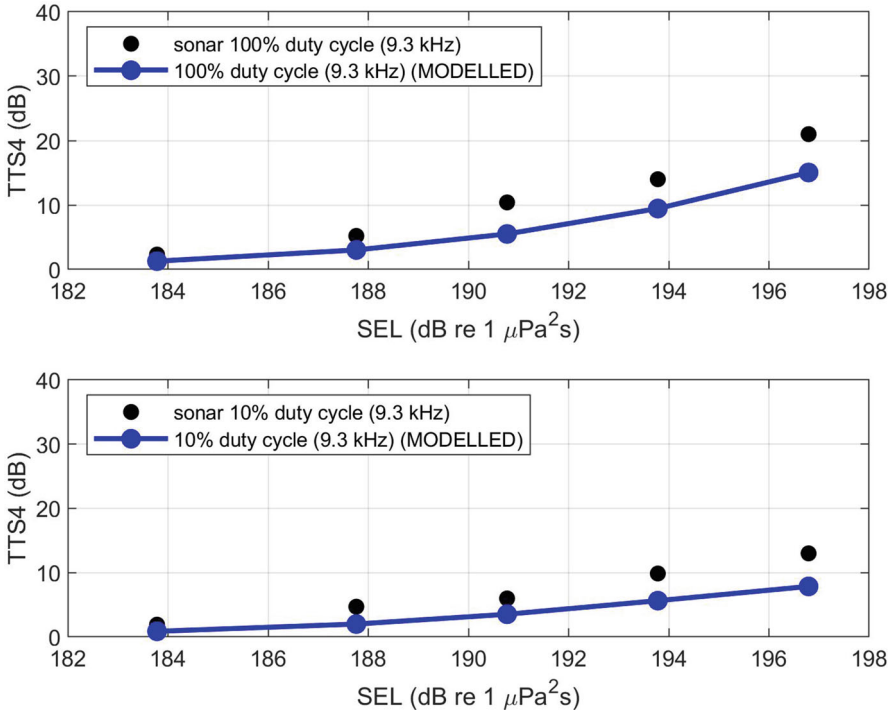

**Fig. 5** Posterior mean predictions of the MPL model fitted to 1–2 kHz sweeps (blue) compared to observations of TTS growth for 6–7 kHz sweeps (Kastelein et al. 2015) and continuous (top; black) or intermitted exposure at 10% duty cycle (bottom; black)

## Discussion

Based on the literature review, the modified power law (MPL) model was explored as a model for TTS growth in different exposure conditions, as it allowed for accounting for recovery of TTS between exposures.

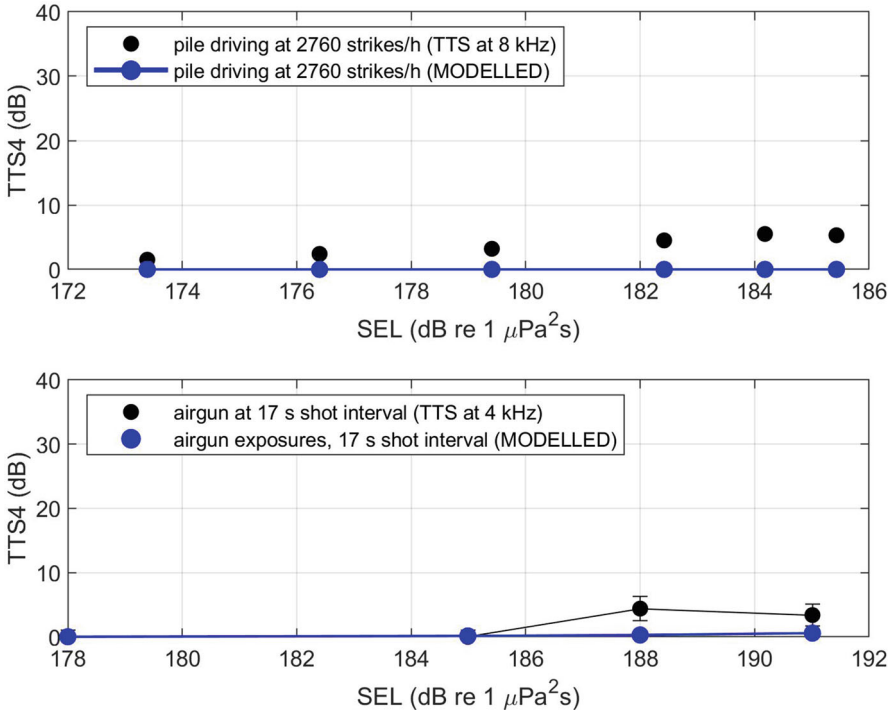

**Fig. 6** Top: predictions of the adapted MPL model for TTS growth for pile-driving exposure (blue) compared to observed TTS growth from Kastelein et al. (2016), using the parameters fitted to the 1–2 kHz sonar growth rate data (Table 1). That study used an average broadband SELss = 145 dB re 1 μPa$^2$s for each exposure, and a duty cycle of 2760 strikes per hour (i.e., exposure duration determined SELcum). Exposure durations ranged between 15 and 240 minutes. Bottom: posterior mean predictions using the MPL model (blue) for TTS growth compared to air-gun exposure (up to ten shots with a double air gun, Kastelein et al. 2017) with mean duty cycle of 17 s

In this study, an adaptation to the MPL model was proposed such that it could be applied to porpoises exposed to intermittent and continuous sound exposures, to investigate whether it explained differences in TTS growth for exposure durations and exposure sound pressure levels (SPLs). The objective was to fit these growth functions to harbor porpoise data in which animals were exposed to intermittent and continuous sonar sounds. This study built on the MPL as applied for bottlenose dolphins by Finneran et al. (2010), by considering observed generic relationships of TTS growth and recovery rates with exposure conditions (Finneran 2015) and then parameterizing these relationships and fitting them to available harbor porpoise data. For this purpose, the original MPL model needed to be extended to make it generally applicable to a wide range of exposure conditions (intermittent as well as continuous).

The success achieved in this study was that the model could match the growth of a reasonably sizeable dataset of TTS growth in porpoises for sonar sounds. However,

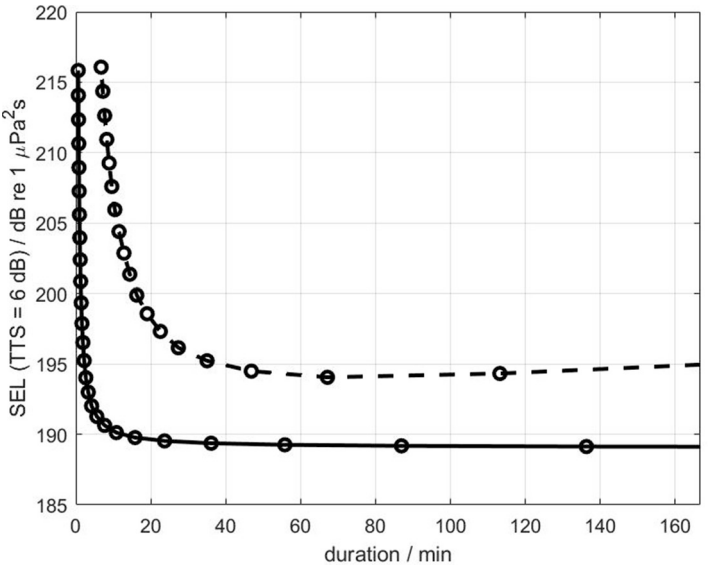

**Fig. 7** Posterior mean prediction of the SEL TTS onset (TTS = 6 dB) threshold as a function of exposure duration for continuous (solid line) and 1 s sonar transmissions at 10 s intervals (dashed).

the modeling results presented in this section should be considered with some caution and only as a first attempt to combine and compare intermittent and continuous exposures of different types (tonal vs impulse) into one comprehensive model.

It was found that the model could reasonably predict TTS growth over a wide range of exposure conditions (SPL and duration) when fitted to a broad set of 1–2 kHz sonar exposures. However, the model underpredicted the growth of TTS observed for sonar at higher frequencies (6–7 kHz), as well as for impulsive air-gun and piling playback exposures. Given what is currently known about the response of mammalian ears to impulse sound and sensitivity at different frequencies, it is not surprising that the model-fit to 1–2 kHz sonar data does not yet yield a good fit to the air-gun and pile-driving TTS data.

The best-fitting compression factor P = 0.31 in the MPL model was found to be consistent with the range of values reported for humans (0.1–0.3, Humes and Jesteadt 1991; Price 2007), and the range of expected values based on the compressive mechanisms that are believed to underlie the growth mechanism. However, these numbers are smaller than $P = 2.4$ found to best explain the TTS growth for dolphins exposed to intermittent sonar sounds (Finneran et al. 2010).

According to Humes and Jesteadt (1991), the MPL model "maintains that threshold sound levels, or their corresponding sound intensities, are not themselves linearly additive. Rather, simple addition holds after the threshold has been nonlinearly transformed to a quantity corresponding to the internal effect associated with

the threshold-level stimulus." This "internal effect" referred to by Humes and Jesteadt (1991) can be interpreted as a reduction in sensitivity, or gain, and from an elevation of the baseline above which sound pressure becomes effective in driving the auditory system (Neubauer and Heil 2004).

There are different mechanisms that lead to a nonlinear relationship between input stimuli and hearing threshold shift. A compressive relationship exists underlying the process resulting in firing patterns of neurons (Heil and Neubauer 2010). Heil et al. (2011) demonstrated that the spike rates in auditory-nerve fibers (ANFs) (leading to perception of the sound) from the IHC on the SPL of acoustic stimuli follow a power-law of $R \sim P^{\beta}$. They find the best fitting value for $\beta = 3$ when the auditory system is driven linearly (i.e., low SPL). Such a relationship implies a $P = 1/3$ relationship in the MPL model. Heil and Neubauer (2010) argue that different relationships reported between the rate and sound pressure ($\beta = 1$–5) may be explained by saturation of neurons which leads to an apparent change in this relationship, which would imply a change in P. Another important factor that causes compression to occur is the amplification by OHCs (Robles and Ruggero 2001). The displacement of the basilar membrane, $D$, is nonlinearly related to the exposure SPL, $L_{p,exp}$, by $\log_{10}(D) \sim 1/B\ L_{p,exp}$ (Robles and Ruggero 2001). In different mammals (chinchillas, cats, and Guinea pigs), it is found that for low SPL the relationship is typically linear ($B = 20$), but for higher SPL the basilar membrane displacement scales with SPL are $B \sim 40$–$60$ (Robles and Ruggero 2001), and that $B$ also depends on the location along the basilar membrane, where compressive nonlinearity is stronger near the base (higher frequencies) and less near the apex (lower frequencies). This implies that the compression phenomenon along the BM is approximately $P = 1/3$ (for $B = 60$) to 1 (for $B = 20$). Since both mechanisms (compression by BM dynamics and the nonlinear relationship between BM displacement and neuron firing rates) can act at the same time. It can therefore be expected that the compression factor is not necessarily a constant, but may lie in the range of values for $P$.

To better understand the compression factor, TTS summation experiments (as in Humes and Jesteadt 1991), or two-tone masking experiments (as for Humes and Jesteadt 1989), should be carried out to independently establish the value of $P$ in porpoises.

Some adaptations could be considered in further development of the model. Currently, the SEL measured on the timescale of the hearing integration time (200 ms) was considered to contribute to the TTS growth in the MPL model. The choice of reference time will have a different effect on how much the sound on this timescale adds to the TTS growth (Eq. 4.2). For the continuous 1–2 kHz sonar exposure with constant SPL, the choice of $t_{ref}$ (200 ms vs shorter timescales of 1.4 ms, corresponding to the dynamic timescales of neurons; Zylani et al. 2009) did not affect the TTS growth in the MPL model for the 1–2 kHz sound exposures. However, for impulse sounds such as pile driving and air guns with large variations in amplitude over short timescales (compared to the hearing integration time), as well as frequency of the sound exposure, the choice of a smaller $t_{ref}$ can lead to different TTS growth. Future studies should therefore consider the model sensitivity on adopted timescale for TTS growth in the MPL model.

Other exposure metrics describe the characteristics of the sound, such as frequency-weighted and band-filtered peak sound pressure on a shorter timescale, which more directly relate to the dynamics of the basilar membrane and may possibly better explain the difference between the TTS growth of different impulsive sounds and higher frequency sonar exposures. For instance, the AHAAH model (Price 2007a, see Sect. 2.4.4) assumes an increase in risk that is proportional to the number of cycles, and the amplitude of displacement of the basilar membrane. For high-amplitude sound, nonlinear effects within the ear can affect the amount of energy reaching the inner ear; hence, the time-dependence of the pressure waveform becomes relevant. Considering success of the AHAAH (Price 2007a) for predicting the TTS and PTS in humans and cats, it is worthwhile exploring the possibility to use biomechanical models (Tubelli and Ketten 2019) for predicting the dynamics of the basilar membrane, which according to the Price (2007a) model are a good predictor for hearing loss for loud impulse sounds. Such models will be informative for understanding the response of the porpoise hearing to impulse stimuli, which helps to inform and motivate appropriate frequency weighting functions for impulse sound and can be used to understand the role of middle ear responses on the sensitivity of porpoises to sound exposure.

The current model did not assume TTS growth rates from individual exposures to be frequency dependent. This may explain the slower predicted growth compared to the 6–7 kHz sonar exposure. Including a frequency weighting may help alleviate this mismatch, although recent measurements of TTS susceptibility at higher frequencies (Kastelein et al. 2019a, b) suggest that TTS growth may not grow faster at even higher frequencies, and hence the frequency dependence of TTS growth should be investigated further.

Currently, the posterior mean estimates of the parameters for recovery ($c_1$ and $c_2$) suggest a recovery rate on the timescales of the silences considered in this study (10–20 s) that is much smaller than the recovery rate extrapolated from observed longer timescale (minutes to hours) recovery in porpoises (see Kastelein et al. 2015; Finneran 2015). In principle, this is not unexpected, as the $\log_{10}(t / t_4 \text{ min})$ term that is typically fitted to long-term recovery (Finneran 2015) will diverge for small timescales, which seems physically unrealistic. Future approaches should aim to match the recovery relation from short scales to longer timescales in order to be consistent with measured recovery rates for longer timescales at which TTS is actually measured.

More measurements of TTS growth under different exposure conditions are clearly required to obtain more confidence in this model. The benefit of a model framework as the one presented here is that it allows to build hypothesis that can be tested. For instance, the model suggests a deviation from the equal energy rule for relatively short exposures (a few minutes), which can be tested experimentally. The model can also be applied to other species (such a delphinids) for which TTS growth information is available. However, there are likely some inherent limitations to the MPL model. For instance, in other species TTS sometimes shows a delayed growth (i.e., continued growth after the end of the exposure, e.g., Luz and Hodge 1971; Finneran 2015), and processes such as cochlear toughening (Hamernik et al. 2003), middle-ear responses, and afferent feedback are not explicitly included in this model approach.

## Conclusion

Based on the literature review, different possible approaches for incorporating the impulsive and intermittent sound into a generic TTS growth model were identified. An adaptation to the modified power-law (MPL) model was used to explain TTS growth data collected for harbor porpoises for intermittent and continuous sound exposures. The MPL model was considered a promising method to predict TTS growth in different exposure conditions, as it can include recovery of TTS between pulses. The model was adapted to apply to intermittent as well as continuous exposures, by cumulating the TTS over subsequent exposure periods at a timescale corresponding with the auditory integration time. The study explored how to apply the model to TTS growth in harbor porpoises.

Some adaptations were necessary to overcome two issues: (i) the TTS induced from single exposures were too low to cause observable amounts of TTS; (2) recovery on the timescales of the shot interval was not directly measurable.

Based on generic parametric relationships between TTS and exposure parameters, the model was fitted to measure TTS growth in harbor porpoises. It was found that the model could reasonably predict TTS growth of intermittent and continuous 1–2 kHz (LFAS) sonar sounds over a wide range of exposure conditions but did not yet successfully explain the (limited) dataset of TTS growth for 6–7 kHz (MFAS) sonar and intermittent impulse sounds. Although the adapted version of the MPL model considered here should be considered preliminary, the reasonable fit to the observed data for a wide range of exposure conditions looks promising and should be explored further.

**Abstract**

Human use of aquatic environments is increasing, elevating ambient sound levels through the introduction of more man-made noise. The implications of marine mammal species being subject to increased noise levels can range from masking of ecologically important signals to injury and even death. Successful mitigation relies on characterizing the risk and understanding the level of disturbance on the focal species. Considering the noise-induced changes in effective conspecific communication and echolocation by cetaceans, for example, could be a useful metric for managers when considering both the level of effect and efficacy of control or prevention measures. The estimated reduction in range from a maximum, under minimum ambient or historical conditions, gives a means to quantify impact and make comparisons over time and space. This may add to evidence-based means to design and test mitigation measures aimed at reducing acoustic disturbance for cetacean species.

## Introduction

Underwater soundscapes are dynamic. The acoustic landscape of an area encompasses all the biological, geophonic, and anthropogenic noise sources in the area, which differ on temporal and spatial scales. Soundscapes are shaped by contributions of natural abiotic and biotic sounds and human-derived noise. Abiotic sources such as wind, waves, and precipitation contribute substantially to the ambient noise levels. Biological sources such as invertebrate choruses and whale calls also define an area's soundscape. Anthropogenic additions are quickly becoming a ubiquitous contribution to aquatic sound fields. Determining the components of a soundscape and the relationship between natural and human-derived noise is critical for understanding the impacts it may have on animals using the area (Pijanowski et al. 2011).

Increases in ambient noise levels in comparison to pre-industrial conditions have been reported globally. In areas particularly impacted by commercial shipping, increases in excess of 12 decibels (dB) have been reported in the low frequencies (Hildebrand 2009). This increase in noise is concomitant to an increase in size and number of vessels in the global merchant fleet. These inputs are focused around shipping routes, as well as in waters around coastal cities and near major ports which also experience greater tourist-based and recreational traffic (Andrew et al. 2002; Frisk 2012; New et al. 2015). Smaller, often non-commercial, vessels also contribute to the mid- to high frequencies.

## Anthropogenic Noise as a Stressor

Elevated underwater sound levels from man-made sources are increasingly being recognized as a stressor for marine mammals that use acoustics as their principal means to send and receive information. Acoustic cues, received passively or via the echo of the animals' own signals, guide orientation and navigation, aid foraging and prey capture, and maintain group cohesion or social contact. The ambient sound level forms the acoustic scene that is interpreted and determines the range over which acoustic signals are effective.

Elevation of ambient sound may elicit a physiological and/or behavioral response in individual animals or groups. The impact on the animal, and, therefore, to some degree the response, is dependent on the received characteristics of the sound. Aspects such as the frequency, duration, intensity/amplitude, area impacted, and whether the noise is impulsive or continuous can instigate different responses. A scale of possible responses and physical effects has been described (see Erbe et al. 2019; Southall et al. 2019; Southall 2021).

On an individual level, the increase in noise may initiate modified calling or swimming behaviors. These may include the cessation of important behaviors or habitat use, thus altering energy budgets; increased physiological stress; a change in hearing sensitivity; and physical injury, especially in the hearing apparatus, or, in extreme cases, lead to the death of the animal (Erbe et al. 2019; Southall et al. 2019, 2021). Richardson et al. (1995) suggested four zones of sound propagation that

describe the spatial extent of acoustic signals and the implications of disturbance. First, and the most spatially extensive, is the zone of audibility, which is the area within which a sound exceeds an animal's hearing threshold and is detectable above background noise. This has also been termed the animals' "reverberation space" (Clark et al. 2009) and could also encompass the zones of detection and discrimination described by Erbe et al. (2016). Next, the zone of responsiveness is the region within which a reaction to the sound may occur, this is where signal recognition and interpretation occurs (Erbe et al. 2016), and the receiver acts in the way that was intended by the signaler. The zone of masking (Richardson et al. 1995) reflects the area in which the exchange of biologically significant sounds could be impacted by external noise. Within this is the zone of hearing loss, discomfort, or injury, where the sound level causes a threshold shift or hearing damage. The extent of these zones depends on characteristics of the sound and its receiver, as well as acoustic transmission properties of the area (Richardson et al. 1995; Johnson and Tyack 2003).

Sub-lethal effects include noise interfering, or masking, acoustic signals that are being sent and received by marine mammals. Cues from conspecifics, prey, predators, and those used as navigational aids may be obscured (Simmonds et al. 2004; Erbe et al. 2016, 2019). The simultaneous presence of a noise at the same frequency as an animal's signals can reduce the efficacy of the signal, decreasing the range over which a call may be detected. For communication and socially derived calls, the foreshortening of the communication space (Clark et al. 2009; Hatch et al. 2012; Burnham et al. 2023) hinders contact calling between conspecifics. The calls, whistles, burst pulses, and "clicks," for example, which animals utilize in communication, are critical. This includes social calls used for cooperative behaviors, breeding, or mother-young recognition and reduces success of navigation, aggregation, group coordination, and foraging. Typical acoustic responses to noise by marine mammals are to call louder, longer, or more often (NRC, 2003). The Lombard effect describes the noise-triggered adaptation of signal production, drawing on the phenotypic plasticity of acoustics use in vertebrates, to increase the amplitude of call to try and overcome the interference (see Kunc et al. 2022). This response has been noted in several cetacean species (e.g., Holt et al. 2009, 2011, 2015; Dunlop et al. 2014; Guazzo et al. 2020; Helbe et al. 2020; Thode et al. 2020). Also, the timing and direction of calling can be modified to allow for spatial, temporal, or co-modulation masking release (Erbe et al. 2016). However, these strategies of altered or increased vocal output can alter energetics of calling, which can have fitness consequences for the individual.

The amplitude and frequency of the noise are pertinent for the masking calculations, but also the rate of onset, intensity, rise time, length of exposure, repetitiveness, and spatial and temporal scale of the noise also shape the physiological response and whether it is seen on an individual or population level (Castellote et al. 2012). Near-distance and short-term reactions to acoustic disturbance have been described through observation and experimentation for several marine mammal species. These include longer dive times, shorter surface intervals, evasive movements to shield young, and increased swimming speed (e.g., Norris 1994; Gordon and Moscrop 1996; Frankel and Clark 1998; Croll et al. 2001). Avoidance behaviors

and displacement from critical breeding, rearing, and feeding areas have also been attributed to noise exposure. Marine mammals have changed vocalization rate and composition in response to noise. Alteration in call patterns includes frequency shifts, changes in energy levels of vocalizations, or making signals longer or more repetitive (e.g., Nowacek et al. 2007; Weilgart 2007; Tyack 2008; Rolland et al. 2012; Janik 2014). Modulation in the timing and directional components of calls has also been noted, with animals seeking temporal or spatial masking relief mechanisms by calling when noise levels are reduced or in orientations away from the source (Erbe et al. 2016). In some cases, calling can cease for extended periods (weeks to months), which may have serious behavioral implications.

Anthropogenic additions to ambient noise have been listed as a key threat to marine mammal populations and one of the factors that could hinder their success, survival, or recovery (see Weilgart 2007). For animals that rely so heavily on sound, the implications of masking, one of the lesser impacts of increased noise levels, have wide-ranging implications for both immediate- and long-term survival by reducing the ability to send and receive important information (Holles et al. 2013; Wale et al. 2013; Voellmy et al. 2014).

## Masking as a Metric

Noise additions can partially or fully reduce the audibility of signals over extensive spatial scales, where even a remote noise source could obscure a faint signal (Erbe et al. 2022). Although masking is a sub-lethal effect, it could underlie the behavioral and calling modifications noted in response to noise introductions. It reduces the capacity for cetaceans to communicate with conspecifics (e.g., Blackwell et al. 2013) and to gather acoustic information that could enhance their long-term success and survival (e.g., Holles et al. 2013; Wales et al., 2013; Voellmey et al. 2014). The extent of the masking is dependent on the spectral, temporal, and spatial relationship between signal and the masking noise (Southall et al. 2007).

In the absence of audiogram data, it is assumed that cetacean hearing is the most sensitive in the frequencies in which they call. Also, it is assumed that the impacts of masking will be highest in these frequencies, with noise sources interfering with the effective use of acoustic signals. Therefore, to be able to take the "whale perspective" (see Burnham 2017; Popper et al. 2020), frequencies pertinent to the focal species should be considered, with noise sources in these frequencies eliciting the greatest concern. This would mean considering the frequencies of calls in the species' full repertoire, from social conspecific calls to echolocation signals.

Conspecific communication calls transfer information between senders and receivers (Bradbury and Vehrencamp 2011). The range over which these calls are effective is defined by the distance over which they can be detected and acted upon by the intended receiver. The maximum range, however, is the distance over which these call types are discerned above minimal background noise levels. Echolocation range is determined by the distance over which a signal or "click" can be transmitted from a whale to a target and the returning signal be received at a level exceeding the

background noise and at an amplitude great enough to be both identified and interpreted. Masked echolocation signals and, therefore, the reduction of the echolocation range (Au et al. 2004) mean that the distance over which a signal can be transmitted and the returning signal be discerned and deciphered is reduced as a result of an obscuring noise. Both the communication and echolocation ranges are defined by the signal emitted and the ambient noise levels of the sound field that it is being projected into. The soundscape, therefore, defines the area or range over which these signals can be successfully employed.

The potential of a noise to be a source of masking can be estimated through empirical data. The calculations consider the co-occurrence of whales' calls and noise and the overlap between the signal and noise frequency and amplitude parameters. The change of effective communication or echolocation signals for a cetacean is expressed as a proportional reduction of the maximum range, calculated under historic, ideal, or minimum ambient sound levels as a reference (see Clark et al. 2009; Hatch et al. 2012; Burnham et al. 2023). This minimum sound level is used to describe the maximum range that communication calls and echolocation occurring in differing noise scenarios can then be expressed as a percentage of. Conveyed this way, masking becomes a metric of potential impact. This metric is a useful and intuitive means to express the impact of acoustic disturbance to managers and policy makers while taking an animal-centric approach. Calculating proportional rather than absolute changes allows comparisons over time and space. In this way, the masking metric could indicate areas most affected by the noise sources and where mitigation strategies are most needed. This expression of masking could also be used to represent the amount of time or space over which the whales are impacted by noise.

## Masking and Its Implications of Acoustic Disturbance

The masking effect on whale species from anthropogenic noise was first highlighted by Payne and Webb (1971) while considering the use of low-frequency calls by baleen whales to retain conspecific contact. The maximum range of 20 Hz fin whale (*Balaenoptera physalus*) calls was estimated under three noise scenarios. These were a moderate noise level, used to represent the low-frequency sound levels in the oceans at the time the work was undertaken when commercial shipping was active, and average and quiet pre-propeller ambient sound levels. These calculations showed substantial reductions in call range under the moderate noise compared to the quiet condition (Payne and Webb 1971). This study highlighted not only the importance of the acoustic modality to whales to retain their "herd" but also the impact that altered soundscapes can make on the efficacy of their calling. Further, Hatch et al. (2012) quantified the loss of communication space for the North Atlantic right whale (NARW, *Eubalaena glacialis*) at current shipping levels compared to pre-industrial ambient sound levels. This was defined by a difference of 10 decibels (dB) between the historic and current sound fields in the low frequencies where contact calls of NARW are focused (71–224 Hz; Urazghildiiev and Clark 2006;

Hatch et al. 2012). Recordings showed the ambient sound levels to be elevated up to 20 dB since the mid-twentieth century (Scheiefele and Darre, 2005; Hatch et al., 2008, 2009). This resulted in a 63–67% loss on average in area over which calls between conspecifics would be audible and a maximum of 87% lost communication space during noisy periods compared to the historic levels (Hatch et al. 2012).

For toothed whale species, the calculation of call range has refined researchers' perception of call function. Calculations by Jacobs (2019), for example, demonstrated that sperm whale (*Physeter macrocephalus*) coda calls were most likely used to communicate to nearby conspecifics as a within-group social display, rather than a longer-distance display of group membership which was the previously held presumed use (see Rendell and Whitehead 2003). This too can inform researchers on the social structure and group dynamics of odontocete species. The implications of commercial shipping noise on communication calls and echolocation signals for killer whales (*Orcinus orca*) have been shown by Burnham et al. (2023), comparing noise levels resulting from the current levels of commercial shipping to a derived minimum ambient sound level, where vessel and abiotic (wind and wave) noise is absent.

Both the work by Hatch et al. (2012) and Burnham et al. (2023) consider the implications of commercial shipping on an endangered whale species in ecologically important areas used for foraging. The focal areas of both works represent critical whale habitat, yet also have considerable commercial and recreational vessel traffic. Stellwagen Bank National Marine Sanctuary (SBNMS), the main area of the work by Hatch et al. (2012), is a highly productive area in the southern portion of the Gulf of Maine. The area is also, however, one of the most intensely used by commercial and recreational fisheries and encompasses the shipping lanes to Boston Harbor. Similarly, the Salish Sea, the waters around southern British Columbia and northern Washington State, the area of focus for the work by Burnham et al. (2023), sees commercial vessels transiting to ports in Vancouver, Seattle, Victoria, Nanaimo, Port Angeles, and Tacoma, and represents a major shipping corridor between Asia and North America. The shipping lanes in this area overlap greatly with known feeding areas for the endangered southern resident killer whales (SRKW). Whereas the work by Hatch et al. (2012) is a comparison over time, Burnham et al. (2023) use data from the same time period to look at the additions of noise from commercial vessels directly to the ambient soundscape. The principal consideration in this analysis was the potential implications to foraging behaviors resulting from these additions. By extending the calculations from purely reporting the difference in sound levels in decibels for these two conditions to a more biologically relevant metric, and expressing one as a proportion of the other, allowed Burnham et al. (2023) to empirically describe the acoustic disturbance to the whales in this area and discuss the change in soundscape in terms of its possible ecological impact.

Aggregate noise models using automatic identification system (AIS) vessel data and sound transmission models have shown that the Salish Sea and surrounding areas have the highest ambient noise levels along the British Columbia coast (Erbe et al. 2012). Commercial vessels and their rate of passage are consistent throughout the year, emitting persistent noise into the ambient sound field. Bulk carriers or

container ships are the most frequent vessels (Veirs and Veirs 2006; Erbe et al. 2012; Veirs et al. 2016), with each passage shown to elevate the sound levels approximately 20 dB re 1 μPa in frequencies below 10 kHz relative to ambient levels (Veirs et al. 2016). A similar, but more fine-scale, model than that used by Erbe et al. (2012) highlighted noise increases in the shipping lanes, in shallow water, and in regions where vessels turn or maneuver within the Salish Sea. This model also allowed the consideration of the changes in sound levels through the water column, considering typical swimming depths and diving depths of whales to be able to better understand their perceived soundscape. An upper water column estimate represented traveling behavior, a mid-water depth was used for prey search and capture depths, and 100 m reflected the maximum repeatable foraging dive depth for SRKW as logged by animal-borne tags (see Wright et al. 2017; Baird 2000, Baird et al. 2005; Tennessen et al. 2019a, 2019b). This allowed a more comprehensive understanding of the impacts of vessel noise on the whales feeding in this area. Changes in the sound levels in frequencies that reflected communication calls and echolocation signals were considered. Conspecific communication calls of SRKW include whistles (2–17 kHz; Ford 1989; Thomsen et al. 2001) and burst pulse sounds (1–15 kHz; Ford 1989) as social signals. These pulsed calls may also have modulated higher- or lower-frequency components (Miller and Bain 2000). The frequency range of 1–40 kHz was considered to encompass the full repertoire of social signaling among SRKW, with the distance possible for conspecific calling estimated from parameters and source levels described by Holt et al. (2009, 2011). Ultrasonic echolocation signals of SRKW in the 15–100 kHz range (Heise et al. 2017) are for foraging and navigation (Ford 1987, 1989, 1991). Au et al. (2004) previously considered the implications on echolocation from changes in sea state and the addition of abiotic noise. For their calculations, Au et al. (2004) used a 50 kHz echolocation signal to find a model average-sized chinook salmon (*Oncorhynchus tshawytscha*) under differing sea state and rain conditions. The same candidate frequency of 50 kHz, signal source levels, and target strength of the average chinook salmon were replicated from the definitions used by Au et al. (2004) to estimate the signal interference from commercial vessels (Burnham et al. 2023). Greater range reductions over a greater spatial extent were apparent for the communication call frequencies compared to the echolocation candidate frequency at each depth considered and through time. For the communication frequencies, reductions were greatest October to March, when sound transmission was most effective (Vagle et al. 2021). During this period, calculations suggested a 90% reduction in the conspecific call range. The impacts of commercial vessels at 50 kHz were confined to the shipping lanes, with the distance over which signals could be accurately sent, received, and detected by an individual reduced in excess of 50% at all times and in all areas of the Salish Sea due to commercial vessel traffic. During the winter months, the model outputs suggested that communication calls and echolocation signals would not exceed background noise levels from commercial vessel transits. The reductions for both signaling types were greatest at the 50 m depth, representing the typical swimming depth of chinook salmon prey (Wright et al. 2017). Also, the areas most impacted by noise, quantified by the greatest reduction especially in the

communication frequency range, were foraging areas (Olson et al. 2018; DFO 2021).

A more reduced acoustic range indicates the increased likelihood that the source of noise would create a negative effect. Being expressed as a proportional reduction allows direct comparison between both noise sources and frequency ranges considered and allows a comparable examination of noise impacts through time and space. The analysis on SRKW by Burnham et al. (2023) showed the noise resulting from the presence of commercial vessels would be of greatest concern during the winter months. However, knowledge on SRKW presence and distribution during this time is poor, and so the full implications of the noise relative to whale habitat use cannot be defined. Movements of SRKW and their timing are tied to prey. The sightings in the Salish Sea between April and September are linked to the migration of chinook salmon, whereas winter movements may follow chum salmon (*Oncorhynchus keta*) runs (Osborne 1999; Vélez-Espino et al. 2014), but the correlative strength is yet to be determined. When interpreting the acoustic impact over horizontal and vertical space, it is necessary to keep the potential changes in habitat use and prey in mind. Reductions in communication call range could hinder the coordination in prey location and capture and then the sharing of fish post-kill (Ford and Ellis 2014; Wright et al. 2016). The reduction of range in echolocation reduces the area over which prey could be identified and pursued, reducing prey availability (Au et al. 2004; Sato et al. 2021).

Applying these same methods of modeling to calculations of reduced acoustic ranges to wind speed data, to represent wind and wave noise in the soundscape, showed that even at the highest wind speeds and at times or in locations where wind noise was substantially elevated, the natural noise source would not meet or exceed that of commercial vessel noise. The greatest reduction in wind noise scenarios was to 40% of the maximum range, which was consistent with theoretical estimates calculated by Au et al. (2004) in higher sea states or periods with heavy rain. The excess of the vessel noise was particularly highlighted for SRKW echolocation frequencies, where the anthropogenic source outweighed wind noise in the shipping lanes. This simple subtraction showed the anthropogenic component of the Salish Sea soundscape is the dominant input over time and space and the main acoustic disturbance to SRKW signaling and sound reception. Existing variability and gradients in ambient noise levels are important aspects to consider when designing management plans. The consideration of wind-derived noise is one means of considering the natural, non-biological sound field components. The clearer the understanding of which component of the soundscape is dominant over various spatial and temporal scales, the more effective the mitigation measures of human-derived noise will be.

## Masking as a Metric for Management

The expression of anthropogenic noise impacts through masking quantified as a reduction in effective signaling range could be beneficial for managers designing mitigation strategies. It could suggests avenues to reduce the disturbance or

highlights regions where measures should be prioritized. At their simplest, these range reductions are calculated using the maximum detection range of calls, with this defined by a signal-to-noise ratio (SNR) that exceeds zero, under different noise scenarios. This, however, may not acknowledge the need to have a greater SNR to clearly decipher the information encoded in the calls or signals. This does also not consider the hearing thresholds from audiogram data that is available for some species. A variable representing hearing sensitivity could be included in future iterations of agent-based modeling techniques to better estimate the impact of the noise sources on whales and would add a correction factor to the absolute range estimations. As weighting may be given to different frequencies in the vocal or listening range, the results of the model output could also be weighted by the importance of the area to the whales, for example, if it was applied to critical habitat representing a foraging or breeding area, or weighted in terms of the observation rate or residency time of whales in a locale.

Plasticity in calling may also allow for mitigation of noise on the use of acoustics. Inclusion of altered amplitude of communication calls (e.g., Foote et al. 2004; Holt et al. 2009, 2011, 2015; Dunlop et al. 2014; Guazzo et al. 2020; Helbe et al. 2020; Thode et al. 2020), altered inter-pulse interval in echolocation has been noted (e.g., Lammers et al. 2004; Madsen et al. 2005; Morisaka et al. 2011), or modification in timing and direction of calling to allow for spatial, temporal, or co-modulation masking release (Erbe et al. 2016) to model calculations may help develop more realistic scenarios. Currently, without these refinements, models represent the worst-case scenario for masking by commercial traffic with much refinement still needed.

The potential acoustic impact from recreational vessels is also being increasingly realized (e.g., Hermannsen et al. 2019). The presence of these vessels is much harder to quantify for many areas as they are not mandated to carry an AIS transceiver. However, they can have a notable influence on the soundscape, especially in the higher frequencies. The inclusion of small vessel traffic into models will likely increase the impact of vessel noise and reduce effective acoustic ranges even further than has so far been demonstrated.

The approach discussed in this chapter advocates for taking a species-centered or even individual approach to understanding disturbance of ecologically relevant signals and is a better means to quantify the potential effect of noise additions than soundscape descriptions alone. Several analyses in masking (e.g., Clark et al. 2009; Hatch et al. 2012; Burnham et al. 2023) demonstrate that increases in anthropogenic sound sources reduce the extent over which these acoustic signals may be effective. This has implications for successful navigation, group cohesion and foraging, and prey capture. Particularly in areas like SBNMS (Hatch et al. 2012) and the Salish Sea (Burnham et al. 2023), which have been identified as critical habitat for species and encompassing important foraging regions, vessel noise threatens acoustical acuity for prey location, pursuit, capture, and sharing. For more social species like SRKW, masking limits the area over which prey is captured. Also, the number of individuals and/or distance between the group members over which the prey might be shared would also be lessened, reducing the overall successful outcome of foraging. This may then have health implications for individuals and the success of populations.

Metrics expressed as a percent of habitat or time individuals or populations are impacted by a certain level of acoustic disturbance could be a useful tool to present to management agencies. For example, expressing the amount of designated critical habitat that would be subject to 50% or greater reduction in communication or echolocation signals at a particular time or the proportion of time spent in the critical area that a whale is subject to a certain level of range reduction gives a direct dose-response type of figure to a manager. These form a tangible presentation of effect and clearly tie the noise additions to a definable impact. This might be most usefully applied to migrating species, for example, when the ecological relevance and the time period that whales are present are more strictly defined.

It should also be noted that the masking metric adds more evidence and quantification of acoustic disturbance to already documented changes in swimming and calling behaviors for whale species in the physical and acoustic presence of vessels (e.g., Holt et al. 2009, 2011, 2015, 2021; Dunlop et al. 2014; Williams et al. 2014; Guazzo et al. 2020; Helbe et al. 2020; Thode et al. 2020). For many species, there are undoubtedly implications for the cumulative effects from multiple stressors or the same stressor repetitively that could be present in much of a species' range that have yet to be fully described (e.g., Christiansen et al. 2015; Montes et al. 2020; Silber et al. 2020). Also, masking precedes auditory injury or changes in hearing ability through auditory fatigue and temporary threshold shift (TTS) or a permanent change in sensitivity or threshold shift (PTS). A masking metric could help guide mitigation measures to the areas most needing noise reduction before anthropogenic additions meet or exceed the levels that might instigate TTS, PTS, or physiological stress responses. The dose-response relationships, ultimately leading to changes in distribution and success as a result of ocean noise, have yet to be conclusively determined for cetaceans. The ultimate response of habitat abandonment may be a direct result of acoustic disturbance or an indirect impact through changes in prey availability. This could be through startle or displacement responses of the whale, or equally by its prey, or reduced detection of prey as a result of increasing ambient noise levels (e.g., Sato et al. 2021). This would make the effect of acoustic disturbance on foraging possibly hard to disentangle the behavioral responses from prey decline.

Analyses using masking as a metric of impact serve as one of the building blocks for scenario development and noise-level predictions. This could aid evidence-based management actions. Predicted near-future increases in vessel traffic and capacity internationally will heighten the risk of acoustic disturbance for many cetacean species, and techniques like those discussed in this chapter may help determine their effect.

**Abstract**

Offshore wind farms are part of the transition to renewable sources of energy, and both the total numbers and sizes of wind turbines are rapidly increasing. While the impact of underwater sound related to construction work has been in the focus of research and regulation, few data exist on the potential impact of underwater sound from operational offshore wind farms (OWF). Here, the knowledge gained on operational noise from OWF and its potential effects on marine mammal behavior is synthesized. In a case study, effects of a 10- and 20-MW direct drive OWF turbine on the hearing of marine mammals were assessed using a simple model spreadsheet based on geometrical spreading loss and hearing types as defined by NMFS/NOAA. Effects over 24 h exposure from a single turbine ranged between a few meters and a little over 700 m depending on the effect (permanent threshold shift (PTS)/temporary threshold shift (TTS)) and hearing group investigated. In general, impact ranges for PTS were small (i.e., up to 50 m from the sound source) and are thus likely negligible. The same was true for TTS impact ranges for 10 MW. However, impact ranges for TTS from a 20 MW

turbine could reach a little over 700 m for low-frequency cetaceans which could bridge distances between wind turbines. Thus, impact areas from single turbines might overlap and the whole wind farm can be considered an impact area. It is concluded that for larger size wind turbines, operational noise needs to be considered in sufficient detail as a part of the environmental impact assessment in the wind farm planning phase. In addition, further observations and modeling efforts are necessary to increase the accuracy of the estimates.

## Introduction

Within the fast-growing research area of aquatic noise, the effects of marine renewables, especially offshore wind farms (OWF), have received special attention. This is because plans to develop OWF have become ever more ambitious, not only in Europe where the industry has established itself in the past 20 years but also in many other areas such as off the US East coast, off the coast of Taiwan, Australia, and China. As the industry grew, so did the need to understand the impacts on marine life. Research on offshore wind farm-related noise and its effects on marine mammals has been undertaken since 20+ years with a focus on European waters and species that are most abundant there such as harbor porpoises (*Phocoena phocoena*) and to a certain extent harbor and gray seals (*Phoca vitulina* and *Halichoerus grypus*). Up until recently, the scientific consent was that construction noise is the main issue if impact pile driving is being used due to the relatively high sound intensities and consequently large impact ranges associated with this activity. Operational noise was not considered an important topic due to the much lower sound intensities during that phase (see reviews by Madsen et al. 2006; Thomsen et al. 2006, 2016). These findings were corroborated by field studies which found little adverse impact of existing OWFs on porpoises and seals (Thomsen et al. 2016). However, recently, Stöber and Thomsen (2021) found indications that behavioral impact areas from larger size wind turbines, such as those planned to be installed in the future, could overlap and the whole wind farm might be considered an impact area. They concluded that for larger size wind turbines, operational noise needs to be considered in sufficient detail as a part of the environmental impact assessment. Yet, Stöber and Thomsen (2021) also pointed out that further observations and modeling efforts are necessary to increase the accuracy of the estimates.

One issue that was largely left out in the study by Stöber and Thomsen (2021) was the effect of underwater noise from future turbines on the hearing of marine mammals in the form of temporary and permanent hearing threshold shifts (TTS and PTS). Intuitively, this was not perceived as an important issue since operational noise levels from future turbines are still relatively low compared to the impact

criteria TTS and PTS (NMFS 2018; Southall et al. 2019). However, as proven in a milestone investigation on harbor porpoises in captivity, even relatively low-level exposure to continuous noise can lead to TTS if exposure duration is long (Kastelein et al. 2012). Noise from OWF turbines in operation is more or less permanent, and some investigations indicate that porpoises might get attracted to wind farms perhaps because they represent refugees from fishing activities or due to higher fish abundance resulting from an artificial reef effect (see review by Thomsen et al. 2016). Thus, it is worth exploring whether the concerns about behavioral impacts from offshore wind farms in operation are also valid for hearing impairment.

This chapter builds on the study by Stöber and Thomsen (2021) to include the potential of operational noise from offshore wind farms for hearing impairment in the form of TTS and PTS. First, the recent findings by Stöber and Thomsen (2021) are summarized. This is followed by a case study estimating impact ranges for PTS and TTS for different marine mammal hearing groups for 10 and 20 MW OWF turbine. The chapter closes by discussing the results with an emphasis on pointing out knowledge gaps and priorities for further investigations.

## Summary of Recent Findings

Previous reviews of state of knowledge about operational noise have been published by Madsen et al. (2006), Thomsen et al. (2006), and Thomsen et al. (2016). Two more recent investigations by Stöber and Thomsen (2021) and Tougaard et al. (2020) have performed a systematic analysis that should be summarized here quickly:

- OWF operational sound is originating in the nacelle with most energy below 1 kHz. Another source of sound is wind-induced vibration of the tower. The sound is transmitted through the tower and then radiated from the foundation into the water. Thus far, different foundation types (i.e., monopiles, tripod, jackets, and gravity-based) do not seem to lead to systematically different sound profiles (Tougaard et al. 2020).
- The broadband rms SPLs normalized to 1 m distance from the source ranges from 129 to 166 dB re 1 μPa m (nominal power = 0,45–6,15 MW; Stöber and Thomsen 2021). Similarly, Tougaard et al. (2020) found turbine noise levels 10–20 dB below the received levels measured from ships for the same distance.
- Emitted sound levels increase with turbine size (Tougaard et al. 2020: 13.6 dB/decade in meters) and wind speed (Tougaard et al. 2020: 18.5 dB/decade in m/s).

Tougaard et al. (2020) concluded that the noise footprint of individual turbines is small compared to other sources such as ships. However, they also demonstrated that cumulative noise levels from an entire wind farm could be elevated above background noise up to a few kilometers from a wind farm under very low ambient noise conditions. Based on the existing data, Stöber and Thomsen (2021) extrapolated a broadband source level of 170 dB re 1 μPa m for a 10 MW turbine with a gearbox.

The broadband source level of a 10 MW direct drive turbine was assessed to be 10 dB quieter (160 dB re 1 μPa m). Using existing regulatory criteria, a 10 MW direct drive turbine was expected to cause behavioral response in marine mammals up to 1.4 km distance from the turbine, compared to 6.3 km for a turbine with gearbox (Stöber and Thomsen 2021).

## Potential for Hearing Impairment (TTS and PTS)

Building on the work by Stöber and Thomsen (2021), a case study on the potential of future OWF turbines (10 and 20 MW) for hearing impairment in the form of TTS and PTS was undertaken. For the 10 MW direct drive turbine, the broadband sound pressure level of 160 dB re 1 μPa m as derived by Stöber and Thomsen (2021) was used. For the estimation of the source level for a 20 MW turbine, the data by Tougaard et al. (2020) was reevaluated and new fits of the dependence of the SPL on the power and wind speed were derived considering only the monopile datasets. Applying these pure monopile trends, a source sound pressure level of 182.4 dB re 1 μPa m was derived. Then 10 dB were subtracted to arrive at an estimate for a direct drive turbine, which leads to a final source level of 172.4 dB re 1 μPa m for a 20 MW for this turbine type.

The impact ranges for TTS and PTS for the different marine mammal hearing groups were calculated using the NOAA/NMFS spreadsheet tool (available from https://www.fisheries.noaa.gov/national/marine-mammal-protection/marine-mammal-acoustic-technical-guidance). According to the supplied information in the spreadsheet tool, a weighting factor adjustment of 2 kHz was applied. The propagation loss coefficient was set to 15 which is between special and cylindrical spreading and close to transmission loss characteristics in many coastal waters where OWFs are being planned (see, for example, Madsen et al. 2006; Thomsen et al. 2006). The exposure duration was set to 24 h.

Effects over 24 h exposure from a single turbine ranged between a few meters and a little over 700 m, depending on effect (PTS/TTS) and hearing group investigated (Table 1). In general, impact ranges for PTS were small (i.e., up to 50 m from the sound source) and are thus likely negligible. The same was true for TTS impact ranges for 10 MW. However, impact ranges for TTS from a 20 MW turbine could reach a little over 700 m for low-frequency cetaceans which could be larger than distances between wind turbines. Thus, impact areas from single turbines might overlap and the whole wind farm can be considered an impact area.

## Discussion

This chapter indicates that underwater noise from 10- to even 20-MW OWFs in operation will likely not lead to any significant impacts due to auditory injury in marine mammals even if the animals stay on the wind farm area for a day. Even temporary hearing impairment might not be an important issue for the future 10 MW

**Table 1** Impact ranges in isopleth to threshold (meters) for a projected 10 MW and 20 MW OWF turbine for different marine mammal hearing groups (PTS and TTS thresholds, see NMFS 2018; Southall et al. 2019)

| Hearing group | Low-frequency cetaceans | Mid-frequency cetaceans | High-frequency cetaceans | Phocid pinnipeds | Otariid pinnipeds |
|---|---|---|---|---|---|
| **10 MW** | | | | | |
| **PTS isopleth to threshold (meters)** | 4.9 | 0.3 | 4.3 | 2.6 | 0.2 |
| **TTS isopleth to threshold (meters)** | 105.6 | 6.0 | 92.6 | 56.5 | 4.1 |
| **20 MW** | | | | | |
| **PTS isopleth to threshold (meters)** | 32.9 | 1.9 | 28.8 | 17.6 | 1.3 |
| **TTS isopleth to threshold (meters)** | 708.6 | 39.9 | 620.9 | 379.2 | 27.6 |

turbines. However, for larger turbines, the noise generated can lead to effects that need consideration because sound levels from individual devices might overlap, making the whole wind farm area a zone of impact. Acoustic interference between sounds from different turbines was not investigated, but it is likely that the cumulative sound field resulting from interference and then emitted from an OWF is larger than individual sound fields just added up. It is theoretically possible that impact ranges for cumulative TTS (i.e., over 24 h) are larger than those for behavioral avoidance. And then animals might stay in the area and experience TTS. There is also the possibility that marine mammals are attracted to the wind farm area due to artificial reef effects and that they prioritize feeding against moving away because of the operational noise exposure. Looking at the vast amount of planned OWF in some regions and the considerable size of some project areas (see, for example, Global Offshore Renewable Map | 4C Offshore), this potential issue needs further investigation. This is especially true if we consider that many future wind farms are being planned in sea areas that overlap with important habitats of low-frequency large baleen whales for which the impact ranges in this case study were the highest compared to all other hearing types.

However, the results obtained with the simple model applied here come with considerable uncertainties. Looking at the relatively large distances traveled by many marine mammals on any given day, it could appear unlikely that these animals will stay in the relatively small project areas for 24 h. Thus, the estimated TTS areas seem theoretical. Animal movement modeling, for example, using individual-based modeling has great potential to make impact assessments more realistic, leading to more accurate predictions of animals exposed to a pressure (see Thomsen et al. 2019).

It is also worth pointing out that changing any of the variables of the applied model leads to considerable differences in the results. For example, reducing the weighting factor adjustment from 2 kHz to 1 kHz will lead to a considerable

reduction in impact ranges for high-frequency cetaceans. Local sound propagation might also be very different from the 15 log (R) spreading law chosen here leading to completely different impact ranges. Furthermore, the simplistic model approach used here does not account for acoustic properties of the seabed and local bathymetry which hugely influence sound transport. It is recommended to apply numerical modeling to improve the precision of the assessment.

One important concept that was not applied is the "effective quiet" as defined by Finneran (2015) as the highest SPL that would not produce a significant TTS or affect recovery from a TTS produced by a prior, higher-level exposure. Finneran (2015) then indicate that for harbor porpoises, this value could be 124 dB re 1 μPa and cites the study by Kastelein et al. (2012) mentioned above in support of this conclusion. Kastelein et al. (2012) did not investigate directly into "effective quiet" but rather showed that very low sound exposures can lead to significant TTS in porpoises when exposure duration is long. The 124 dB re 1 μPa was the lowest sound level that led to TTS. To the authors' knowledge, effective quiet is unknown for low-frequency cetaceans and applying just an arbitrary value would be very speculative.

## Conclusion

This study confirms earlier work by Stöber and Thomsen (2021) who pointed at potential effects of operational OWFs on marine mammals that should be considered more thoroughly in regulatory management. But it is also evident that the presented results should be interpreted with caution. They should represent a starting point for a necessary discussion about environmental costs of OWF facilities and nothing more.

**Acknowledgments** The authors would like to thank Jonas von Pein for the help in calculating the broadband SPLs.

**Abstract**

It is well known that short loud sounds and longer quieter sounds can produce hearing loss. The idea that equivalent sound energy results in equivalent hearing loss founds our thinking about hearing loss, including regulations to protect hearing (e.g., NIOSH 1998). But it is also recognized that similar level sounds with different temporal characteristics may result in different amounts of hearing

loss. This is codified for regulatory purposes (e.g., NMFS 2018) as lower thresholds for predicting hearing loss in marine mammals exposed to impulsive sounds compared to non-impulsive sounds. Currently, a qualitative approach is used to classify sound sources, which is problematic because sources can produce various sounds, some sources do not neatly fit into either category, and sound characteristics change with propagation.

Kurtosis is a measure of the probability distribution of received sound levels. For hearing, kurtosis appears to better predict hearing loss from exposure to some sounds with differing amounts of transients. The kurtosis of a signal can be used to adjust the received level, allowing for a smooth transition between impulsive and non-impulsive sounds. The adjustment focuses on sounds instead of sources, allows for the consideration of propagation effects, and includes the animals' hearing frequency sensitivity.

Kurtosis · Impulsive · Non-impulsive · Hearing loss · Marine mammal · Regulatory thresholds

## Introduction

It has long been known that short loud sounds may cause hearing loss as well as longer quieter sounds (reviewed by Akay 1978). This observation led Eldred et al. (1955) to suggest that exposure to equivalent sound energy results in equivalent hearing loss, the equal energy hypothesis (EEH). The EEH has formed the basis of our thinking about hearing loss, including regulations to protect hearing in humans (e.g., NIOSH 1998).

It has been shown repeatedly, however, that the EEH does not accurately predict the extent of hearing loss – in general, exposure to short loud (impulsive) sounds are thought to result in more hearing loss than longer duration sounds of equivalent sound energy (Ward 1962; Hamernik et al. 2003; though see Mooney et al. 2009 for a counter example). In their study on chinchillas, Hamernik et al. (2003) investigated how the amplitude distribution of received sound affects hearing loss. While keeping the total sound energy and spectra the same, Hamernik et al. (2003) presented sounds with Gaussian-distributed amplitude levels and non-Gaussian distributed amplitude levels produced by inserting high-level transients into otherwise Gaussian-distributed noise. The non-Gaussian noise with high-level transients produced greater hearing loss.

With respect to hearing loss in marine mammals, Southall et al. (2007) recognized that temporal aspects of sound may result in different amounts of hearing loss and proposed lower thresholds for "impulsive" sounds compared to "non-impulsive" sounds. The current regulatory thresholds for predicting hearing loss in marine mammals are 13–18 dB lower (for auditory frequency-weighted sound exposure level, SEL, thresholds in the different hearing groups) for impulsive sounds than

non-impulsive sounds (Finneran et al. 2017; NMFS 2018). However, how to determine whether a sound is impulsive or non-impulsive is not defined.

A qualitative approach is currently taken to classify sound sources (NMFS 2018). For example, impact pile driving and seismic air guns are assumed to always produce impulsive sounds, while sonar-type sources, including multibeam echosounders, are assumed to always produce non-impulsive sounds (NMFS 2018). The qualitative approach with guidance by exemplar is problematic, however, when considering the variety of sounds that sources can produce and that some sources do not neatly fit into one category, such as down-the-hole hammering that consists of drilling (non-impulsive) and hammering (impulsive) (Guan et al. 2022). The problematic nature of the qualitative approach is further evident when noting that sound characteristics change with propagation. Sound tends to spread out in time as it moves away from the source. Sounds, such as those produced by air guns, may be pulsatile near the source but, because of differences in multipath arrival time, may be a nearly constant rumble far from the source (e.g., see Martin et al. 2017).

## Defining Impulsive and Non-impulsive Sounds

### Qualitative Definitions

ISO (2016) defines "impulsive sound" as "sound characterized by brief bursts of sound pressure." NMFS (2018) defines impulsive sources as those that "produce sounds that are typically transient, brief (less than 1 second), broadband, and consist of high peak sound pressure with rapid rise time and rapid decay" and defines non-impulsive sources as those that "produce sounds that can be broadband, narrowband or tonal, brief or prolonged, continuous or intermittent) and typically do not have a high peak sound pressure with rapid rise/decay time that impulsive sounds do." In these definitions, NMFS (2018) cites standards for measuring sound levels in air (NIOSH 1998; ANSI/ASA S1.13-2005 (R2010); ANSI S3.20-1995; ANSI/ASA S12.7-1986) but removes quantitative criteria, which may result in different interpretations. For example, ANSI (S1.13-2005 (R2010)) does not preclude harmonic signals (including frequency modulated sounds) from being classified as impulsive. The qualitative definitions used by the Finneran et al. (2017) are similar to NMFS (2018) but do state that harmonic signals with more than ten cycles are considered a steady state (non-impulsive). And there are other classification approaches, such as TG Noise (van der Graaf et al. 2012), which defines an impulsive sound as one "for which the effective time duration of individual sound pulses is less than ten seconds and whose repetition time exceeds four times this effective time duration."

NMFS (2018) calls out impact pile driving and seismic air guns as examples of impulsive sources and active sonar as non-impulsive. Sonar sources, such as multibeam echosounders (MBES), however, can produce high-level sounds with shorter-duration signals and a more rapid rise to high pressure than impact pile driving or seismic air guns (Fig. 1). MBES are classified by NMFS (2018) as non-impulsive

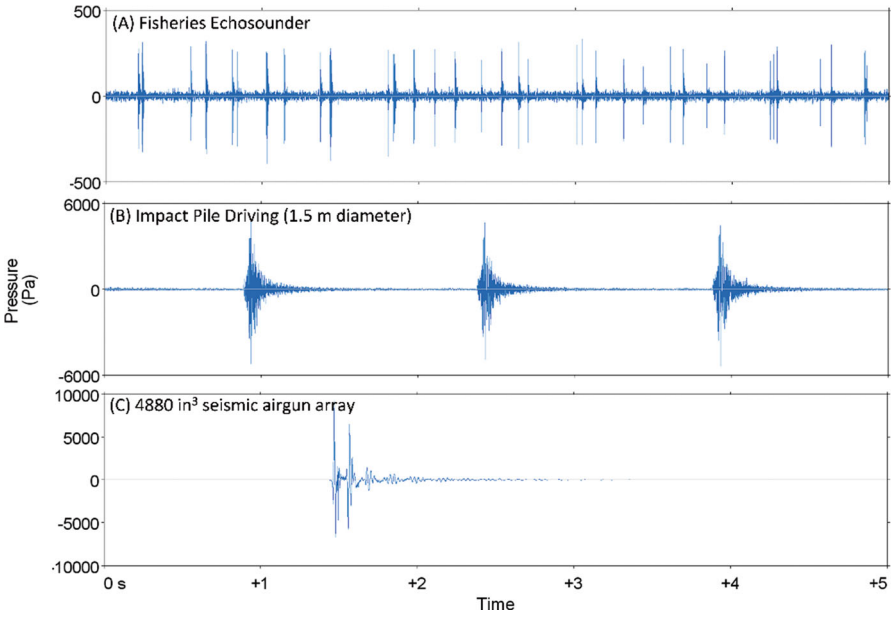

**Fig. 1** Five-second sound pressure time sequences of three anthropogenic sources: (**a**) a fisheries echosounder recorded at ~500 m distance; (**b**) impact pile driving (1.5 m diameter pile) at 541 m distance; and (**c**) a 4880 $in^3$ seismic air gun array recorded at ~700 m distance

and use the non-impulsive thresholds for predicting permanent hearing threshold shifts (PTS) despite producing signals that fit within the qualitative descriptions of impulsive sources.

## Quantitative Definitions

Quantitative definitions to classify signals as impulsive or non-impulsive to better gauge their potential impacts on hearing have been suggested. Harris (1991) suggested an impulse factor that is easily calculated as the sound level measured using impulse weighting (35 ms decay constant) minus the sound level measured with either fast or slow time weighting (0.125 or 1 s time constants, respectively) on standard in-air sound level meters. Based on Harris (1991), Southall et al. (2007) recommend an impulse factor (the difference in sound level meter measurements using continuous and impulse settings) of greater than 3 dB to distinguish between impulsive and non-impulsive sounds. Using the Harris (1991) approach of comparing sound levels measured using impulse weighting to fast weighting in the examples in Fig. 1, the fisheries echosounder is 11.3 dB, impact pile driving is 18.3 dB, and seismic air gun is 22.9 dB.

Kurtosis, the over- or underrepresentation of data in the tails of a distribution, has also been suggested as a proxy for the impulsiveness of sound. For hearing, kurtosis (ISO 2017) is a measure of the probability distribution of received sound levels (Müller et al. 2020) and has been successfully used to predict hearing loss in terrestrial mammals from exposure to sounds with differing amounts of transients (Qiu et al. 2020). In marine mammals, there are few data available on the effectiveness of using kurtosis for predicting hearing loss. von Benda-Beckmann et al. (2022) found that for harbor porpoise exposed to intermittent sounds with silent intervals of 1–13 s, kurtosis-corrected frequency-weighted SEL accurately predicted TTS (for TTS <10 dB) but kurtosis-correction was not predictive of TTS for exposure to continuous sounds.

The kurtosis of a signal with Gaussian-distributed received levels (white noise), which can serve as a baseline, has a kurtosis of 3. Qiu et al. (2020) found that signals with greater kurtosis are associated with greater hearing loss (hair cell damage), with the amount of hearing loss asymptoting for signals with kurtosis greater than 40 (using a 40 s window for calculating kurtosis). A sound signal that has a kurtosis of 0–3 could sensibly be classified as non-impulsive for regulatory purposes, while a sound signal with a kurtosis greater than 40 could be classified as fully impulsive. The kurtosis in the Qiu et al. (2020) examples is 7.2 for the fisheries echosounder, 58 for impact pile driving, and 494 for the seismic air gun. Using kurtosis, the source classifications differ somewhat from using the Harris metric, because the echosounder is only marginally impulsive.

## A Kurtosis Adjustment?

Using qualitative definitions to classify sources as impulsive or non-impulsive leads to inconsistently classified received sounds. With PTS thresholds for evaluating potential impacts differing by 13–18 dB (depending on hearing group), misclassification could result in missed predictions of injury or injury predictions when none would occur.

Using a binary classification scheme (impulsive and non-impulsive) further complicates the situation. For sources that can produce various sounds, should all their sounds be classified the same? And, conversely, should identical sounds that are classified differently because they come from different sources be assessed using different thresholds? The transients that Hamernik et al. (2003) added to the noise were not necessarily impulses, and the overall sound signal was not necessarily impulsive. There was an overrepresentation of high sound levels in the presentations that resulted in greater hearing loss compared to baseline noise with the same sound energy. Increasing the proportion of high-level sounds in a signal smoothly increases the amount of hearing loss (up to a point) as opposed to a step change in hearing loss that would suggest discreet classification into two categories.

To better predict hearing loss in individuals exposed to signals with overrepresentation of high sound levels, Goley et al. (2011) suggested adjusting the reported sound level based on the logarithm of the ratio of the signal kurtosis, $\beta$, to the kurtosis of a Gaussian signal, $\beta_G$, multiplied by a scaling factor, $\lambda$, as shown in the equation below:

$$L'_{E,W} = L_{E,W} + \lambda \log_{10} \frac{\beta}{\beta_G} \text{ dB},$$

where $L_{E,W}$ is the reported sound level and $L'_{E,W}$ is the adjusted level.

Taking, for example, the SEL threshold for high-frequency (HF) cetaceans exposed to non-impulsive sounds with an HF-weighted SEL of 173 dB re 1 μPa$^2$·s and impulsive sounds as HF-weighted SEL of 155 dB re 1 μPa$^2$·s (NMFS 2018), there is an 18 dB difference. The kurtosis of a Gaussian signal ($\beta_G$) is 3. Assuming a signal with a kurtosis of greater than 40 is fully impulsive, dividing 18 dB by the logarithm of the kurtosis ratio (40/3) gives a $\lambda$ of 16.0. Substituting into the equation above, the equation below could be used to adjust SEL for HF cetaceans:

$$L'_{E,\text{HF}} = L_{E,\text{HF}} + 16.0 \log_{10} \frac{\beta}{3} \text{ dB}, \quad 3 \le \beta \le 40 \, .$$

To evaluate the potential of a sound to cause hearing loss (PTS) in, e.g., HF cetaceans, the process is to: (1) calculate the kurtosis of the received sound, $\beta$, (limiting $\beta$ to be between 3 and 40); (2) use the equation to find the adjusted SEL; and (3) compare the adjusted SEL to the non-impulsive SEL threshold for PTS (NMFS 2018). Only the non-impulsive threshold (HF-weighted SEL of 173 dB re 1 μPa$^2$·s for HF cetaceans) is needed because adding to the SEL is equivalent to reducing the threshold. In other words, scaling the metric by the kurtosis adjustment precludes the need to scale the threshold by the "impulsiveness" of the signal. Gaussian distributed signals with kurtosis of 3 or less will receive no adjustment to SEL, so their effective threshold is equal to the non-impulsive threshold (SEL of 173 dB re 1 μPa$^2$·s for HF cetaceans). Pulsed signals with kurtosis of 40 or higher will have an effective PTS threshold equal to the impulsive PTS threshold (HF-weighted SEL of 155 dB re 1 μPa$^2$·s). Sounds with kurtosis between 3 and 40 will have effective thresholds between the non-impulsive and impulsive PTS thresholds. In this way, there is a smooth transition between signal types. Sounds with some impulsiveness (intermediate kurtosis) will incur some penalty but would not necessarily be considered impulsive.

Changes in the spectral content of a signal affect the kurtosis calculation. Because the best hearing frequency range varies with species, species-specific weighting functions should be applied before the kurtosis calculation. In this way, the kurtosis value, and the apparent impulsiveness of a signal, is specific to the hearing group. Martin et al. (2020) calculated kurtosis for real signals for different hearing groups. Martin et al. (2020, their Fig. 6b) found that a fishing vessel with an echosounder has a kurtosis value of ~3 when unweighted or when weighted for low-frequency (LF) cetaceans. When weighted for HF cetaceans (classified as "very high frequency

cetaceans" according to the nomenclature of Southall et al. (2019)), the kurtosis is ~20. When the recorder was in the beam of the echosounder, kurtosis approached 20 for LF weighting but was greater than 100 for HF weighting.

## Summary

Binary categorization of sound sources as "impulsive" or "non-impulsive" based on qualitative definitions may lead to misclassifying received sounds and inaccurately assessing potential impacts on animals. Physiological studies of terrestrial mammals find that differences in hearing loss resulting from exposure to differently structured sounds of the same total energy is predicted by the distribution of received levels and quantified by the signal's kurtosis. The impulsive and non-impulsive thresholds for predicting hearing loss in marine mammals (e.g., NMFS 2018) establish the sound types that may affect hearing as end points but not the transition between the types. Using an adjustment factor based on kurtosis allows for a smooth transition between the end points (Fig. 2), recasts the focus to the received sounds instead of the sources, and accounts for the hearing sensitivity of animals (hearing groups).

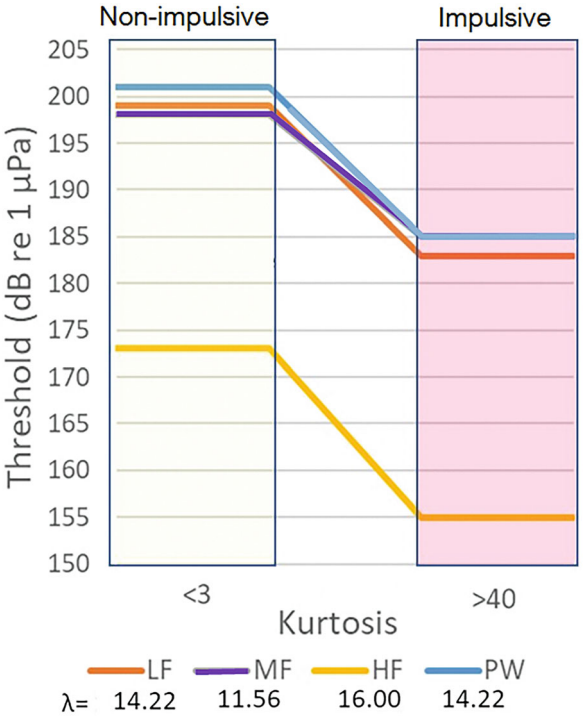

**Fig. 2** The NMFS (2018) sound exposure level (SEL) thresholds for predicting marine mammal hearing loss using a kurtosis adjustment for transitioning between impulsive and non-impulsive received sounds. Hearing groups: *LF* low-frequency cetacean, *MF* mid-frequency cetacean, *HF* high-frequency cetacean, and *PW* pinniped in water

**Abstract**

Anthropogenic sounds can negatively impact marine mammals, limiting their ability to effectively forage or communicate, displacing them from a portion of their range, or causing physical harm. To date, potential impacts of sounds associated with mobile offshore drilling units (MODUs) on cetaceans have not been investigated. Acoustic recordings were collected at 1–2 km and 20–40 km from three MODUs to investigate variation in the acoustic occurrence of odontocetes with distance from the MODUs.

The *West Aquarius* MODU, *West Hercules* MODU, and *Stena Forth* MODU acoustic measurements lasted for at least 2 months each and included at least 1 min in 20 with high enough sampling rates to record the echolocation clicks of delphinids, beaked whales, and sperm whales. Recordings in the general area of the operations from previous years were also available. A comparison of the odontocete acoustic presence near the operations to the acoustic presence at longer distances showed a substantial difference in acoustic occurrence for dolphins, pilot whales, and beaked whales that could not be attributed to masking of detections by sounds from the operations.

## Introduction

Mobile offshore drilling units (MODUs) are large platforms used to drill oil and gas wells in the ocean for exploration and extraction. For deep water operations, there are two common forms – semisubmersible rigs and drill ships. In waters greater than ~200 m the MODUs typically hold their position over the wells using dynamic positioning (DP) thrusters. During environmental assessments of drilling operations, the underwater sound from the drill rigs and their support vessels are considered as possible threats to marine life, along with the sounds from vertical seismic profiling (see Further Readings).

Drilling operations typically take 2–4 months at each well. Over the past several years off Eastern Canada, JASCO Applied Sciences (JASCO) has made acoustic measurements of deep-water MODU drilling operations by the semisubmersibles *West Aquarius* and *West Hercules* as well as drill ships *Stena Forth* and *Stena IceMax*. The acoustic monitoring was required by the Canadian regulators during the drilling of the first well for each project (see Further Readings). To verify predictions for sound levels from the drilling programs, measurements were made close to (1–2 km) and relatively far from (20–40 km) the MODUs, the latter being where the sound pressure level was expected to drop below 120 dB re 1 $\mu Pa^2$.

In all cases it was noted that ultrashort baseline (USBL) beacons signals at 25–27 kHz were a prominent component of the acoustic footprint of the MODU operations. It is understood that the beacons are used to help the dynamic positioning systems keep the drill rigs positioned above the well head. Comparable sounds in the USBL frequency band are sonar and echosounders which have been associated with avoidance, or at least a cessation in echolocation, by beaked and sperm whales (Cholewiak et al. 2017; Stanistreet et al. 2022).

The purpose of this analysis was to compare the acoustic presence of odontocetes near the MODUs with their acoustic presence far from the MODUs and, when possible, comparing occurrence before and during MODU presence. The goal was to determine if there was a measurable effect of MODUs, similar to that reported from sonar and echosounder sounds.

## Methods

### Measurements

For drilling projects undertaken by BP Canada Energy Group ULC (Project 1), ExxonMobil Canada Ltd (Project 2), and the Chinese National Offshore Oil Corporation (Project 3), JASCO collected acoustic recordings at 1–2 km and 20–40 km

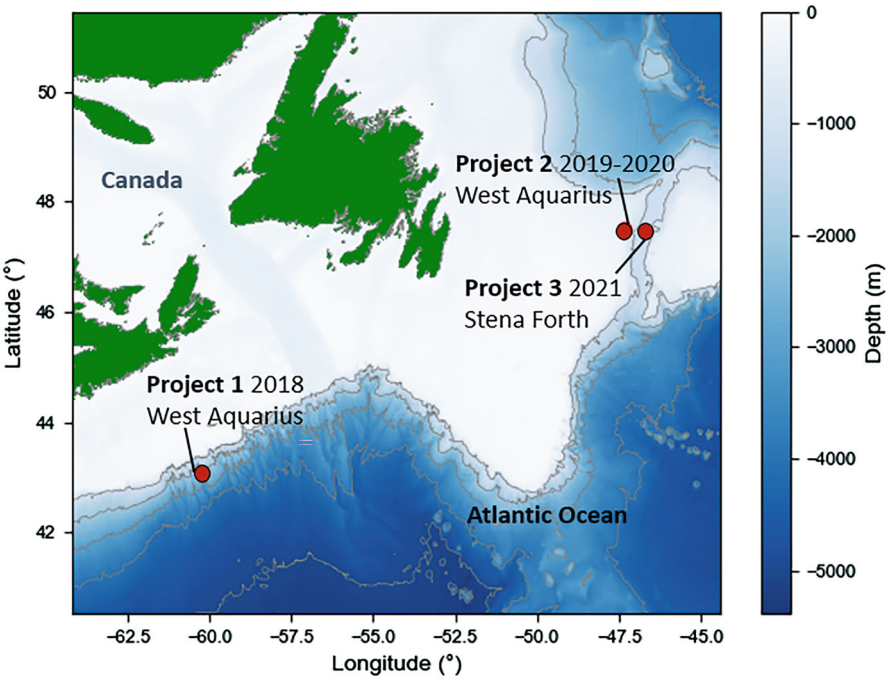

**Fig. 1** Project sites considered in the odontocete analysis

**Table 1** Overview of the recording programs: sampling rates, duty cycles, recording time frame, distance to the MODU, and water depths. Data were also collected at a lower sampling rate on Projects 1 and 2 but are not considered here

| | Sampling Rate (duty cycle) | Deployment period | Distance from MODU (km) | Water depth (m) |
|---|---|---|---|---|
| **Project 1** | 375 kHz (2 of every 10 min) | April–Aug 2018 | 2 | 2384 |
| | | | 20 | 2060 |
| **Project 2** | 512 kHz (1 of every 20 min) | Sept 2019–May 2020 | 2 | 300 |
| | | | 33 | 875 |
| **Project 3** | 128 kHz (continuous) | April–July 2021 | 1 | 1157 |
| | | | 40 | 666 |

from MODUs to investigate variation in MODU sounds and cetacean acoustic occurrence with distance from the MODUs (Fig. 1 and Table 1; see Further Readings for additional information on the projects).

All recordings were made using autonomous multichannel acoustic recorders (AMARs; JASCO, Dartmouth, NS, Canada) and M36 hydrophones (Geospectrum Technologies Inc, Dartmouth, NS, Canada, sensitivity approximately −164 dBV/Pa). The hydrophones were calibrated on deployment and retrieval using G.R.A.S. pistonphones. The hydrophones were located near the seabed using short float-on-a-rope-style moorings.

## Data Analysis

The basic analysis applied to all the data followed the Welch (1967) method: time series audio data were converted to power spectral densities using the fast Fourier transform (FFT) with a 50% overlap and a Hann window. A frequency-dependent calibration curve for the hydrophone and recorder was applied to the spectra. The spectra were then summed to generate decidecade sound pressure levels as needed for the analysis of sound pressure levels and sound exposure levels (Heaney et al. 2017). Sound exposure levels weighted for the hearing sensitivity of marine mammals from duty cycled recorders were computed using the methods from Martin et al. (2019a).

The acoustic presence of marine mammals was determined by (1) applying a Suite of automated marine mammal detectors; (2) based on the automated detector results, selecting a subset of the full dataset to be manually analyzed for marine mammal presence; and (3) comparing automated and manual results to assess and optimize automated detector performance. An automated contour detector was employed to identify periods of tonal whistles in the data (Martin et al. 2014). The automated contour detector operates on a per-frequency basis to detect signals that stand out from the background, then joins adjacent time frequency cells to create a contour that is compared to known species-dependent contour shapes. The automated contour detector identified two types of whistles. Whistles above 5 kHz were categorized as dolphins and were believed to be produced by one or more species of small dolphins (e.g., *Lagenorhynchus acutus* and *Lagenorhynchus albirostris*). Whistles with a fundamental frequency below 5 kHz were categorized as pilot whales (*Globicephala melas*) or killer whales (*Orcinus orca*).

Odontocete clicks were identified using an automated time series detector classifier (Martin et al. 2019b). This detector employs a short time span (0.333 millisecond) long Teager-Kaiser detector to identify possible echolocation clicks (Kandia and Stylianou 2006). The possible clicks are analyzed to measure three time series properties: the number of zero crossings in the waveform (i.e., click duration); the time between zero crossings (i.e., click center frequency); and whether the time between zero crossings is uniformly increasing (characteristic of beaked whale clicks). By computing the Mahalanobis distance between the measured and known properties of each species, the click was classified to a species.

A subset of acoustic files was manually validated for odontocete acoustic occurrence to assess and optimize automated detector performance for each AMAR deployment (Kowarski et al. 2021).

When automated detectors performed poorly, defined here as a Precision less than 0.75, the automated results were not included in the present overview of potential MODU impacts. The occurrence results were summarized in terms of the distributions of the percent of days in which the species were detected at the close and far recording stations.

## Results

A 30-s spectrogram of a typical period of USBL communications is shown in Fig. 2. The power spectral density distributions at each of the recording sites is shown in Fig. 3. The −3 dB bandwidth of the signal was 24–27 kHz, with sound extending out to 22–29.5 kHz. Figure 2 shows that there are periods of multiple seconds between the communications where detection of odontocete clicks would not be masked by the USBL pulses. The background sound levels are almost identical to those at the distant recorders when the communications are not occurring. The detection of odontocete whistles in the 5–15 kHz band is expected to only be modestly affected by the MODUs based on the slight increase in the power spectral densities in that band closer to the MODUs.

The sound levels shown in Fig. 3, particularly for Project 2, were substantially elevated near the MODUs. It was hypothesized that the Project 2 levels were higher than for Projects 1 and 3 because Project 2 occurred in winter, or perhaps due to the

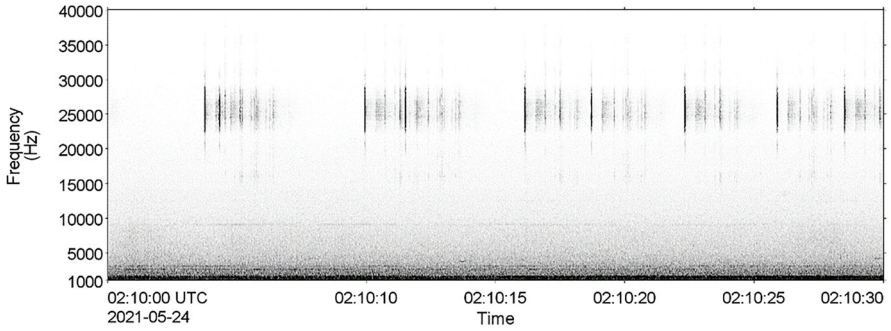

**Fig. 2** Thirty seconds of data from Project 3 in May 2021 showing typical USBL pinger communications. Note that there are periods of many seconds without USBL activity

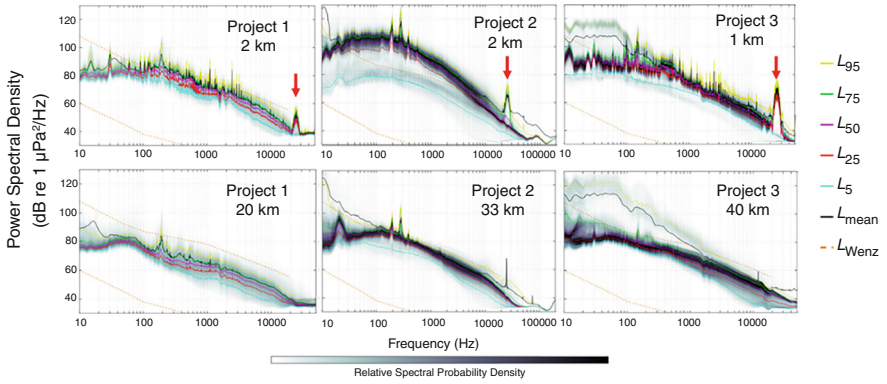

**Fig. 3** Power spectral densities of the soundscape recorded at each of the sites. Top row: the recorders close to the MODUs; bottom row: the recorders at 20–40 km from the MODUs

shallower water depths (Table 1). The levels at Project 2 were high enough that they exceeded the low-frequency cetacean temporary threshold shift levels on most days (Fig. 4, assuming the animals did not leave the area over that 24-hour period). The low-frequency sound levels increased at the end of Project 3 due to the commencement of a nearby seismic survey. For all three projects, the auditory frequency weighted daily SELs hovered near the high-frequency cetacean temporary threshold shift (TTS) threshold for auditory impairment, but were significantly below the mid-frequency cetacean TTS threshold (Fig. 4, using the thresholds defined in NMFS (2018) and assuming animals did not leave/avoid the area around the MODUs).

Analysis of the data revealed the acoustic occurrence of many odontocetes including dolphin whistles (whistles from unknown small dolphin species), delphinid clicks (clicks from small dolphins, killer whales, and pilot whales), pilot and killer whale whistles (these can be difficult to differentiate and there may be some errors in their identification), sperm whales (usual clicks; *Physeter macrocephalus*), narrow-band high-frequency (NBHF) clicks of porpoise (*Phoecena phoecena*) or Kogia (*Kogia breviceps*, *Kogia sima*), northern bottlenose whales (*Hyperoodon ampullatus*), True's (*Mesoplodon mirus*) or Gervais' (*Mesoplodon europaeus*) beaked whales (these signals could not be confidently differentiated to the species level, but are likely True's based on location), and Cuvier's beaked whales (*Ziphius cavirostris*). Automated detector performance varied across datasets, with some instances where manually validated results were considered a more reliable indication of species presence, even though only a subset of data was analyzed.

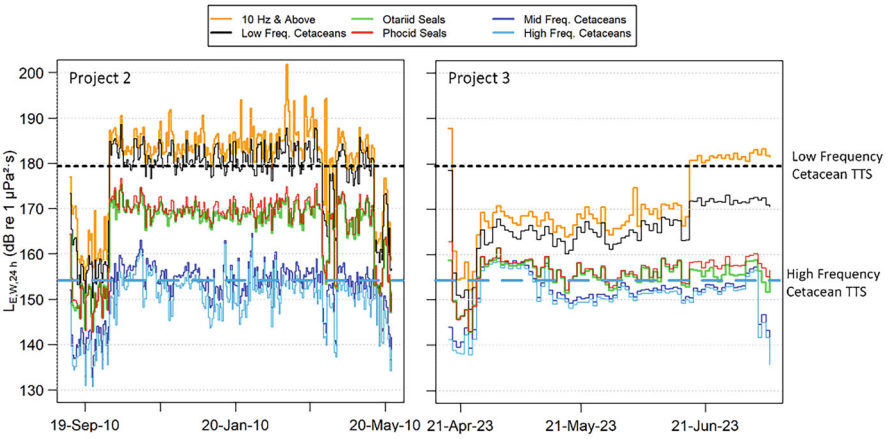

**Fig. 4** Daily auditory frequency weighted sound exposure levels for Projects 2 and 3 (see NMFS 2018 for details on the frequency weightings). The mid-frequency cetacean TTS threshold is 1 dB below the low-frequency cetacean threshold. The low-frequency group includes the large baleen whales. The mid-frequency group includes most dolphins, the beaked whales, sperm, and killer whales. The high-frequency group includes porpoise, kogia species, and some dolphins

The range of automated detector performance metrics was considered when interpreting results. For example, Fig. 5 provides evidence that delphinid clicks were more common at 40 km (present on 95% of days) than 1 km (present on 42% of days) from the MODU. It must be considered that at 40 km, the *per file* Recall was 10% higher than at 1 km, meaning that the detector missed 10% more true calls there. If one assumes that this performance differential transfers to *daily* Recall (which is certainly an overestimate) and consequently increase the occurrence at 1 km to make it artificially more comparable to 40 km, delphinid clicks become present at 1 km on 52% of days. With this artificial increase in occurrence, the acoustic occurrence of delphinid clicks remain substantially higher at the 40 km site. This exercise of considering whether Recall of automated detectors was skewing the interpretation of results was completed for each species and the overall trends (where the signal was more common) remained unaltered.

There was evidence that acoustic signals were more common further from the MODU for dolphin whistles, delphinid clicks, True's/Gervais' beaked whales, and Cuvier's beaked whales (Figs. 6 and 7). Trends in the occurrence of dolphin whistles and delphinid clicks are arguably most convincing given the consistency across all three projects (Fig. 6). No evidence of masking was found to explain these trends. In addition, there was some evidence of more frequent occurrence further from the MODU for both killer and pilot whale whistles (Fig. 6). However, the strength of these observations was weakened as they were often based on manual results and there was one instance where detections were more common close to the MODU (Fig. 6; pilot whale, Project 2).

Some odontocete acoustic signals either did not show trends related to distance from MODU or their acoustic occurrence was too low to reasonably assess impacts.

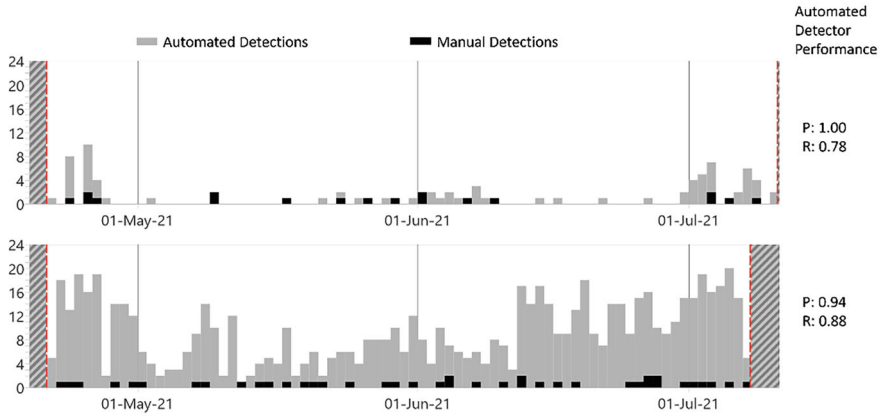

**Fig. 5** Number of hours in each day with delphinid clicks recorded at (top) 1 km and (bottom) 40 km from April to July 2021 (Project 3) with automated detector performance metrics per 10 min included along right side. The grey areas indicate hours of darkness from sunset to sunrise (Ocean Time Series Group 2009). Hashed areas indicate when there was no acoustic data and red dashed lines indicate the start and end of recordings

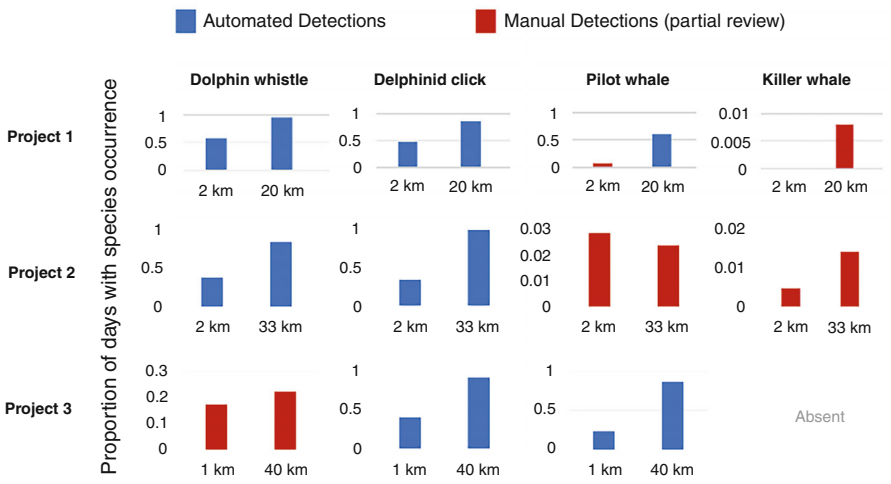

**Fig. 6** Bar plots showing the proportion of recording days that delphinids were manually detected (red) or automatically detected (blue) at recording station 1–2 km and 20–40 km from the MODU. Manual results cannot be directly compared to automated results given that only a proportion of data was reviewed while all data had automated detectors applied. Note that *y*-axis are different among species to show patterns between stations and years

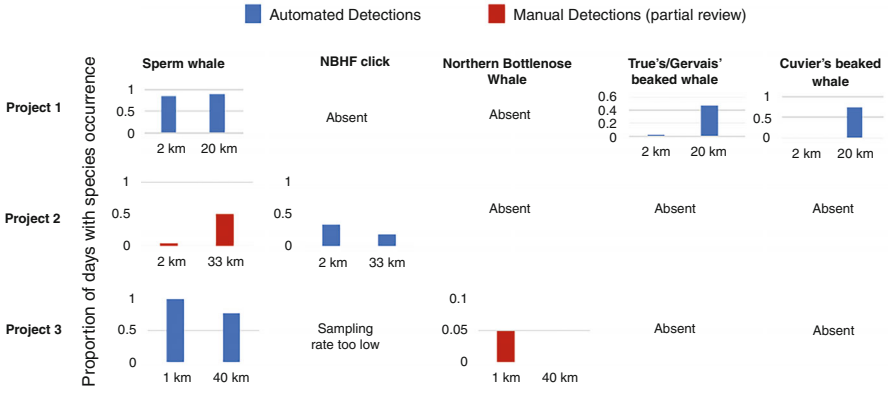

**Fig. 7** Bar plots showing the proportion of recording days that sperm whales, NBHF, and beaked whales were manually detected (red) or automatically detected (blue) at recording station 1–2 km and 20–40 km from the MODU. Manual results cannot be directly compared to automated results given that only a proportion of data was reviewed while all data had automated detectors applied. Note that *y*-axis are different among species to show patterns between stations and years

Sperm whales did not show consistent evidence of days with detections trending with distance from MODU (Fig. 7). There was low occurrence of both NBHF and northern bottlenose whales in the acoustic data, limiting the ability to assess trends, though the data available suggests no trend regarding distance to MODU (Fig. 7).

## Conclusion

The results indicate that MODUs impact nearby marine life. Evidence was particularly strong for impacts to delphinids, followed by True's/Gervais' and Cuvier's beaked whales. These species either reduced their vocal activity in the presence of the MODU, remaining in the area and potentially experiencing auditory impairment (if the remained close enough to the MODU), or the animals avoided the area and were displaced from habitat.

Impacts must be better understood and quantified for effective species management and future project planning. We recommend that studies be conducted to quantify the scale of avoidance of USBL pingers by different species of odontocetes. Questions of interest include which species are affected, how far from a USBL pinger is avoided, and the time scale after cessation of the pinger activity needed for the species to return to baseline activity levels. As a minimum, it is recommended that future PAM around MODUs include data from before, during, and after operations, ideally with pre-operation's information from more than 1 year. A structured autonomous exposure experiment could also be considered where a USBL source is deployed at the seabed, with autonomous recorders at ranges of 1, 3, 10, and 30 km. The USBL pinger would be programmed to cycle on and off for a day at a time, then 2 days, 4 days, 8 days, and 16 days to examine return rates to baseline activity. Controlled exposure experiments could also be considered with tagged animals and/or acoustic directional tracking of individuals and groups that would provide valuable insight into the species behavioral responses. Information could be collected and made available to researchers by marine mammal observers stationed onboard MODUs. For example, they can estimate the distance sighted animals are from the MODU, the animal's behavior, and report how long they remain in the area. This would allow an estimate of whether auditory impairment is reached.

MODU operators should consider whether the use of USBL can be reduced or mitigated in any way, such that levels fall below risk to auditory impairment of marine mammals or operations occur when and where fewer species are expected to be impacted.

**Abstract**

The emergence of ambient sound due to ship noise has adverse effects on pinnipeds. This chapter is focused on analyzing potential disturbance behavior of inhabitant animals when exposed to sound from ferry vessels. Three adult free-ranging ringed seals were tagged with GPS tracking devices to reveal their transiting tracks in the Gulf of Riga. Analysis of the telemetry data demonstrates their regular routes are between the Gulf of Riga and Väinameri to forage and rest. During transiting, the seals are likely being exposed to underwater anthropogenic

noise emitted from the ferry vessels. Impact of loud continuous anthropogenic noise and very close presence of fast-moving vessels on the seals are possibly predicted from the disruption patterns on regular dive profiles. Disturbed behaviors can be noticed when the seals dive deeper or perform multiple short dives and surfacing coincide to close encounters with the ferries. Received levels (RLs) that cause reactions on the seals are estimated from modeled underwater sound propagation.

## Introduction

One of the inhabitant marine mammals that can be found in Estonian waters is ringed seals (*Phoca hispida*). The seasonal presence of ice makes this region a safe place for them to live specifically to provide protection for their pups from predators (Sundqvist et al. 2012). The tendency of the world's increasing temperatures to reduce the area of ice cover is considered as one factor that is decreasing the chance of pups to survive, classifying this species under the category of vulnerable and protected (Helcom 2013). The vast increase of ship traffic and offshore constructions are also considered as negative factors for the seals in the Baltic Sea (Syrjälä et al. 2020; Tougaard et al. 2020).

The low-frequency radiated noise from anthropogenic activities is known to have adverse effects for marine biota including pinnipeds (Erbe et al. 2019). Previous studies have demonstrated that either free-ranging seals or seals in captivity communicate through calls (Mizuguchi et al. 2016; Stirling 1973). The simultaneous presence of anthropogenic noise and their calls could potentially reduce their communication space and experience auditory masking (Clark et al. 2009; Erbe et al. 2016). Moreover, research has shown unusual reactions of phocids to strong sounds. For example, experiments with harbor seals (*Phoca vitulina*) showed an increase in the median distance from the location of the sound source that simulated broadband wind generators (Koschinski et al. 2003). Both gray seals (*Halichoerus grypus*) and harbor seals show aversive behavior when stimulated with various sound signals including 0.5 kHz sine. The obvious response was they were moving away from the sound source when exposed to sound pressure levels of 144 dB (Götz and Janik 2010). It was also noted that masking thresholds were revealed on two ringed seals in captivity when they were exposed to tonal stimuli of 102 dB. The use of tagging devices together with sound level measurements in gray and harbor seals revealed their uncommon reactions when they were having close encounters with ships. Gray seals terminated their ascending dive prior to completion of the surfacing as the observed disturbance reactions. On the other hand, harbor seals reacted differently by diving deeper and staying in deeper places before the sound pressure reduced. These phocids' reactions and their behavioral hearing threshold (BT)

(ISO 2017) can be found in Mikkelsen et al. (2019a, b). Yet, the predicted levels that cause onset disturbance behaviors of seals are still lacking.

The objective is to find the impact of low-frequency continuous anthropogenic noise on the ringed seal. The analysis focuses on diving profiles of tagged, transiting ringed seals while crossing a noisy ferry route. The disturbance behaviors are assessed by comparing diving profiles that are situated in two different acoustical situations. Avoidance reactions of the seals' movements to the strong acoustical sources are also further analyzed. Estimates were made of the disturbance levels that resulted in interrupted diving profiles using sound propagation modeling.

## Methodology

### Study Location

The study took place in the narrow strait, Moonsund, Estonia, which is situated between Muhu Island and the mainland as depicted in Fig. 1. The location is very shallow water considering the maximum depth within the vicinity does not exceed 20 m. Also, it is usually freezing during winter time, which provides a good protection for the ringed seals' pups from predation. In addition, the acoustical monitoring using passive recorders revealed the presence of the gray seals in the region (Prawirasasra et al. 2019, 2021).

Two shipping lanes cross the monitoring location. One has moderate ship traffic levels through Moonsund that connects the Baltic Proper in the north and the Gulf of Riga in the south. Another lane is a 7-km-long busy ferry route that connects Virtsu and Kuivastu. The latter can be categorized as busy traffic considering more than 24–30 daily crossings occur from each direction with durations between crossings varying between 0.5 and 5 h depending on the hours. During the study, there were three operating ferries of M/S Regula, Viire, and Scania sailing in these ferry routes. According to the schedule, most of the ferries cross the strait during the day and two ferries are traveling from the opposite harbors at the same time with the average sailing speed being around 9–10 knots.

### Tagging Devices and Seals' Handling

A device tag that was used in the observation was a GPS Phone tag made by Sea Mammal Research Unit (SMRU), St. Andrews, UK. The telemetry tag collects geolocations onboard at 20-min increments with Fastloc® GPS. Ambient seawater pressure sensors measured the dive depth with 0.1 m resolution. Therefore, the threshold of dive detection was set to 1.5 m to separate between diving and time spent at surface. Dive profiles were constructed from nine recorded depth positions during the diving, which were saved from the measurement at the end of each dive (McConnell et al. 2004).

The tagging devices were attached to three free-ranging adult ringed seals who were previously caught with custom designed tangle nets. Glue was used to attach

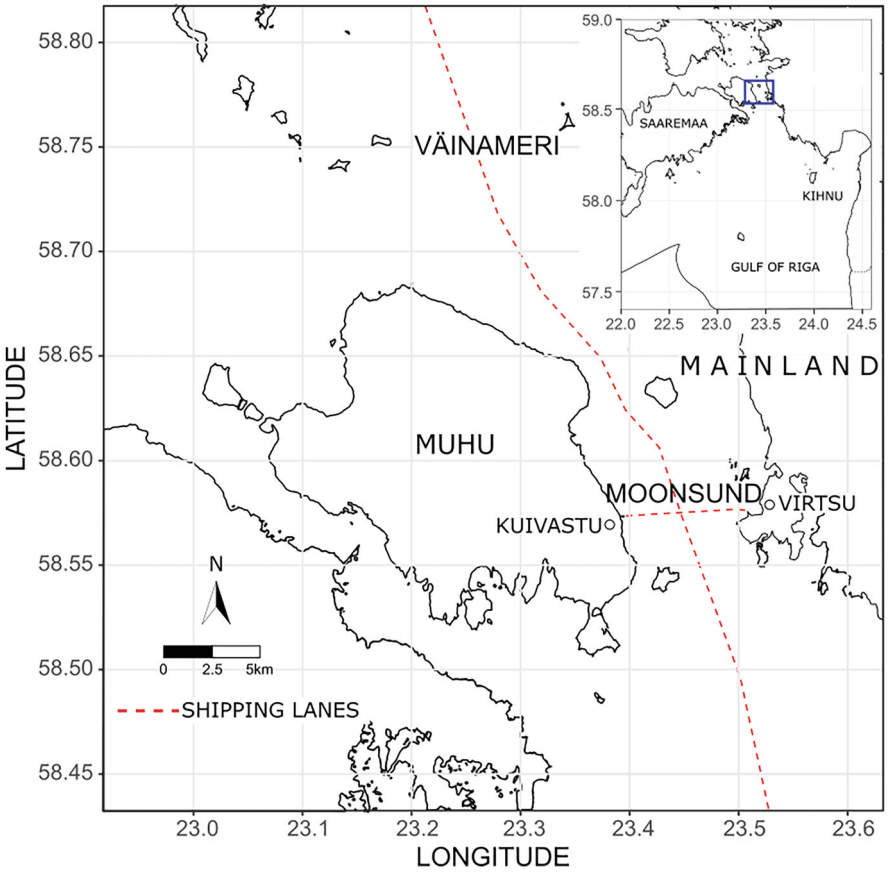

**Fig. 1** A map of the observation area, Estonia. The area is highlighted by a blue rectangle on a larger map in the top right corner inset figure. (Figure is adapted from Prawirasasra et al. (2022))

the device in the upper neck area using quick setting epoxy resin. The captured seals were released in the shortest possible time after the monitoring devices were DEPLOYED. Location of the captures was in the ringed seals' haul out in Väinameri in May 2009. The adult ringed seals were expected to have had prior experience to being exposed to the ship noise. Thus, their naive reaction to a new unnatural event was unlikely to happen.

## Estimation of Ferry's Source Level (SL) and Underwater Sound Propagation Modeling

The underwater sound propagations radiated from the moving sound sources were modeled using Quonops Online Service (Guelton et al. 2013). The acoustical source

of continuous anthropogenic noise was predicted by the RANDI model (Breeding et al. 1994). The modeled SL was verified from measurement of sound radiation of M/S Regula in June 2018. Radiated noise from the ferry was recorded at the closest point of approach (CPA) of 800 m to the hydrophone. The hydrophone was submerged underwater at 15 m depth. However, an accurate measurement of a ship's source spectrum can be performed when requirements are fulfilled such as deep location of the measurement (ISO 2019). Thus, the SL of the ferry can be estimated by predicting the transmission loss (TL) in an isovelocity sound speed profile using the following equation:

$$\mathrm{TL} = 20\ \log 10\ (H/1\ m) + 10\ \log 10\ [(R - H)/H] \tag{1}$$

With $R$ in meter is horizontal radius from ship to the hydrophone and $H$ is depth in meter of the water column. By substituting $R$ and $H$ with the measurement conditions, SL of the M/S Regula can be estimated after the prediction of TL value. The comparison analysis between modeled and estimated SL resulted in a fairly good agreement between them. Therefore, the RANDI model of M/S Regula could be used as a SL for acoustical sources in the underwater sound propagation modeling. In addition, the modeled SL of M/S Regula was also suitable for other operating ferries considering similar physical dimensions and sailing speed.

Underwater sound propagation in shallow water is different from deep water due to higher limiting or cutoff frequencies. Previous observation of RL spectra of ship noise in the vicinity demonstrated the existence of strong attenuation at lower frequencies (Jensen et al. 2011; Prawirasasra et al. 2021). It shifts the dominant frequency of shipping into higher frequency compared to suggested frequencies by Marine Strategy Framework Directive (MSFD) (Decision 2017). A frequency of 500 Hz one-third octave band (TOB) was used for underwater sound propagation modeling instead.

Snapshots of Quonops noise map were generated to predict the radiated ambient noise levels at particular positions of the acoustical sources. Natural ambient noise was approximated by selecting a point at a large distance from the ship with less acoustical impact from noise radiation from the acoustical sources. Excessive sound pressure level (SPL) was determined by comparing RLs at the position of the seals and the natural ambient noise levels.

## Dive Profiles

The telemetry data were analyzed by subsetting based on geographical coordinates extending from 1.5 km to north and south of the ferry route. The dive profiles were constructed from varying recorded depth positions in time. Meanwhile, the use of automatic identification system (AIS) of ship location reports and geographical coordinates of tracking data from each tag was possible to calculate the horizontal

distances between ships and the seals. The "regular" patterns of the dive profiles were referred to undisturbed behaviors of the seals during the crossings.

Irregular dive profiles were determined when compared to previously defined "regular" dive profiles. The assessment of the mismatch patterns was done by visual comparison. Irregularity of dive profiles in the vicinity of the ship might be an indication of disturbed behavior of the seals. The possible reactions can be variables in durations of dive/surfacing or dive depths. In Mikkelsen et al. (2019a), the regular dive profiles were interrupted in the presence of loud noise. The noted disruptions can be identified when the gray seals dived deeper and remained underwater. Another possible reaction were drastic changes in either diving speeds or dive directions. However, the current tracking data consists only of the averaged speed values between two sequential surfacing; therefore sudden responses are less probable to be noted.

## Result

### Analysis of Tracking Data

The monitoring periods of tagged seals started from May 2009 and ended in October 2009 without covering their breeding period in February and March. Each tag was identified by "A," "B," and "C." Analysis on tracking data showed that journeys of the tagged seals ended either in the Väinameri or the Gulf of Riga through Moonsund. Those destination locations were most likely associated with their resting and foraging activities (Halkka and Tolvanen 2017). The trajectories of their movements during monitoring periods are shown in Fig. 2.

Altogether, the three ringed seals crossed the ferry route at least 36 times with most of the travels being performed during the day. Time series analysis of their tracking data revealed that the tagged seals spent most of their time in the Gulf of Riga in the summer compared to autumn months. The transit corresponds to the Gulf of Riga (57.5°) and Väinameri (59°), which are represented in a time series of latitudes as depicted in Fig. 3.

### Regular Dive Patterns of Ringed Seal

A regular dive profile could be identified when the seals were separated more than 500 m away from the ships. The low RL of radiated ship noise seemingly did not disturb the crossing seals as their dive profiles remained regular. Notable features of regular dive profiles consisted of comparable durations between sequential diving and surfacing periods that continued for 3–5 min and 30 s, respectively (Kelly and Wartzok 1996). Another observed feature was dive depths. The transiting seals tended to dive close to the sea bottom while crossing (Crawford et al. 2019). The examples of undisturbed behaviors of the crossing seals are illustrated in Fig. 4.

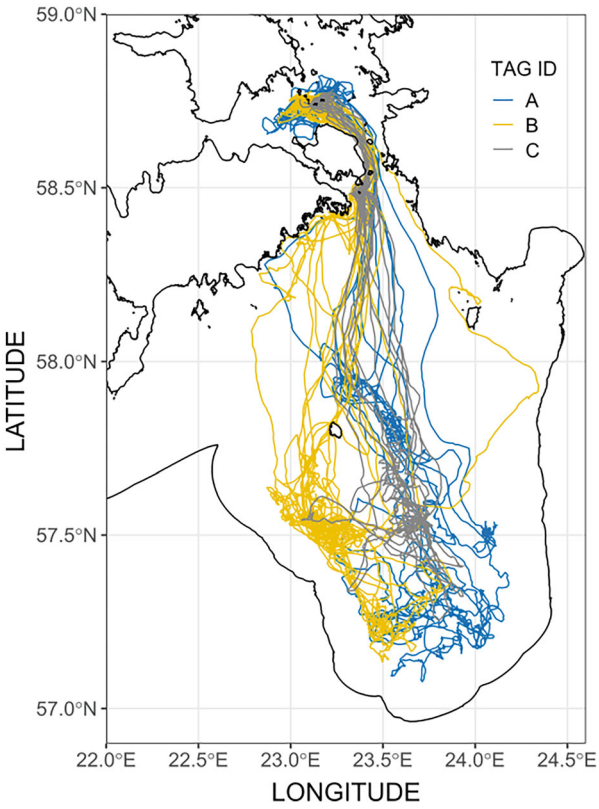

**Fig. 2** Trajectories of three tagged ringed seals in the whole period of monitoring. Blue, yellow, and gray color lines indicate "A," "B," and "C." (Figure is adapted from Prawirasasra et al. (2022))

## Changes in Dive Profiles

Despite having similar crossing time with the ferries, the collisions between them rarely occurred. Reconstructions of their movements showed that they only had three close encounters with distances less than 50 m. In the first case, seal "C" had a close encounter with the M/S Regula when traveling to the Gulf of Riga. Analysis on the dive profile showed there were no reactions of "C" to the approaching ferries as the regular dive profiles remained observed. On the other hand, two other cases that were experienced by "B" and "C" showed potential disturbance reactions of the tagged animals. Changes in dive profiles corresponding to varying distances from the ferries are illustrated in Fig. 5. "B" traveled to the north and was at least 800 m away from Viire preceding to having close encounters with the M/S Regula. In such distances, radiated noise from Viire did not affect the transiting seals. At the CPA of M/S Regula, "B" dived to the bottom of the sea to avoid the noise source, while previously "B" had a longer surfacing. Such reactions can be considered as a natural response in the presence of danger and it can be interpreted as an indication of

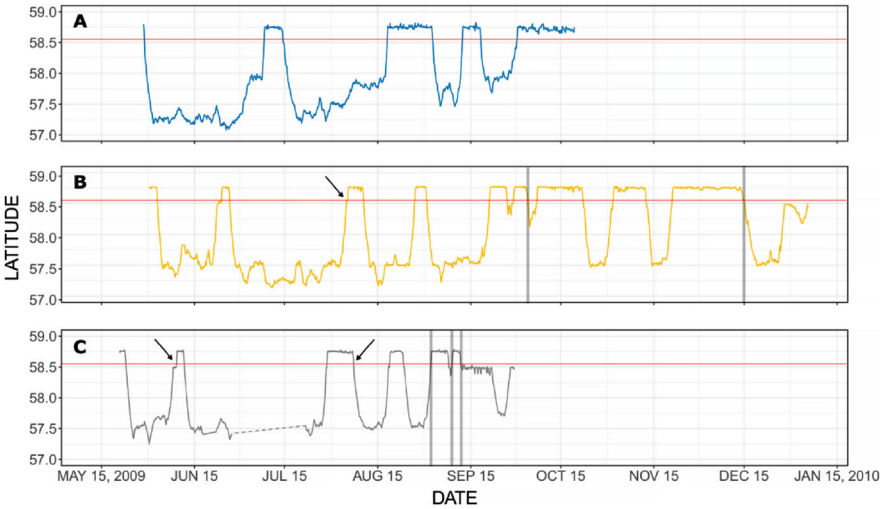

**Fig. 3** Plot of time versus latitude coordinates of transiting seals (**a**) "A," (**b**) "B," and (**c**) "C." The latitude coordinates of the ferry route are indicated by the horizontal red lines. Performed journey during nights is signified by the vertical gray bars. Arrows indicated the close encounters of the seals with the ferries. Dashed line shows the missing transmitted data. (Figure is adapted from Prawirasasra et al. (2022))

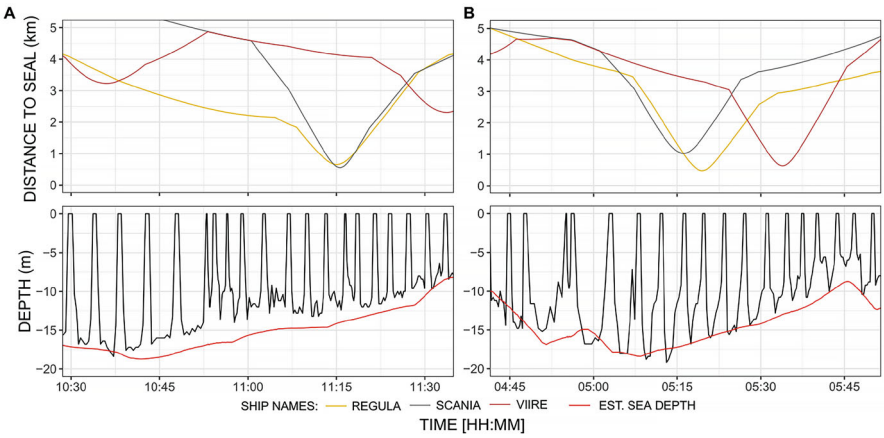

**Fig. 4** Identified regular dive profiles of (**a**) "A" and (**b**) "C" crossing seals. Undisturbed behavior remains observed when the ferries were at least 500 m away from the seals. The bathymetry is shown by the red line

behavioral reaction (Fig. 5a). More prominent reactions were shown in another case as depicted in Fig. 5b. "C" was situated at a distance of 35 m to M/S Regula and started to do multiple short dives and surfacing in very short durations. The tagged seals continued underwater for 32–48 s and went to the surface for 4–12 s. Thus,

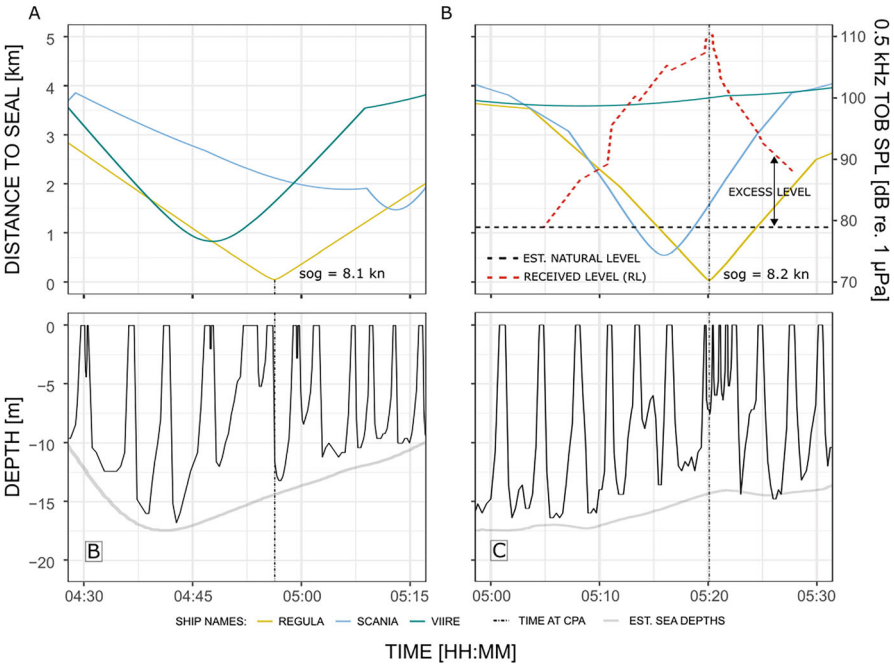

**Fig. 5** Observed potential disturbance reactions of the seals to approaching ferries. No indications of disturbed behaviors when the seals are at least 500 m away from the ferry. The interrupted dive profiles can be noted in the form of diving deeper in (**a**) and more prominent reactions in multiple short dives and surfacing are shown in (**b**). The latter happens when the tagged seal is being exposed to a sound excess of 110 dB at 0.5 kHz TOB. M/S Regula's close encounters to the tagged seals along with their reactions within 50 m to "B" and 35 m to "C" are depicted at (**a**) and (**b**). Upper figures indicate the distances of the ferries to the seals and dive profiles of the crossing seals are shown in lower figures. The varying modeled RLs at the "C" positions due to the traveling ferries are indicated in red-dashed line at (**b**). The estimated natural sound is shown in black-dashed line. The sound excess is defined as the relative levels between RLs and natural sound. The yellow, blue, and dark green lines show the distances of M/S Regula, Viire, and Scania ferries to the tagged seals. The sailing speeds of M/S Regula at the CPAs were 8 knots. Time of CPAs are shown by vertical black dash-dotted lines. (Figure is adapted from Prawirasasra et al. (2022))

these reactions can be suggested as disturbance behaviors of the seals when being exposed to loud ship traffic noise and having near collision with the ships. While in the previous encounters with the Scania at larger distances, no reactions were shown.

Meanwhile, the varying RLs at the positions of the tagged ringed seals corresponding to changing relative distances to the ferries can be approximated. The BT can be estimated at the moment when the irregularities of the dive profiles were starting to be noticed. In this case, the reactions of the ringed seals were observed after the seals were stimulated by 110 dB at 0.5 kHz TOB or when the sound emerged 30 dB above the natural sound. The approximation of RLs and sound excess are illustrated at the upper right figure in Fig. 5b.

## Discussion

The tracking analysis has shown that the tagged ringed seals crossed the Moonsund 36 times with only 3 close encounters with the ferries. However, the irregularities in dive profiles can be observed only in two cases. The interruptions might be associated with their reactions to the ship traffic noise. In the first case, the reactions of the tagged seals dived deeper in the presence of loud anthropogenic noise. The seals continued underwater until the sound pressure returned to acceptable levels. In the second case, the occurrence of more pronounced irregular dive patterns happened. The seals traveled by performing multiple short dives and surfacing that occurred in very short durations. The surfacing reactions might be noise mitigation to reduce the intensity when being exposed to loud anthropogenic noise (Sills et al. 2015).

Other observed variables, traveling direction, and swim speed were analyzed from the two close encounter cases with disturbances. However, no indications of flight or significant avoidance reactions were indicated by the seals toward the very close, fast-approaching vessels. Even more, the seals kept swimming at constant paces. Possibly the objects have been well habituated in the presence of the ship traffic along with low resolution of recorded data where only average speed can be predicted without showing sudden reactions.

The assessment of BT that resulted at 110 dB in 0.5 kHz TOB can be compared to previous investigation with phocids (Mikkelsen et al. 2019a). This study demonstrated that the reaction of the gray seal can be noted when being exposed to 92 dB in 0.5 kHz TOB or 113 dB in broadband of continuous anthropogenic noise. In another study with harbor seals as documented in Kastelein et al. (2006), the reaction of the seals can be notified at level of 107 dB at 24 kHz of sound stimuli. The flight reactions of the seals seem not possible to happen considering available anthropogenic sound sources in the region as the estimated BT was considerably lower than referenced in Götz and Janik (2010). Moreover, the observed reactions matched with one of listed behavioral responses in Southall et al. (2021), and it can be categorized as low reaction (1) on the severity scale.

## Conclusions

Telemetry tags have been used to monitor the transiting route of three ringed seals. The tracking data demonstrated the regular transiting routes of the seals between Väinameri and the Gulf of Riga corresponding to their rest and forage activities. The Moonsund can be considered as an important transiting area for the ringed seals as they crossed it twice in a month. The ferry traffic that connects Kuivastu and Virtsu and crosses the Moonsund can be considered as the main contributors of anthropogenic noise in the location.

There is no solid evidence of seals' flight reactions when they are being exposed to loud ship noise. The exposed seals keep their swim direction and speed even when receiving the loudest possible noise. The lack of notable changes might indicate the tagged seals have been habituated with the presence of ferry traffic noise. In addition,

the reactions possibly do not appear considering the available data. Only average speed can be estimated; thus no abruptness can be identified.

Underwater continuous noise emitted from ferries seemingly has a low impact on traveling seals. According to the spatial movement analysis from 3 tagged seals, exposure to louder noise occurs only in 2 out of 36 crossings resulting in identified possible disturbance behaviors. The crossing seal swam with several short dives and surfacing that happen in very short durations. It is observed when the seals receive 110 dB at 0.5 kHz or when the ambient noise exceeds 30 dB at 0.5 kHz above the natural level. The obtained results are quite similar with the cited literature even though the number of cases is very small. The complete report of this chapter has been published in Prawirasasra et al. (2022).

**Abstract**

Temporary threshold shifts (TTS) have been studied in a variety of aquatic organisms from fish to marine mammals, but never in sea turtles. Here, turtle TTS was measured in air, and the in-air to underwater sensitivity difference was used to estimate TTS in water in an aquatic turtle. Red-eared sliders (*Trachemys scripta elegans*) were exposed to broadband noise in air for 24 h, and auditory sensitivity was assessed by auditory evoked potentials from the brainstem before exposure, immediately after exposure and during the following recovery period. All animals showed a depression of sensitivity immediately after exposure and full recovery 3–5 h after exposure. Based on differences in hearing thresholds in air and water, the exposure would be equivalent to 111 dB $L_{eq}$ (re 1 μPa) for aquatic sound, resulting in a sound exposure level of 160 dB re 1 $\mu Pa^2 s$ from the 24 h exposure. It is likely that long-term underwater sound level exposure at such levels will cause underwater TTS in turtles.

## Introduction

Temporary threshold shift (TTS) is an intermittent reduction in auditory sensitivity caused by sound exposure that has been studied in a variety of terrestrial as well as aquatic organisms. TTS is probably caused by intense exposure of inner-ear processes, for example, in the hair cells, the hair cell synapse, or in the auditory nerve fibers (Ryan et al. 2016). Studies of TTS are important both for understanding the control of sensitivity of the ear and for environmental regulation, since the onset of TTS is a convenient estimate of the threshold for physiological effects of noise (Saunders and Dooling 2018). However, recent studies of TTS in some mammalian species caution that even though sensitivity (measured by audiogram thresholds) recovers after noise exposure, there might still be permanent physiological damage, leading to cochlear synaptopathy and loss of auditory nerve fibers (Liberman and Kujawa 2017). Thus, an understanding of the mechanisms underlying TTS is necessary in order to assess the potential environmental threat of intense anthropogenic sounds.

For turtles in general, and particularly for the seven marine species, there are no data on TTS thresholds. This is unfortunate, as sea turtles are endangered, raising concerns about the added impact of environmental noise (Martin et al. 2012). In fact, very little is known about hearing in sea turtles, and especially their underwater hearing (Willis 2016). In-air and underwater hearing thresholds have been measured in green sea turtles (*Chelonia mydas*, Ridgway et al. 1969; Piniak et al. 2016), loggerhead turtles (*Caretta caretta,* Bartol et al. 1999; Martin et al. 2012; Lavender et al. 2014), and leatherback turtles (*Dermochelys coriacea,* Piniak et al. 2016) using physiological (auditory evoked potentials) or behavioral assays. In addition, in-air thresholds have been obtained from Kemp's ridley (*Lepidochelys kempii,* Ketten and Bartol 2006). Sea turtles have a similar frequency range of in-air and underwater hearing between 50 Hz (the lowest frequency studied) and 1000 Hz and most sensitive frequencies around 300–500 Hz. This frequency range is similar to in-air hearing abilities in all turtles and tortoises measured so far (e.g., Wever 1978).

Sensitivity thresholds are difficult to compare due to different experimental setups and stimulation methods (e.g., sound in air and water, or direct vibration of the tympanum). As shown in Fig. 1, the lowest thresholds to underwater sound, based on auditory evoked responses, is reported at 80 dB re 1 μPa for *C. caretta* (Ketten and Bartol 2006), and 85 dB re 1 μPa in *C. mydas* (Piniak et al. 2012) and juvenile *D. coriacea* (Piniak et al. 2016). Audiograms measured by auditory evoked potentials usually show higher thresholds than behavioral audiograms, and in one case where auditory evoked response audiograms are compared to behavioral audiograms in one loggerhead turtle the shape of the audiograms is similar, but behavioral thresholds on average 8 dB lower (Martin et al. 2012). Even though differences in methodologies may preclude a detailed comparison with between studies, these data

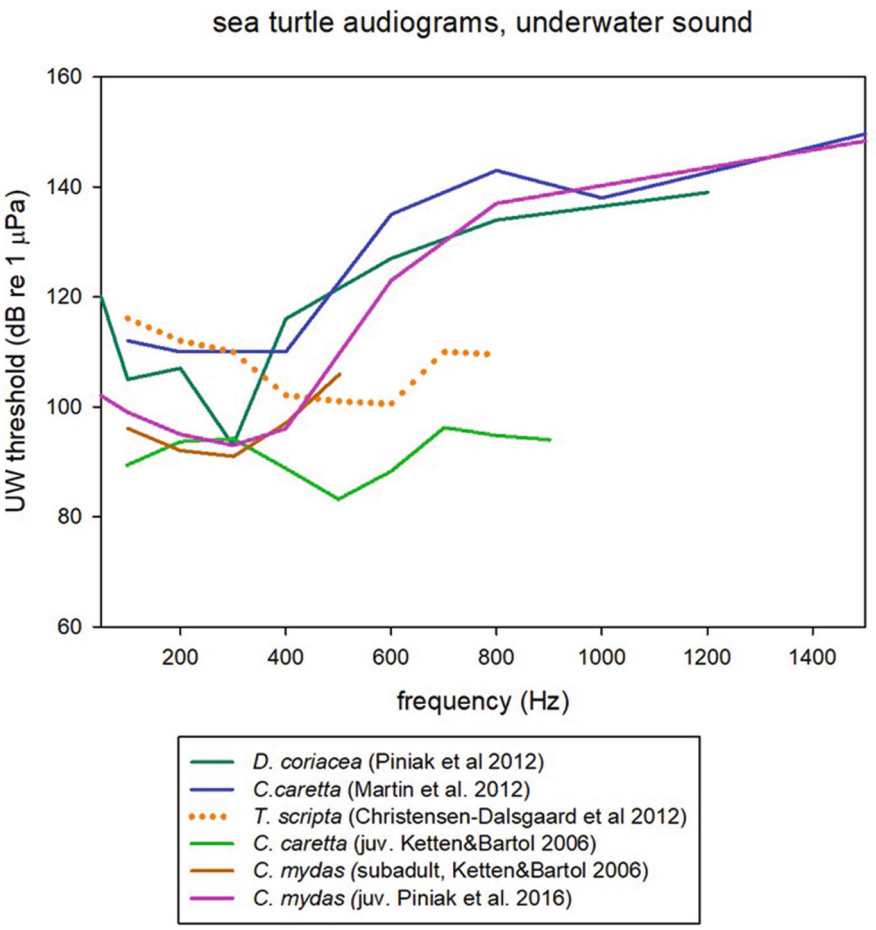

**Fig. 1** Underwater audiograms of sea turtles. Sensitivity to underwater sounds of different species of sea turtles, based on data from Piniak et al. (2012), Martin et al. (2012), Ketten and Bartol (2006 and 2008), and Piniak et al. (2016). An underwater audiogram of *Trachemys scripta*, based on data from Christensen-Dalsgaard et al. 2012, is shown for comparison

indicate that marine turtles are almost as sensitive to underwater sound (within their limited frequency range) as are some of the most well-studied fish (Popper and Fay 2011) and pinnipeds (Reichmuth et al. 2013). Turtles are therefore potentially affected by anthropogenic sound, just like some species of fish and pinnipeds. In addition, there are behavioral indications that marine turtles are disturbed by aquatic sound: Loggerhead turtles will actively avoid or dive in response to airgun sounds (O'Hara and Wilcox 1990; DeRuiter and Larbi Doukara 2012).

This chapter investigated TTS in a freshwater aquatic turtle, the red-eared slider (*Trachemys scripta elegans).* Although the slider is more amphibious than the marine species, the basic configuration of its ear and auditory sensitivity (Fig. 1) is similar to marine species (Ridgway et al. 1969; Christensen-Dalsgaard and Manley 2013). It has

been shown that the red-eared slider's ear is adapted for underwater hearing (Christensen-Dalsgaard et al. 2012), and it is by far the most well-studied turtle with respect to hearing. Like other turtles and tortoises, it has a tympanic middle ear, where the vibrations of the cartilaginous tympanic disk are coupled to the inner ear by the single middle ear ossicle, the columella (homologous to the mammalian stapes). In air, the turtle is less sensitive than other tympanate vertebrates, but the specializations of the middle ear, most notably an air-filled middle ear cavity, make the slider sensitive to underwater sound pressure in the 200–1000 Hz range, with best sensitivity around 400 Hz and lowest thresholds at 80 dB re 1μPa. The audiogram has the same shape in air and water, and the sound pressure thresholds are 5–12 dB higher in water than in air (Christensen-Dalsgaard et al. 2012).

The inner ear of the red-eared slider has been the subject of intensive studies (reviews in Manley 1989; Fettiplace 2020) facilitated by the extraordinary ability of turtle nerve tissue to survive under low oxygen tension. The auditory papilla (basilar papilla) is short, containing approximately 1100 hair cells, innervated by 1350 afferent fibers (Manley 1989) and covered by a tectorial membrane. Electrical resonance of the hair cells caused by negative feedback between repolarizing K-currents and depolarizing Ca-currents account for most of the frequency tuning in the papilla (Fettiplace 2020). Thus, the slider would be an excellent model to study the effects of TTS on the hair cells.

In this study of TTS in red-eared sliders, turtles were exposed to noise in air for 24 h (Gaussian white noise, approx. 80 dB Leq at the turtle). The auditory sensitivity was measured by recording auditory evoked potentials from the brainstem in lightly anesthetized turtles (Christensen-Dalsgaard et al. 2012) before exposure, immediately after exposure, and during the following recovery period. In all animals there was a depression of sensitivity immediately after exposure and full recovery 3–5 h after exposure.

## TTS in the Red Slider

Auditory evoked responses were measured in six red-eared sliders stimulated with transient "clicks" (a half-cycle 4 kHz sinusoid) and tone-masked clicks using the difference between the response to the clicks and to the masked click as a measure of the sensitivity to the tone (mABR, see Brandt et al. 2018; Christensen-Dalsgaard et al. 2012). An example of the click response from one animal, before noise exposure, is shown in Fig. 2. From such measurements, the threshold could be calculated as a fixed signal-to-noise ratio of the brain stem response.

The initial threshold shift after their 24 h noise exposure was measured in each turtle right after sedation. During the 24 h exposure the turtle was placed into a bin with a bit of water to prevent dehydration (but without water level covering the eardrums) and food. The light in the chamber was turned off during the exposure.

The difference in thresholds (dB before and after noise exposure) is shown in Fig. 3, both showing the difference in threshold when stimulated with a transient "click" and when using 500 Hz. For the click response the median difference was 13 dB, and at 500 Hz the median difference was 20 dB. For both stimuli, threshold

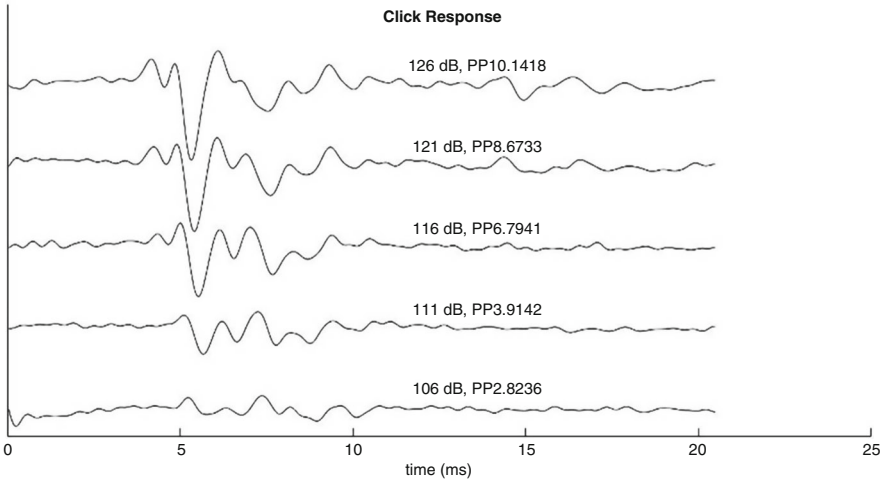

**Fig. 2** ABR with click stimulation. Example of the auditory brain stem response of a turtle to a transient "click" (half-cycle sinusoid at a nominal frequency of 4 kHz) showing traces at five stimulus levels (air-borne sound, dB re 20 μPa, peak equivalent). The numbers on the traces are the peak-peak amplitude of the brain stem response

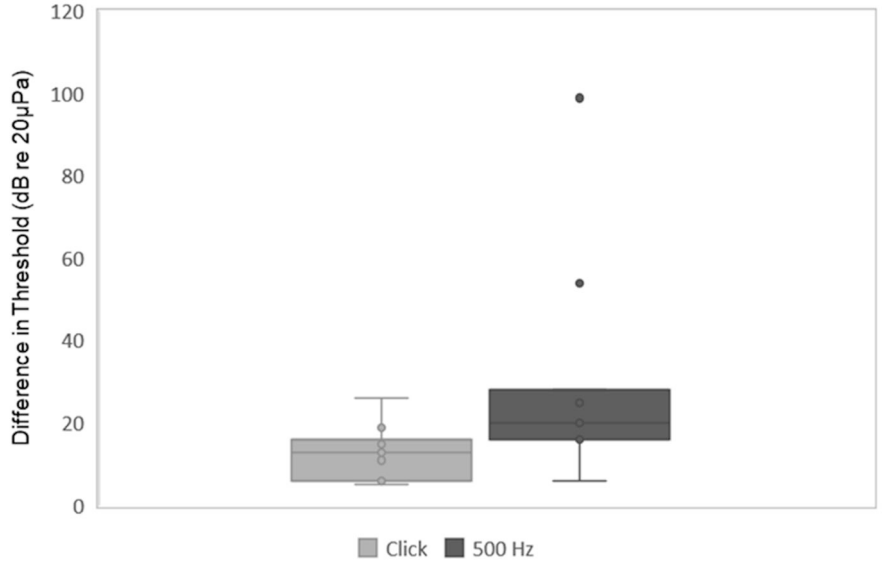

**Fig. 3** Difference in click and tone threshold directly after noise exposure. Threshold shift of auditory brain stem responses immediately after 24 h noise exposure, showing both threshold shift of click and a 500 Hz tone

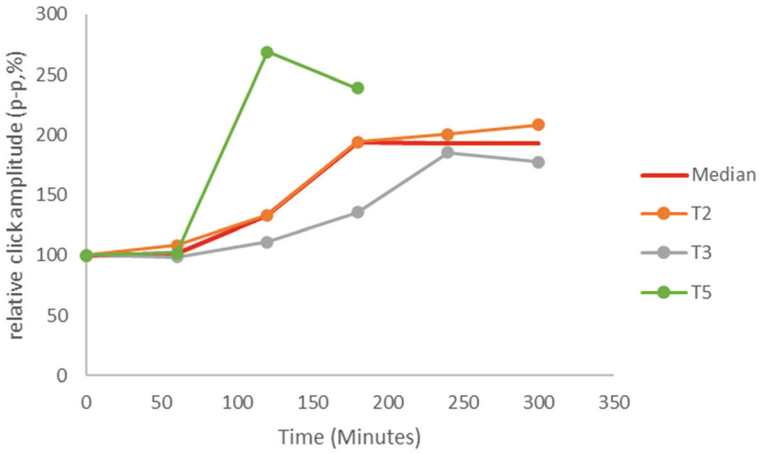

**Fig. 4** Recovery from noise exposure. Recovery of auditory brain stem response to click stimulation after noise exposure, shown for three individuals (T2, T3, and T5) and the median response. The peak-to-peak brain stem responses are measured relative to the response immediately after noise exposure (in units of %)

differences were statistically significant (Click: $p = 0.005$; 500 Hz: $p < 0.01$). There were considerable individual differences in the threshold shifts, especially for tonal stimulation at 500 Hz, with for one individual reaching 99 dB.

After recording the initial threshold shift, the recovery time of each individual was measured by hourly measurements of sensitivity to stimulation by clicks. The click amplitude (percent) relative to the initial click amplitude postexposure was plotted in Fig. 4. An amplitude increase was observed over time in three turtles, with a median of 4 h for the turtles to recover to a preexposure amplitude (approximately 200% of the initial postexposure amplitude). In all animals, thresholds were reduced after initial noise exposure. While three of the turtles recovered in the 5 h observation period, the other turtles brain stem response either did not increase or increased only slightly throughout the measurements. In all animals the thresholds had recovered to preexposure levels a month after exposure.

## Implications of Noise Exposure

The study reported here clearly show that a moderate noise exposure at 80 dB $L_{eq}$ in air produces a measurable TTS, on average 13 dB for click thresholds and 20 dB for tone thresholds, in red-eared sliders.

Although the turtles were exposed to air-borne sound, which is easier to control than underwater sound, these preliminary results may indicate how turtle hearing is affected by underwater sound exposure. The pressure thresholds are approximately 5–12 dB higher in water than in air for this species (Christensen-Dalsgaard et al. 2012). We may therefore assume that the in-air sound exposure level used in this

study (80 dB $L_{eq}$ re 20 μPa) corresponds to an underwater sound exposure of 111 dB Leq re 1 μPa, assuming a 5 dB higher pressure threshold in water and compensating for the different reference pressures used in air and underwater. The corresponding sound exposure level during 24 h exposure in water is 111 dB + $10\log_{10}(24{\cdot}60{\cdot}60)$ = 160 dB re 1 $\mu Pa^2s$. Note that the noise levels reported here are not weighed by the turtle audiogram and therefore the exposure level within the turtle's hearing range resulting in TTS is probably lower.

Harbor seals (*Phoca vitulina)* and harbor porpoises (*Phocoena phocoena*) are some of the most well-studied marine species regarding TTS, and they have TTS thresholds ranging from 140–200 dB re 1 $\mu Pa^2s$, depending on stimulus frequency (Tougaard et al. 2022). For several species of fish, exposures at 180 dB re 1 $\mu Pa^2s$ resulted in up to 20 dB TTS (Popper et al. 2005), but fish data are very variable, both depending on the species and the experimental methodology. The results of especially marine mammals are thus comparable (even though the range is huge) with this study's finding from turtles. When addressing concerns for anthropogenic noise affecting marine animals, it is important not only to address fish and marine mammals but also any potential effects on turtles. Many sources of anthropogenic underwater sounds generate exposure levels above 160 dB re 1 μPa. This may include, for example, nearby ships, pile driving while constructing wind farms, and air guns while searching for oil and gas (Richardson et al. 1995). Since marine turtles have underwater hearing abilities comparable to the red-eared slider (Figure 1), sea turtles should be a concern for protective measures.

hawksbill turtles *Eretmochelys imbricata* in a pool were exposed to synthetic sounds, an impulsive sound, Helicopter Long-Range Active Sonar (HELRAS) down-sweeps, and recordings of killer whale *Orcinus orca* vocalizations. Typical responses were increased swimming speed and/or changes in swimming pattern or direction, but the pure tones, impulsive sound, HELRAS, and killer whale sounds elicited no response. Strong responses occurred to series of 0.2–1 kHz up-sweeps with 100% duty cycle, duration 0.5 s, and sound pressure level >151 dB re 1 μPa. Above this threshold, the spectrum, frequency modulation, and temporal pattern of the sounds, and the behavioral state of the turtles, determined their response. Most responses occurred during exposure to sounds with frequencies between 0.2 and 1 kHz, within the hearing range of turtles. This pilot study suggests that turtles respond to high-amplitude, low-frequency anthropogenic sounds and that deterring sounds should be low in frequency and temporally and spectrally complex.

## Introduction

Sea turtles consist of seven species in the superfamily Chelonioidea, of which six are threatened (IUCN categories Vulnerable, Endangered, and Critically Endangered; https://www.iucnredlist.org) and one is Data Deficient. Sea turtles have streamlined shells, large paddle-shaped fore flippers adapted for propulsion, and rear flippers for steering. Except when laying eggs on beaches, they remain at sea (Gulko and Eckert 2003; Lutz et al. 1996).

Turtles are incidentally injured or killed during industrial, fishing, and recreational activities at sea (Eckert and Eckert 2005; Lester et al. 2013; Ramirez et al. 2017; Swimmer and Brill 2006), so methods to deter them from areas where these activities take place are needed. High-amplitude sounds have been used to deter other marine animals (Thompson et al. 2020), and knowledge of turtle hearing and responses to sound could be used to generate sounds that deter turtles. Such knowledge could also be used to avoid accidental deterrence of turtles from ecologically relevant areas, such as those used for resting, breeding, and feeding, by anthropogenic sounds.

Little is known about the importance of sound in the ecology of turtles, but turtle ear anatomy is most suited to hearing under water via bone conduction in the skull (Christensen-Dalsgaard et al. 2012; Lenhardt et al. 1985; Willis et al. 2013). The hearing of three of the seven species has not been tested at all (hawksbill turtle *Eretmochelys imbricata*, olive ridley sea turtle *Lepidochelys olivacea*, Australian flatback sea turtle *Natator depressus*). In the remaining four species, underwater hearing sensitivity has been quantified by using auditory evoked potentials (presenting an acoustic stimulus and recording neural responses from electrodes on the

**Table 1** Summary of published information on underwater hearing in the four sea turtle species that have been subject to relevant research. Most sensitive hearing is defined as within 10 dB of maximum sensitivity

| Species | Hearing frequency range | Most sensitive hearing | Source |
|---|---|---|---|
| Atlantic green turtle *Chelonia mydas* | 0.1–0.5 kHz | 0.2–0.4 kHz | Bartol and Ketten 2006 |
| Loggerhead sea turtle *Caretta caretta* | 0.024–1 kHz | 0.2–0.5 kHz | Lavender et al. 2014; Lenhardt et al. 1983; Martin et al. 2012 |
| Kemp's ridley turtle *Lepidochelys kempii* | 0.1–0.5 kHz | 0.1–0.2 kHz | Bartol and Ketten 2006 |
| Leatherback sea turtle *Dermochelys coriacea* hatchlings | 0.05–1.2 kHz | 0.1–0.4 kHz | Piniak et al. 2012 |

head; Table 1; see Bartol and Ketten 2006; Lavender et al. 2014; Lenhardt et al. 1983; Martin et al. 2012; Piniak et al. 2012). Popper et al. (2014) proposed sound exposure criteria for sea turtles based on the very few published data and recommended increased research on the effect of sound on sea turtles.

So far, only a few attempts have been made to identify sounds that could deter sea turtles from dangerous areas, and all involved loggerhead sea turtles *Caretta caretta*. O'Hara and Wilcox (1990) investigated the avoidance response of loggerhead sea turtles to low-frequency high-intensity sounds generated with two types of airgun, firing at two pressures. Most of the energy of the sounds was at 0.025 kHz, but energy was present up to 0.7 or 1.0 kHz, depending on the airgun type. The turtles mainly reacted to the airguns firing at the higher pressure (140 kg/cm$^2$) by moving ~30 m away from the sound source. Moein et al. (1995) investigated the use of airguns with spectra 0.1–1.0 kHz to repel juvenile loggerhead sea turtles from hopper dredges. Avoidance of the airguns was observed upon first exposure, but after three exposures, the turtles became habituated to the stimuli. DeRuiter and Doukara (2012) observed the responses of 164 wild loggerhead sea turtles to broadband impulsive sound produced at very high levels during a seismic survey. Turtles that were close to the airguns (median, 130 m; maximum, 839 m) experienced relatively high exposure levels (~191 dB re 1 μPa [peak] at 130 m and ~175 dB at 839 m) and were observed to dive. At least six individuals dove immediately following an airgun shot, often showing a startle response. Diving was interpreted as an avoidance response to airguns. Lenhardt (2002) developed a device aimed at deterring sea turtles from dangerous areas: a vibrating bar, producing light and sounds, that can be placed under a ship. However, this device has not been tested.

The present pilot study assesses the effect of sounds on the behavior of four individuals of two sea turtle species. The results will indicate whether sound stimuli can be used to deter sea turtles from potentially harmful locations and facilitate the development of strategies to reduce turtle mortality or injury. The results are also a step toward the assessment of the effects of anthropogenic sounds on the behavior

**Table 2** Characteristics of the two male Atlantic green turtles *Chelonia mydas* and one male and one female hawksbill turtle *Eretmochelys imbricata* that participated in the sound experiments, including their Archival Resource Key (ARK) numbers

and ecology of sea turtles, required to inform Environmental Impact Assessments of human activities which produce underwater sound at sea.

## Materials and Methods

### Study Animals and Location

The study was conducted with two male Endangered Atlantic green turtles *Chelonia mydas* and one male and one female Critically Endangered hawksbill turtle *Eretmochelys imbricata* (Table 2).

The study took place in an indoor pool at Blijdorp Zoo, Rotterdam, the Netherlands, in 2010. The pool was normally used as a quarantine area for the aquarium department and was not open to visitors or zoo staff, so no disturbance occurred during the experiments. The pool was oval (7.6 m × 5 m × 1 m deep; Fig. 1) and made of plastic. To reduce sound conduction from the floor, it was placed on a layer of Styrofoam. The water level was kept constant. The water was clear so underwater visibility was very good, even over the length of the pool. The water temperature was 24 °C, and the salinity was around 34.5‰. There was no current in the pool during the experiments as the water circulation pump was switched off. A tent was erected over the pool to retain heat and reduce disturbance; the air in the tent was heated to 24.5 °C. The equipment used to produce the sound stimuli and video recording equipment were housed out of sight of the turtles, in a research cabin just outside the tent.

### Video Equipment

The turtles' behavior was filmed from above by aerial camera 1 (Mariscope, model Micro) with a wide-angle lens, which was placed on a pole 3 m above the water

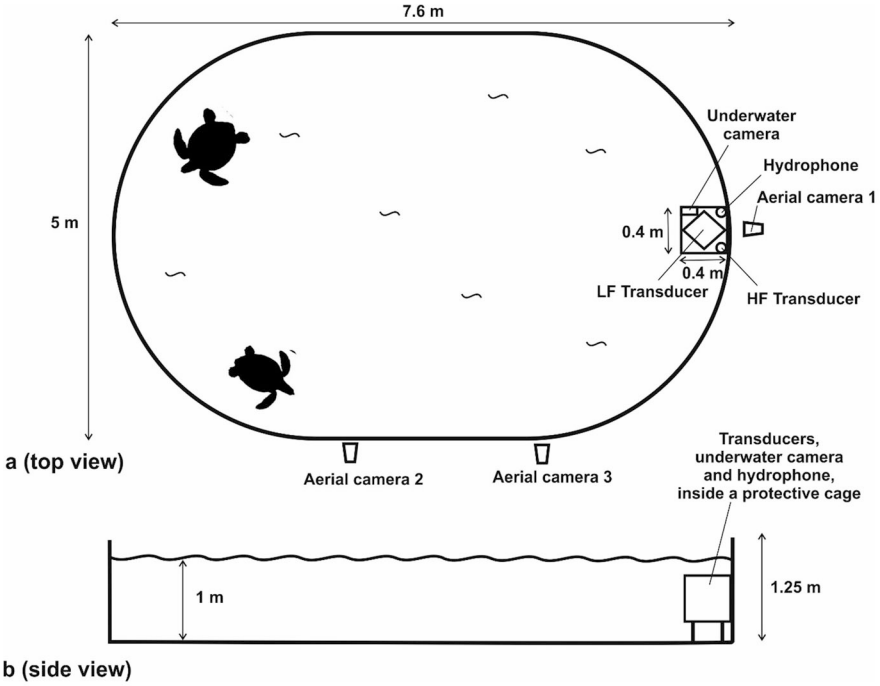

**Fig. 1** The pool at Blijdorp Zoo, Rotterdam, the Netherlands, in which the acoustic experiments were conducted, showing the locations of the low-frequency (LF) and high-frequency (HF) transducers, hydrophone, and aerial and underwater cameras, to scale (**a**, top view; **b**, side view). Sea turtle silhouettes in (**a**) are also to scale: top, Atlantic green turtle *Chelonia mydas*; bottom, hawksbill turtle *Eretmochelys imbricata*

surface at one end of the pool (Fig. 1). The entire surface of the pool was captured on the video image. Two additional aerial cameras (2 and 3) were placed on the long side of the pool. One underwater camera (Mariscope, model Micro) was placed next to the low-frequency transducer inside a protective cage (Fig. 1). The output of the cameras was fed through a video quad splitter and digitized with an analog-to-digital converter (EZ Grabber, Vista version) and then stored on a computer (Medion; Fig. 2). The images from all four cameras were visible to the operators on monitors in the research cabin.

The background noise and the stimuli were recorded via a recording hydrophone (Labforce, model 90.02.01) and a conditioned charge pre-amplifier (SEAMARCO, model CCAMS1000-1). The output of the pre-amplifier was digitized via the analog-to-digital converter and recorded on the computer in synchrony with the video images. The output was also fed to an amplified loudspeaker, so that the operators in the research cabin could monitor the background noise and the test sounds during sessions. Via a microphone and pre-amplifier, comments could be added to the video recordings.

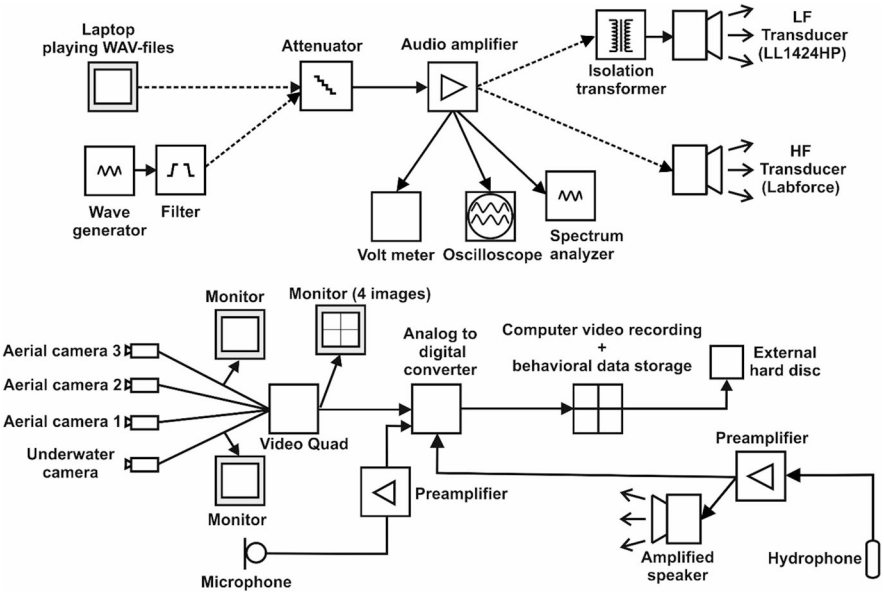

**Fig. 2** Block diagram of the sound generation and control systems (top) and the listening and recording equipment (bottom) used in the turtle behavioral response study

## Sound Equipment and Stimuli

The turtles were exposed to synthetic sounds, an impulsive sound, Helicopter Long-Range Active Sonar (HELRAS) down-sweeps, and recordings of killer whale *Orcinus orca* vocalizations (Table 3).

Of the synthetic sounds, the pure tones, square waves, triangle waves, sawtooth waves, frequency-modulated tones, and white noise bands were generated with a wave generator (Hewlett Packard, model 33120A) and a digital band-pass filter (Krohn-Hite, model 3384; Fig. 2). The other synthetic sounds were created as WAV files in Adobe Audition (version 3.0) and played on a laptop computer with durations 10 s and duty cycle 100%.

For the impulsive sound, the $t_{90}$ signal duration in the pool was 10 ms, and the zero-to-peak sound pressure level (SPL) was 120 dB re 1 µPa. The HELRAS down-sweeps were recorded at sea (see Kastelein et al. 2019). Killer whales are potential predators of leatherback sea turtles *Dermochelys coriacea* (Pitman and Dutton 2004), so killer whale vocalizations that were recorded at Point Retreat, Alaska, USA, were used (frequency range, 0.5–8 kHz; one-third-octave source level, 177 dB re 1 µPa@ 1 m; mean one-third-octave SPL in the pool, 173 dB re 1 µPa). The impulsive sound, HELRAS down-sweeps, and killer whale vocalizations were also played from the laptop computer.

From the laptop, the signals went to an audio power amplifier (Velleman HQ VPA2200MBN), the output of which was controlled with a custom-built digitally controlled attenuator (SEAMARCO AS 2009-01; 1 dB steps; Fig. 2). The sounds were projected under water via two transducers in a protective cage at a depth of 50 cm at

**Table 3** Thirteen sound types and the fundamental frequencies at which they were produced for the behavioral response experiment, comprising 80 combinations of sound type and frequency in total. The turtles were exposed to synthetic sounds (indicated with *), an impulsive sound, Helicopter Long-Range Active Sonar (HELRAS) down-sweeps, and recordings of killer whale *Orcinus orca* vocalizations. Most sounds generated harmonics and thus also contained energy at higher frequencies than those listed here. Details of the 18 sounds (shown here in bold) that elicited responses in the turtles are shown in Table 4. For the synthetic sounds, exposure durations were 10 s, and duty cycles were 100%. Only the sine wave up-sweeps indicated with † were produced with the high-frequency transducer. The sound types are shown in the order in which they were tested. Within each sound type, frequencies were tested in order from left to right and from top to bottom

one end of the pool (Fig. 1). The output of the sound system to the transducers was monitored with a digital oscilloscope (Tektronix 2201), a voltmeter (Agilent 34401A), and a spectrum analyzer (Velleman, PCSU1000; Fig. 2). Sounds up to 16 kHz were transmitted via a low-frequency balanced tonpilz piezoelectric acoustic transducer (Lubell, model LL 1424HP). The theoretical maximum source level that could be produced by this low-frequency transducer was 197 dB re 1 μPa @ 1 m, at 0.6 kHz. The sine wave up-sweeps between 16 and 40 kHz were transmitted with a piezoelectric high-frequency underwater transducer (Labforce, model 90.02.01). The source levels were as follows: for the 16–20 kHz sweep, 124–130 dB re 1 μPa; for the 20–25 kHz sweep, 130–136 dB re 1 μPa; for the 25–30 kHz sweep, 138–139 dB re 1 μPa; and for the 30–40 kHz sweep, 139–140 dB re 1 μPa.

Sound measurements were conducted by TNO (The Hague, the Netherlands) with a hydrophone (Bruel & Kjaer [B&K], model 8105) and a pulse acquisition system

(B&K, model 3560C) with a sample frequency of 65 kHz. The SPL in one-third-octave bands was determined by averaging over 10 s. The system was calibrated with a pistonphone (B&K, model 4223). The measurement hydrophone was at 1.5 m from the transducers at a depth of 0.5 m. Only the sounds that elicited a response (as defined in "Methodology") were recorded and analyzed.

## Methodology

The turtles were placed in the pool in two pairs of two individuals, one of each species. The first pair (male Atlantic green turtle 703938 and male hawksbill turtle 703458) was placed in the pool on 9 April 2010 to habituate to the new environment; tests were carried out on 13 and 14 April. The second pair (male Atlantic green turtle 703714 and female hawksbill turtle 705138) was placed in the pool on 16 April; tests were carried out on 20 April.

A response to a sound was defined as at least one of the two members of both turtle pairs changing its behavior during sound exposure, in comparison to the swimming behavior observed when no sound was produced. In ~80% of the cases, either both members of a pair responded, or both did not respond, and responses were also consistent between the pairs (see "Results").

During the two test days with the first turtle pair (13 and 14 April), the killer whale vocalizations were not tested. The remaining 12 sound types were tested at each frequency (79 combinations of sound type and frequency in total; Table 3), at increasing SPLs, up to the maximum level that could be produced by the system for that sound (determined by the characteristics of the transducers). On 13 and 14 April, each sound was offered at up to three SPLs (10 dB steps), and responses to the lower SPLs were rare. Therefore, in tests with the second turtle pair (20 April), each sound was offered only at the two higher SPLs.

Each synthetic sound was produced for 10 s, and the time between tests was ~8 min. Only sounds that elicited a response in the first turtle pair were also tested with the second turtle pair, alongside the killer whale vocalizations, which lasted 20 s. The turtles in each pair were exposed to each sound at a given SPL only once, except the killer whale vocalizations which were tested four times. In total, 196 exposures, each lasting 10 s (or 20 s for killer whale vocalizations and 8 s for the HELRAS signals), were conducted: 143 on 13 and 14 April with the first pair of turtles and 53 on 20 April with the second pair. Thus, the dataset was derived from baseline observations (9–20 April) and observations during approximately 33 min. of sound exposure, conducted over three test days (13, 14, and 20 April).

## Results

Observations of the turtles when sounds were not being produced, on habituation days and test days, provided a baseline: the turtles spent ~90% of their time swimming slowly, at constant speed, along the pool wall. The remaining ~10% was spent resting on the bottom of the pool, next to the wall.

Responses to sounds, when they occurred, typically consisted of increased swimming speed and/or changes in swimming pattern or direction (including swimming across the middle of the pool, swimming in small circles, and swimming away from the transducer, instead of swimming along the pool wall as usual). Startle responses were not observed: responses typically did not start until 2–5 s after a sound's onset. Once the sound stopped, the turtles' behavior returned to normal within ~1 min. The turtles were not observed to approach or investigate the transducers, and the responses of the second turtle pair, which were only exposed to the sounds which elicited a response in the first turtle pair, were consistent with those of the first pair for those sounds.

Responses were observed during 36 of the 196 exposures (Table 4). The pure tones, impulsive sound, HELRAS down-sweeps, and killer whale vocalizations elicited no response, even at the highest levels that could be produced (e.g., killer whale vocalizations: one-third-octave SPL in the pool, 173 dB re 1 μPa).

Turtles that were resting (lying still on the bottom of the pool; this occurred in 19 exposures) rarely responded to sound. Resting turtles responded only to sounds 9 and 12, by starting to swim. The turtles generally responded only to particular sound types in the 0.2–1 kHz frequency range, to three sounds above this frequency range (sounds 4, 5, and 7), and to sounds with high received SPLs (between 151 and 196 dB re 1 μPa). These SPLs were close to the maximum at which the sounds could be produced with the transducers in the shallow pool. The turtles did not respond to the sounds at SPLs that were 10 dB lower than those reported in Table 4. Of the 0.2–1 kHz up-sweeps, they responded only to those of 0.5 s duration; up-sweeps of shorter (0.3 s) and longer (1.0 s) durations did not elicit a behavioral response (all were produced at the same source level).

## Discussion and Conclusions

Only four captive adult individuals of two turtle species were available for this pilot study, so the results should be interpreted with caution. Statistical analysis could not be conducted due to the low sample sizes. However, this study makes an important contribution to the little that is known about the effects of underwater sounds on sea turtle behavior.

### Response Speed and Individual Responses

Startle responses were not observed in the turtles, even to very loud sounds; they began to respond 2–5 s after a sound began. Response time in turtles is longer than in marine mammals and fish (Boeger and Pie 2006; Robertson et al. 2013).

In most cases, the response or lack of response to a sound was consistent in both turtles of each pair, and responses were also consistent between the pairs. Due to the small sample size, it cannot be determined whether the occasional differences in responses were due to individual differences, age-related differences, or species differences. The differences appeared to be related to the behavioral state: resting

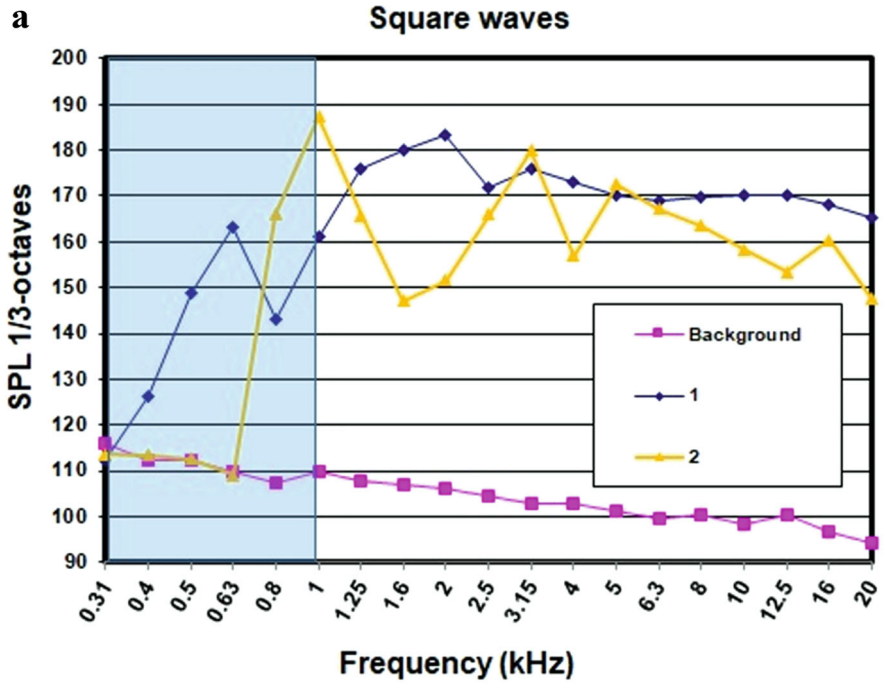
**Table 4** The characteristics of the 18 synthetic sounds which elicited a response in both turtle pairs (see Table 3 for all the sounds produced). For each sound, the table shows the broadband source level (the sound pressure level at 1 m from the transducers), the broadband sound pressure level at 1.5 m from the transducers (~ the general broadband SPL in the pool and thus the mean received SPL by the turtles), and the highest one-third-octave SPL ≤1 kHz (within the hearing range of the sea turtles; see Table 1). The spectra of these sounds are shown in Fig. 3. The exposure duration was 10 s, and the duty cycle was 100% in all cases. The actual frequency bandwidth in the pool was greater than the fundamental frequency (or frequency range) due to characteristics of the transducers and harmonics. In some cases, the harmonics contained more energy than the fundamental frequency (Fig. 3)

| Sound | Sound type | Fundamental or center frequency (kHz) | Signal duration (s) | Broadband source level dB re 1 µPa @ 1 m | General broadband SPL in pool dB re 1 µ Pa | Highest SPL ≤ 1 kHz dB re 1 µPa |
|---|---|---|---|---|---|---|
| 1 | Square wave | 0.6 | Continuous | 190 | 187 | 187 |
| 2 | Square wave | 1 | Continuous | 192 | 188 | 162 |
| 3 | Triangle wave | 0.4 | Continuous | 184 | 180 | 165 |
| 4 | Triangle wave | 8 | Continuous | 191 | 187 | 112 |
| 5 | Triangle wave | 16 | Continuous | 183 | 179 | 112 |
| 6 | Sawtooth wave | 0.6 | Continuous | 194 | 190 | 174 |
| 7 | Sawtooth wave | 16 | Continuous | 180 | 176 | 113 |
| 8 | Frequency-modulated tones | 0.2 | Continuous | 155 | 152 | 138 |
| 9 | Frequency-modulated tones | 0.4 | Continuous | 160 | 156 | 152 |
| 10 | Frequency-modulated tones | 1 | Continuous | 199 | 196 | 196 |
| 11 | Up-sweep (sine wave) | 1–2 | 0.5 repeated | 190 | 187 | 180 |
| 12 | Up-sweep (sine wave) | 0.2–0.7 | 0.5 repeated | 158 | 154 | 150 |
| 13 | Up-sweep (sine wave) | 0.7–1.0 | 0.5 repeated | 183 | 179 | 179 |
| 14 | Up-sweep (square wave) | 0.2–1.0 | 0.5 repeated | 184 | 180 | 179 |
| 15 | White noise band | 0.2–0.4 | Continuous | 164 | 161 | 159 |
| 16 | White noise band | 0.4–0.63 | Continuous | 170 | 167 | 152 |
| 17 | Warble | 0.8–0.2 | 0.1 repeated | 184 | 181 | 178 |
| 18 | Up-sweep (sine wave) | 0.2–0.6 | 0.2 repeated | 154 | 151 | 145 |

turtles were less likely to respond to sound than active turtles. However, not all sounds were tested with resting turtles.

## Responses to Sounds, Audibility, and Sweep Duration

The turtles mainly responded to sounds between 0.2 and 1 kHz (Table 4 and Fig. 3): sounds that fell within the frequency range of their hearing (Table 1; up to ~1 kHz; Piniak et al. 2016; Ridgway et al. 1969). The pool was not deep enough to allow the propagation of sounds below 0.2 kHz. In deeper pools, responses to sounds with frequencies below 0.2 kHz, which are probably audible to turtles, could be tested.



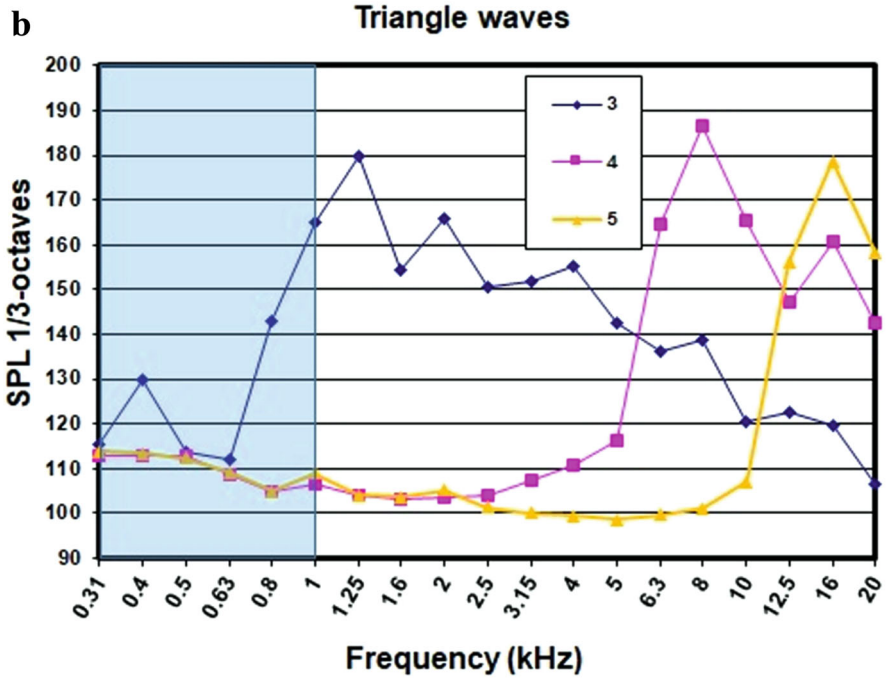


**Fig. 3** The one-third-octave band spectra of the background noise in the pool (**a**) and of the sounds to which at least one of the two members of both pairs of sea turtles responded (**a**–**g**, sounds 1–18; see Table 4). Recording distance: 1.5 m from the transducers. The actual frequency bandwidth in the pool was wider than the fundamental frequency (or frequency range) reported in Tables 3 and 4, due to characteristics of the transducers and harmonics. In some cases, the harmonics contained more energy than the fundamental frequency (for instance, with sound 9 in **d**). Table 4 shows the highest sound pressure levels ≤1 kHz (the frequency band that is shaded in blue), i.e., within the hearing range of sea turtles (see Table 1)

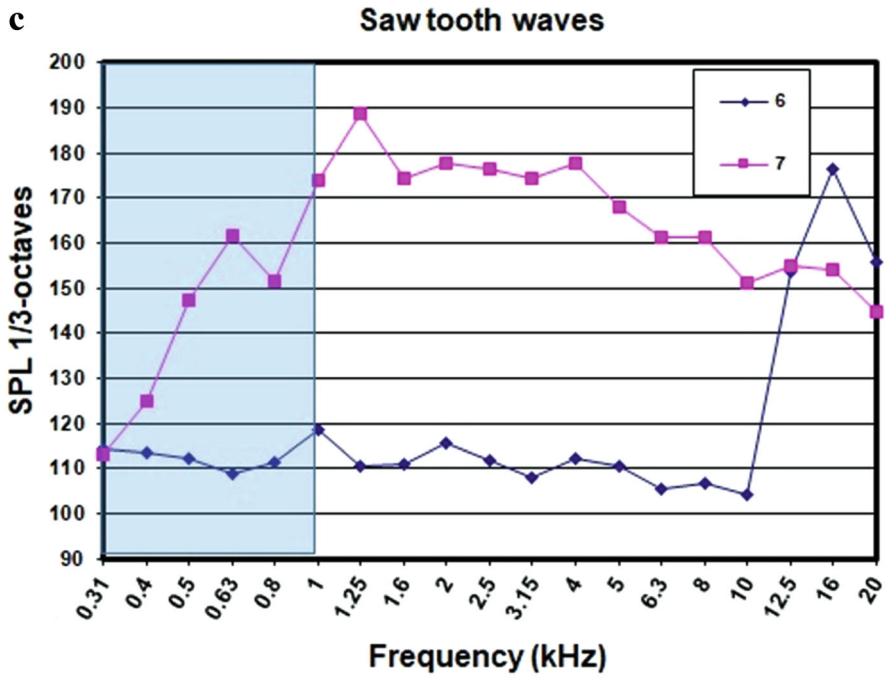

**Fig. 3** (continued)

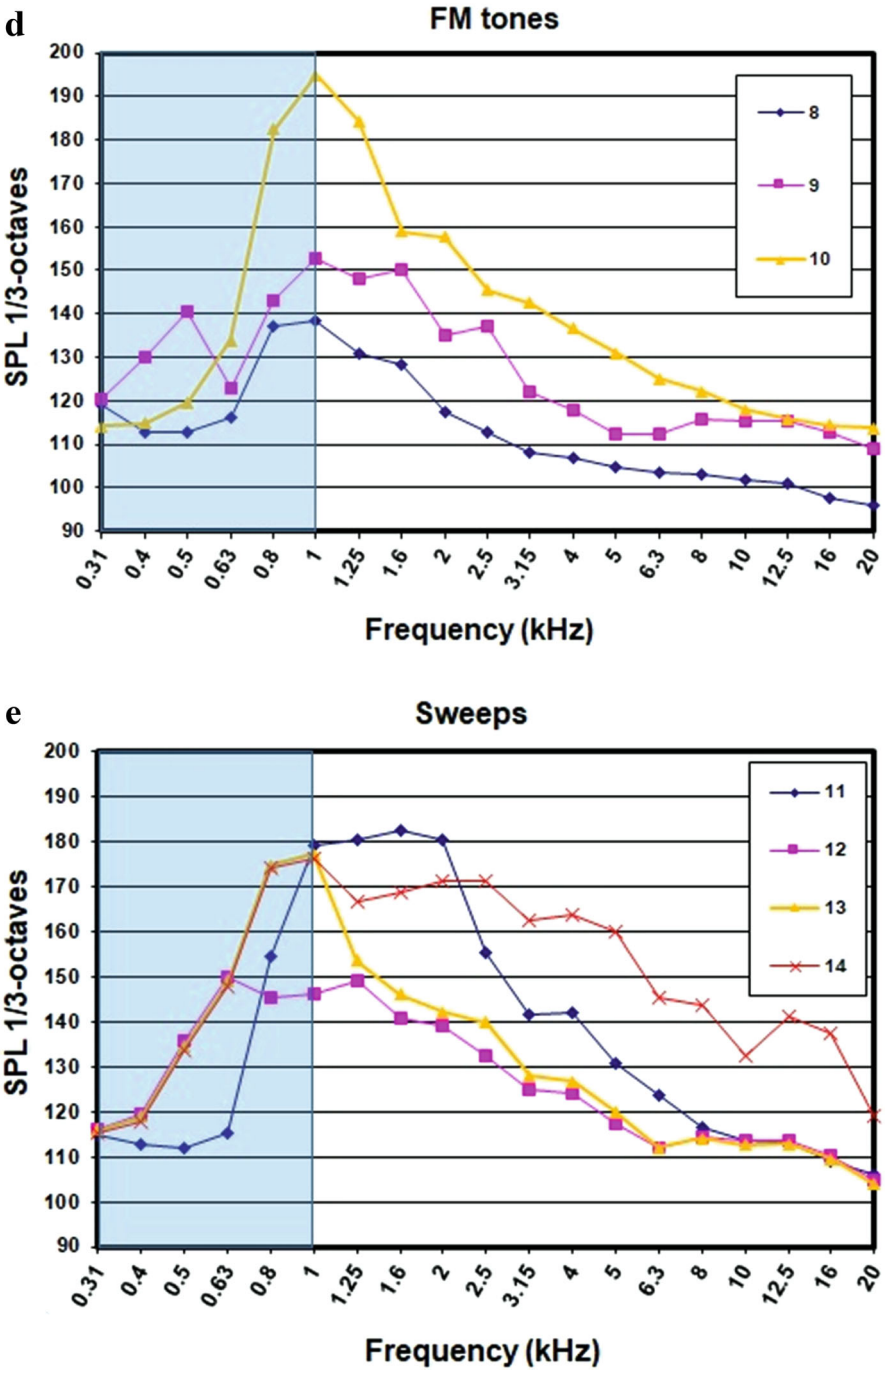

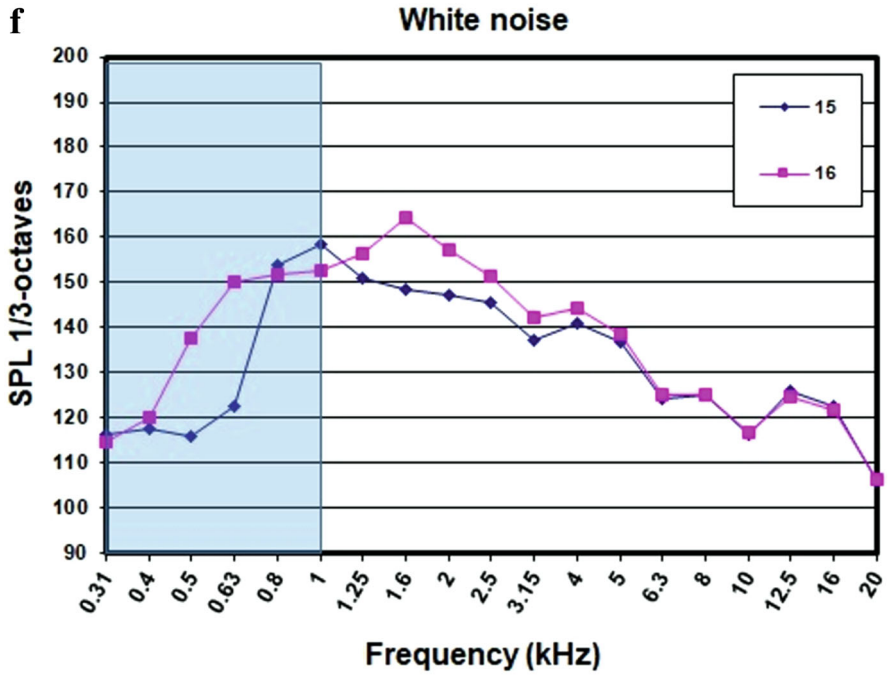

**Fig. 3** (continued)

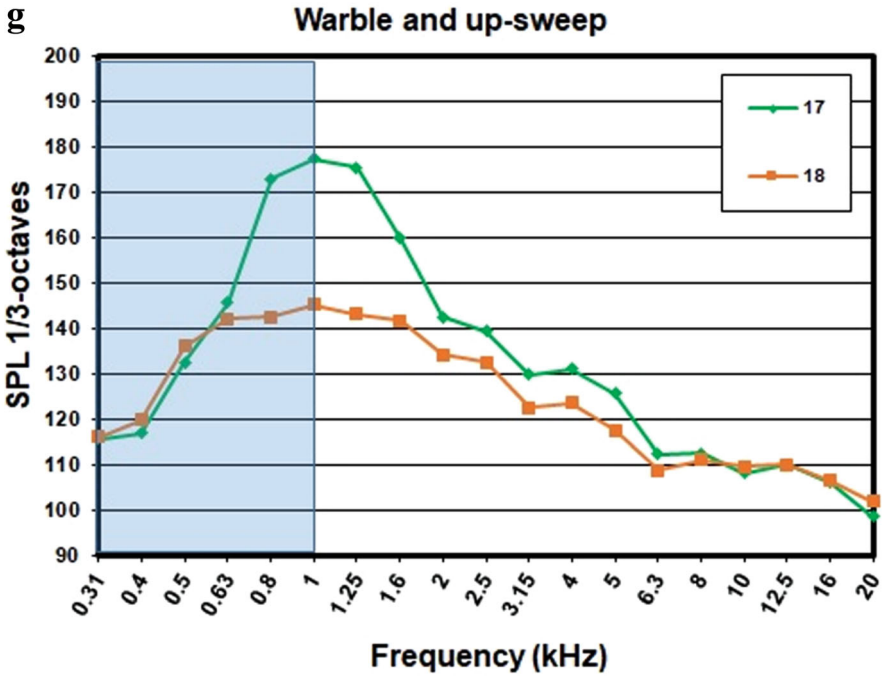

**Fig. 3** (continued)

Of the sounds with fundamental frequencies above 1 kHz, the turtles responded to the 8 and 16 kHz triangle waves and the 16 kHz sawtooth waves (Table 4). They were not expected to respond to these sounds, because the 8 kHz triangle wave (which included energy above the ambient noise at >2.5 kHz), the 16 kHz triangle wave (with energy above the ambient noise at >10 kHz), and the 16 kHz sawtooth wave (with energy above the ambient noise at >10 kHz) are all above the hearing range of the turtles (see Table 1). The energy below 1 kHz in these three relatively high-frequency test stimuli was close to the one-third-octave ambient noise level (112 dB re 1 μPa). It is possible that these high-amplitude, short-wavelength sounds caused resonance in the turtles' bodies, e.g., in the middle ear cavity (see Lenhardt 2002), or in some sections of the respiratory tract. This resonance may have been detected by somatic mechanoreceptors rather than via acoustic energy reaching the cochlea. Sound reaches turtles' ears via bone conduction in the skull, and vibrations may travel via the carapace and vertebrae to the skull (Lenhardt and Harkins 1983). Very low-frequency sounds (<0.04 kHz) can set somatosensory receptors on the skin and around internal organs into sympathetic resonance, which can result in neural activation. Sound at similar levels can also activate the semicircular canals, which can induce positional disturbance.

A strong response was observed to series of 0.2–1 kHz up-sweeps (100% duty cycle) with sweep durations of 0.5 s; a longer (1 s) and shorter (0.3 s) sweep duration elicited no response. Animals may associate up-sweeps with approaching objects, because the Doppler effect may cause approaching objects to produce apparent up-sweeps. The sweep durations (0.3, 0.5, and 1 s) were perceived differently by both operators: the series of short-duration sweeps (0.3 s) was perceived as a continuous sound, while the series of longer sweeps (1.0 s) was perceived as something approaching slowly (it therefore seemed less alarming to the human operators). The 0.5 s sweeps were perceived as most disturbing by the operators. The present study suggests that the temporal pattern plays an important role in eliciting a response in turtles. However, the low-frequency transducer had its resonance frequency at 0.6 kHz, so that the up-sweeps differed temporally not only in frequency but also in amplitude. This may have contributed to the differing effect of the sounds on the turtles. The wider the bandwidth of sweeps in the 0.1–1 kHz band (the hearing range of the turtles), the greater the amplitude modulation was.

## Directionality and Behavior

Responses consisting of diving and surfacing, as reported by Lenhardt (2002), were not observed, perhaps because the pool was rather shallow. In response to some sounds, the turtles moved away from the transducers, though only a small SPL gradient existed (within ~2 m of the transducers, depending on the frequency of the sound). The reverberant environment in the pool probably made it difficult for the turtles to determine the location of the sound source. The turtles did not approach or

show interest in the active transducers. A review of sea turtle responses to low-frequency sounds from airguns used in seismic surveys showed that behavioral responses at sea are often difficult to interpret (Nelms et al. 2016): some turtles exhibit avoidance behavior or dive, but most do not change their swimming or resting patterns abruptly. In agreement with the present pool study, startle responses to sound were not observed at sea (Nelms et al. 2016).

## Use of Underwater Sound as a Sea Turtle Deterrent

The present study shows that sea turtles respond to some complex underwater sounds with energy in the 0.2–1 kHz frequency range, and even to some sounds above their hearing range, which may be detected by sensory systems other than hearing. Recordings of the vocalizations of killer whales, potential predators of leatherback sea turtles (Pitman and Dutton 2004), are unlikely to be effective as turtle deterrents. The SPL, spectrum bandwidth, frequency modulation, and temporal pattern of other sounds determine whether a turtle responds. However, for sound to be effective as a deterrent, turtles must be able to locate the sound source and swim away from it. The nature of their responses (increased swimming speed and/or changes in swimming pattern or direction) suggests that the turtles in the present study would have responded by swimming away from the sound source if they had not been in a small, reverberant, pool. This means that sound could be an effective deterrent. When turtles are resting, it is more difficult to deter them with sound than when they are active (and potentially moving toward a dangerous area), so future research on behavioral responses to sounds should be focused on active turtles.

## Behavioral Responses of Sea Turtles to Underwater Sound

When the turtles responded to the sounds, they did so 2–5 s after the exposure began. Therefore, turtles are unlikely to respond to short-duration sounds. Responses were mainly to sounds between 0.2 and 1 kHz, with a few exceptions. Simple tonal sounds and anthropogenic sounds that are outside the 0.2–1 kHz range are unlikely to affect turtle behavior. Compared to marine mammals, the SPLs required to elicit behavioral responses in turtles are high (>151 dB re 1 μPa), which means that the radius of disturbance areas around most anthropogenic sound sources is smaller for turtles than for marine mammals. Behavioral responses depend on the SPL; on the spectrum, frequency (and possibly amplitude) modulation, and temporal pattern of the sound; and on the behavioral state of the turtle, so it is difficult to produce general acoustic dose-behavioral response functions, as is required for Environmental Impact Assessment. However, compared to marine mammals, sea turtles seem to be less responsive to sound, responding mainly to sounds with very high SPLs in a narrow low-frequency band. At sea, sea turtles may be able to lessen the effects of low-frequency underwater sound by staying near the water surface, where the SPL is often lower (Lenhardt 1994).

## Recommendations for Further Research

The present pilot study shows that several sounds can elicit responses in sea turtles. To increase understanding of how sound affects turtles and how sound could be used to deter them, research with larger sample sizes is recommended (including more turtles and other species, as well as more repetitions and more SPLs per sound type). Research could include:

- Experiments in a larger pool or bay, so that a sound gradient can be created to investigate whether or not turtles avoid sound sources.
- Experiments in a deeper pool or bay, so that lower-frequency sounds can be projected, to investigate whether turtles also show a behavioral response to sounds below 0.2 kHz, which they can probably hear.
- Investigation of whether habituation to sounds occurs and, if it does, whether habituation can be reduced by randomly varying the spectrum or amplitude of the sounds or the temporal patterns of series. Habituation to anthropogenic sound is beneficial as it can lead to reduced harm, but habituation to sounds that are intended to be deterring is detrimental to efforts to deter turtles from dangerous areas.
- Repeated exposures, both to sound types that elicit a response and to similar sounds that do not elicit a response, to determine the repeatability of the responses by the turtles. It is necessary to identify a sound palette type that results in consistent behavioral responses before an effective deterrent sound can be developed.
- Attaching bio-logging tags to wild sea turtles of all species, so that fine-scale movements in response to sound exposures can be examined (Tyson et al. 2017).

**Acknowledgments** We thank Rob Triesscheijn† for creating information signs for the pool, Michael Laterveer for the help with coordination at Blijdorp Zoo, and Henk Zwartepoorte, Peter van Putten, Martijn van der Veer, and several other staff at Blijdorp Zoo for the assistance, including with transporting the turtles from the exhibit to the pool and vice versa. We thank Erwin Jansen (TNO, The Hague) for the sound measurements. We thank Andria Salas for providing some of the turtle hearing literature and Jack Terhune (University of New Brunswick, Canada) for his constructive comments on the manuscript. Funding for data collection was provided by Van Oord Dredging and Marine Contractors B.V. (contract 4601/0033); funding for data analyses and publication was provided by the Living Marine Resources (LMR) program of the US Navy (Contract Number: N39430-23-C-2511). We thank Cuno Langeveld and Heidi van der Meij for their guidance on behalf of Van Oord, and Anu Kumar and Mandy Shoemaker for their guidance on behalf of the LMR program.

**Abstract**

Seabirds are important components of holarctic coastal ecosystems. As humans increasingly utilize these sensitive areas, deep-diving seabirds like alcids face a unique combination of pervasive anthropogenic sound exposure in terrestrial and marine environments. However, the acoustic sensory ecology of this threatened group is largely unknown, which complicates assessment of potential anthropogenic noise impacts. Here, aerial auditory sensitivities and nesting soundscapes are compared between three deep-diving alcids: the colonial-nesting common murre (*Uria aalge*) and Atlantic puffin (*Fratercula arctica*), and the solitary-nesting marbled murrelet (*Brachyramphus marmoratus*). Auditory evoked potentials (AEPs) were used to assess aerial hearing in temporarily sedated wild individuals placed inside a field-deployed anechoic chamber. For all species, AEPs were detected across a 0.5–6 kHz frequency range, similar to other birds with available data. Lowest mean auditory thresholds were between 16- and 35-dB SPL, while hearing was generally sensitive across a range extending from 1 to 3.5 kHz. Short-term soundscape dynamics of nesting habitats were also investigated via passive acoustic recordings which show that nesting acoustic environments can vary significantly among species. Overall, frequencies of sensitive hearing in each species overlap with many anthropogenic noise sources, indicating alcid susceptibility to disturbance from a range of noise types.

## Introduction

Seabirds are prominent and important fauna of many holarctic habitats, acting as biovectors for nutrient transport and keystone species for coastal ecosystems (Whelan et al. 2008). Yet increased anthropogenic utilization of coastal areas has reduced seabird habitats and populations such that seabirds are considered the most imperiled group of birds, with 33% of species listed as either threatened or endangered, and approximately half of all species experiencing population declines (Croxall et al. 2012; IUCN 2014; Lascelles et al. 2016). It is therefore important for future management to understand the pressures placed on these taxa and seabird sensitivities to them (Friesen et al. 2017). Alcids are one group of sensitive seabirds with many life history and breeding traits which may result in increased susceptibility to anthropogenic disturbances. As pursuit divers, individuals spend their adult

life on the open sea and only return to land for breeding, and exhibit late sexual maturity (i.e., several years, Lee et al. 2008), high nest site fidelity (Hatch et al. 2000), monogamous breeding at localized colonies (Hudson 1985), and typically lay a single egg per annual breeding cycle (Bent 1919; Tuck 1961).

Understandably, there is growing concern about potentially negative impacts of anthropogenic noise exposure on the biology and behavior of alcids. Sound is known to be an important communication channel for most seabirds, which rely on the detection of acoustic cues to help facilitate a variety of critical behaviors. As a few examples, vocal communication can facilitate recognition among adult individuals as well as between parents and their offspring (Jouventin et al. 1999; Ligout et al. 2016; Kriesell et al. 2018), and the begging calls of chicks can reflect body condition (Gladbach et al. 2009; Klenova 2015). Noise impacts have been increasingly documented across a wide range of marine and terrestrial animal wildlife (Erbe et al. 2018; Hawkins and Popper 2018; Slabbekoorn et al. 2018), including birds (Halfwerk et al. 2018) yet there are significantly less data on seabird susceptibility to anthropogenic noise. Nesting murres exhibit behavioral changes or flushing in response to gunshots, passing aircraft, and vessels at distances ranging from 50 m out to 5 km (Rojek et al. 2007; Labansen et al. 2021). Additionally, anthropogenic noise such as off-road vehicles and pedestrians decrease adult attendance of nests and hatchling survival in American oystercatchers (*Haematopus palliatus*) and Brandt's cormorants (*Urile penicillatus*, Borneman et al. 2016, Buxton et al. 2017).

These studies suggest that some seabird species are susceptible to disturbance from even low-level noise and underscore the need for more comprehensive assessment of noise impact thresholds. Key to improvements in the understanding, prediction, and mitigation of noise effects is baseline documentation and characterization of a species' acoustic biology, such as hearing thresholds and important features of the acoustic environment within animal habitats. Together, these areas of investigation provide a vital foundation of data for the subsequent assessment of noise impacts, such as physiological and behavioral effects, damage to hearing from acoustic overexposure, and masking of important bioacoustics and communication signals (Dooling and Popper 2016).

This chapter compares data on aerial hearing and nesting soundscapes of three species of pursuit-diving alcid seabirds, the marbled murrelet (*Brachyramphus marmoratus*), the common murre (*Uria aalge*), and the Atlantic puffin (*Fratercula arctica*). The goal is to highlight the baseline characteristics of their acoustic ecology and discuss future research directions important for improved assessment of anthropogenic noise impacts.

## Field-Based Measurements of Aerial Hearing in Alcids

Establishing hearing thresholds underpin all subsequent assessment of acoustic disturbance, potential hearing loss, estimates of auditory masking, and other noise impact criteria (Southall et al. 2019), yet there currently are limited data on seabird auditory sensitivities (Crowell et al. 2015; Larsen et al. 2020; Mooney et al. 2020).

This information gap hinders implementation of targeted noise mitigation measures by making it difficult to extrapolate results across the diversity of some 350 species with different life history, ecology, and evolutionary relationships. For example, the auditory system of diving seabird species has been shaped by different evolutionary pressures than non-diving species due to the pressures of deep diving (Zeyl et al. 2022), and perhaps the significant differences in acoustic properties between air and water (Larsen and Wahlberg 2017). Moreover, diving seabirds face a unique combination of exposures to marine and terrestrial sensory cues and anthropogenic noise (Mooney et al. 2019b). Of particular concern are species in Arctic and subarctic environments where accelerated environmental warming and greater accessibility is projected to increase human encroachment into sensitive coastal ecosystems. Thus, there is a particular need to measure the hearing abilities of Arctic and sub-Arctic seabirds and document unperturbed acoustic environments within their ecosystems.

Empirical measurements of bird hearing have traditionally been collected using psychophysical tests, which provide important perceptual sensitivity information. However, such methods are time-consuming, expensive, and challenging for many species. Alternatively, electrophysiological hearing tests involve the measurement of time-averaged neurological auditory evoked potentials (AEPs) elicited by the presentation of acoustic stimuli. They are a relatively rapid way to measure a subject's overall hearing sensitivity and audible frequency range and allows for measuring untrained and even wild animals. These AEP methods have long been applied to birds in the laboratory (Brittan-Powell et al. 2002) and used for other taxa in the field (often odontocetes) for nearly two decades. However, field AEP methods have only recently been applied to birds, during which they may be safely caught, sedated, tested, and released (Mooney et al. 2019a, 2020).

Field-based AEP techniques have recently been used to collect auditory data from multiple alcid seabirds. This study describes and compares a subset of such data, including audiograms from common murres and marbled murrelets ($n = 5$ per species), and previously published audiograms of a related alcid, the Atlantic puffin ($n = 9$ individuals). All hearing tests followed consistent steps between species, which included subject capture, administration of anesthesia, auditory testing, recovery from anesthesia, and subsequent release back at the capture location. The auditory test methods used here are nearly identical to those previously detailed for the Atlantic puffin (Mooney et al. 2019a, 2020), and thus we only provide a summarized version here. Marbled murrelets were captured at night on the waters of Auke Bay, Alaska, using the spotlighting method (Whitworth et al. 1997), while common murres were captured from nesting ledges at Latrabjarg, Iceland, using a wire noose at the end of a fiberglass pole. Atlantic puffins were captured with a fishing net placed over entrances to clifftop burrows (detailed in Mooney et al. 2019a, 2020). Once captured, individuals were transported for approximately 20 min to a sheltered field-testing site on land where they received anesthesia before being placed in a portable anechoic chamber. Body temperature and respiratory rates were continuously monitored while heart rates were manually checked every 15 min. Once sedated, electrophysiological tests were done to record AEPS using two

subdermal needle electrodes placed dorsal to the auditory meatus and at the vertex of the head. A third grounding electrode was placed along the dorsum. Forty-ms epochs of evoked potential signals were recorded concurrent with production of narrowband tone pips between 0.5 and 8 kHz and at output levels controlled in 1–10 dB steps. For each stimulus frequency and sound level, between 750 and 1000 pips were projected and the concurrent epochs were averaged to extract the resulting AEP from noise. Final threshold calculations were made offline in Matlab (Mathworks, MA, USA) and Excel (Microsoft). For the common murre and marbled murrelet, a linear regression was fit to the AEP response magnitudes of each stimulus frequency as a function of stimulus level, and thresholds were estimated as the intersection of the linear regressions with the zero-AEP-magnitude level. For the Atlantic puffin, thresholds were calculated by fitting the linear regression to the magnitudes of cross-correlation functions across stimulus levels. Thresholds for each bird were plotted as a function of frequency to generate audiograms of aerial hearing sensitivity (Fig. 1).

All the studied alcids heard sounds extending from 0.5 to 6 kHz. Measures of central tendency (mean and median) between all individuals resulted in comparatively similar audiograms (Fig. 1a and b). Lowest mean thresholds were 35 and 30 dB re: 20 μPa for the common murre and marbled murrelet, respectively, and both occurred at 2 kHz. Lowest means thresholds were 16 dB re: 20 μPa for the Atlantic puffin, which occurred at 2.5 kHz (Mooney et al. 2020). Overall, these audible frequency ranges and most sensitive frequencies are similar to the majority of nonauditory specialist birds. Notably, the puffin exhibits mean thresholds that are at least 14 dB lower than the other two alcids across the entire audiogram, with the greatest differences mostly at low frequencies of 750 and 500 Hz. Yet the best way to assess a wild population's "representative" auditory sensitivity is not fully established and the desired metric may be dependent on the desired use of the data (Mooney et al. 2020). For example, when assessing potential impacts of anthropogenic noise, particularly for endangered or threatened species, a conservative estimate of auditory sensitivity may be desired, such as a composite audiogram of the lowest observed thresholds for each species (Fig. 1c).

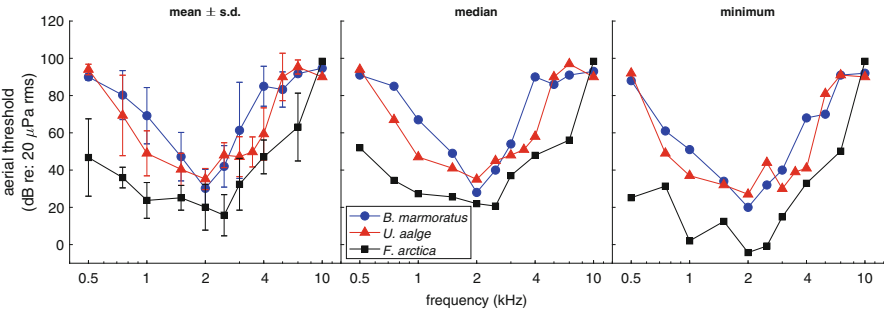

**Fig. 1** Composite in-air AEP audiograms compiled from a subset of data from the Atlantic puffin (black), common murre (red), and marbled murrelet (blue) plotted across different metrics (mean ± s.d., median, and minimum thresholds)

Regardless of which metric is used, these audiograms show the studied alcids (and likely other alcid species) possess generally sensitive aerial hearing akin to many terrestrial birds.

## Environmental Nesting Soundscapes

Habitat-associated soundscapes underlie various ecological processes in a variety of animal taxa, and acoustic cues derived from the surrounding soundscape may be important for seabirds as well. However, there are few studies on aerial soundscape dynamics of many coastal habitats, including seabird colonies. As humans increasingly utilize such areas, it is essential to characterize these soundscapes as a baseline for understanding seabird acoustic biology and thus quantifying the effects of human activity on their acoustic ecology over time. This acoustic sensory information is increasingly valuable for conservation and management efforts (Elmer et al. 2021), yet there are relatively few studies that compare auditory thresholds of wild animals to the noise levels from their particular habitat (Mooney et al. 2018). Nesting soundscapes may be particularly relevant for alcids since a variety of critical behaviors occur within the summer nesting period when they are also most exposed to aerial anthropogenic noise.

Brief snapshots of the nesting soundscape for each of the three studied alcids will be considered here. Passive acoustic recordings were made with a dual-channel Song Meter (SM4) acoustic recorder (Wildlife Acoustics Inc., Concorde, MA, USA) that was placed at known nesting locations of each species. Common murres and Atlantic puffins are colonial nesters along sea cliffs, with common murres congregating on exposed rock ledges and Atlantic puffins burrowing up to 1–2 m into the softer soil atop such cliffs. In contrast, marbled murrelets nest solitarily on large limbs of dominant trees within mature forests, but also occasionally nest on cliffs and on the ground (e.g. Simons 1980; Nelson 2020). For the marbled murrelet, the ambient soundscape was recorded approximately 500 m from a known murrelet ground nest from previous years (Willson et al. 2010, lat: 58.294586, lon: −134.453400). For the common murre, recordings were made at the top of the cliff directly above the short rock ledge where murres were captured for the auditory tests. For the Atlantic puffin, synchronized recordings were made both at the mouth of an inhabited burrow and approximately 1 m inside the burrow. Sounds were recorded either continuously (common murre and marbled murrelet) or on a 25% duty cycle every 4 min (Atlantic puffin) via omnidirectional A2 microphones. Signals were amplified by 16 dB and digitized at a sample rate of 24 kHz before being saved as dual channel .WAV files on SD cards for offline analysis. The A2 microphones were manually calibrated before and after deployments at each site with a 94 dB SPL 1 kHz tone from a calibrated piston-phone. A-weighted sound levels were measured from the recordings in 1-s intervals, and mean (± s.d.) sound levels were then calculated across 1-min bins of the data.

Figure 2 illustrates snapshot aerial soundscapes recorded at nesting sites of the common murre (5 days), marbled murrelet (2 days), and Atlantic puffin (6 days).

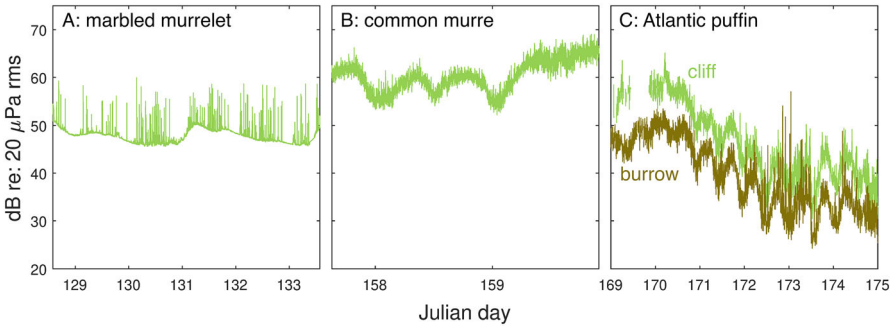

**Fig. 2** A-weighted aerial soundscape levels at nesting sites of (**a**) marbled murrelets, (**b**) common murres, and (**c**) Atlantic puffins. The puffin nesting soundscape is represented both outside and inside a single burrow

All soundscapes contained both biotic and abiotic signals. The seaside soundscapes of the common murre and Atlantic puffin nests were dominated by geophonic and biophonic sound sources (crashing waves and bird vocalizations, respectively) and exhibited the highest general noise levels overall, circa 65 dB re: 20 μPa. The puffin nesting site also exhibited the lowest sound levels circa 30 dB outside the burrow and 25 dB inside the burrow (re: 20 μPa). Baseline sound levels within the forested marbled murrelet nesting area exhibited less variable baseline sound levels between 45 and 55 dB, but this baseline was frequently punctuated by brief but intense (typically low-frequency) sources of anthropogenic sound such as flyovers by planes and helicopters and city traffic from the nearby city of Juneau (~750 m away). Notably, the temporal pattern of the marbled murrelet soundscape levels exhibited a strong diel cycle consistent with the diel nature of the anthropogenic sound encroachment, whereas the seacliff nests of the common murre and Atlantic puffin were clearly influenced by the 12.5 h tidal cycle. It is also noteworthy that time-synced sound levels differed between the inside and outside of the puffin burrow. The puffin burrow acted as a low-pass sound filter which reduced sound levels by an average of 7 (±2) dB across the recording period, with most of this reduction occurring above 1 kHz (Fig. 3).

## Future Research Directions and Anthropogenic Noise Considerations in Alcids

### The Utility of Field-Based Auditory Measurements

The auditory data highlighted in this chapter illustrates the viability of field-AEP techniques to measure hearing from sufficiently large sample sizes of wild individuals (Mooney et al. 2019a, 2020; Smith et al. 2023). With audiograms now documented for 14 of some 350 seabird species, this new method enables valuable data collection from untested species of conservation concern, such as the threatened

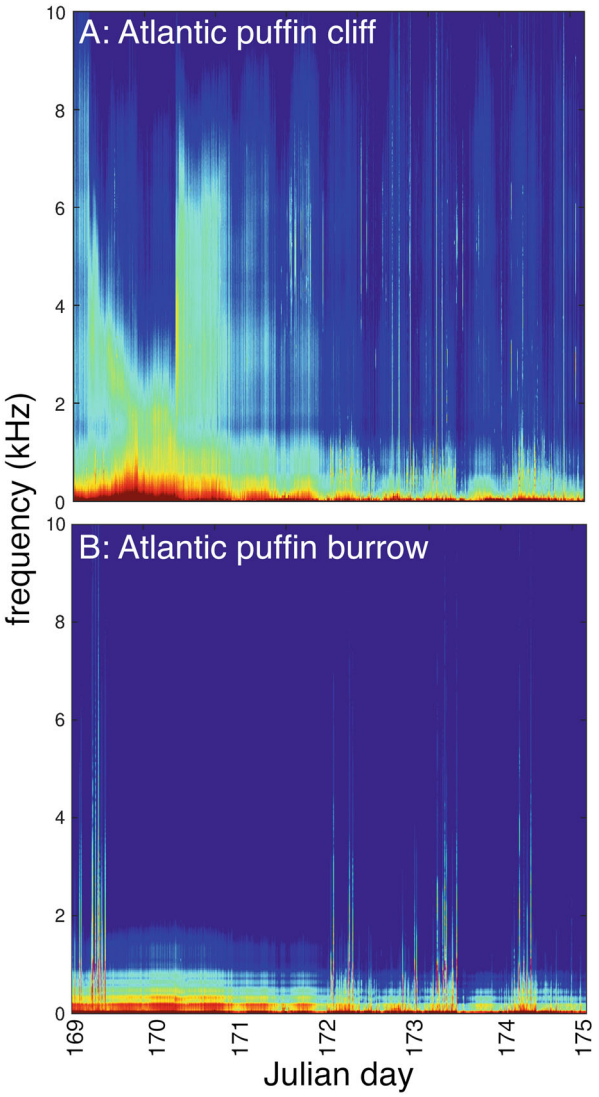

**Fig. 3** Long-term spectral average of an Atlantic puffin nesting soundscape calculated from 6 days of synchronized recordings at the mouth of a cliff burrow (**a**) and 1 m inside the burrow (**b**)

marbled murrelet (newly presented here) or related species like the thick-billed murre (*U. lomvia*) and Kittlitz's murrelet (*B. brevirostris*). In turn, it also foments potentially valuable insight generated through greater comparison. For example, recent anatomical analysis has suggested that the auditory anatomy of diving birds differs from those of fully terrestrial species, perhaps as an adaptation for baroprotection of the auditory system during diving (Zeyl et al. 2022). The audiograms of the deep-diving species studied here exhibit lowest auditory sensitivities that are similar to, or even better than, many fully terrestrial birds. This suggests that

middle-ear structural changes for baroprotection have not hindered aerial auditory reception (Smith et al. 2023) and advocates for additional comparative research on the auditory capabilities and anatomy of diving seabird species.

## Acoustic Overlap and Auditory Masking

The field-based measurement of AEP-derived audiograms shows that frequencies of sensitive hearing in these alcids spectrally overlap with a variety of common anthropogenic sounds. To varying degrees, this overlap includes sound sources in air, such as traffic noise, human speech, and airplanes flying overhead. Only a few studies have directly investigated impacts of in-air anthropogenic noise on seabirds, including the great cormorant (*Phalacrocorax carbo* (Buxton et al. 2017). Thus, with more sensitive aerial hearing than the cormorant (Larsen et al. 2020), these alcids may face similar disturbance at even lower noise level exposures. Notably, some naturally occurring sound levels within the "snapshot" soundscapes of the common murre and Atlantic puffin are akin to anthropogenic noise levels which can have deleterious effects on a variety of terrestrial bird species (circa 55–60 dBA; e.g., Injaian et al. 2018; McClure et al. 2013, 2017). Noise disturbance thresholds identified for terrestrial birds may therefore not be applicable to these species or other seabirds that similarly nest on sea cliffs or other areas exposed to consistent wave noise. This underscores the importance of incorporating species and niche diversity into avian noise-impact criteria, a need identified in other taxa (Popper et al. 2014). Behavioral sensitivity, sound source characteristics, and ambient noise conditions will almost certainly play a role as well, and the comparison of audiograms to environmental soundscape characteristics provides an initial way to consider and explore these factors.

Although acoustic communication in alcids has not been thoroughly studied, many species are known to be highly vocal. This suggests aerial acoustic cues are likely important for alcids, and the preservation of sensitive aerial hearing despite deep-diving in the three species studied here corroborates this notion. Thus, high levels of environmental background noise, including from anthrophonic sources, have the capability to mask potentially important acoustic cues. Comparison of acoustic environments and audiograms can suggest if anthropogenic sounds may fall above natural sound levels typically encountered by individuals, and thus inform what levels of acoustic masking species may naturally be equipped to deal with and provide context for possible levels of anthrophonic disturbance. For most birds studied to date, tonal signals must be around 18–38 dB above the background noise power spectral density (PSD) at the same frequency to be detected (the auditory critical ratio, e.g., Dooling 2002). Assuming similar critical ratios for alcids, Atlantic puffin individuals may experience significant levels of natural masking under the noisiest conditions of their cliffside nesting sites by virtue of their sensitive auditory thresholds (Fig. 4c and d). In contrast, common murres may experience only moderate masking of acoustic signals within their nesting soundscape (Fig. 4b), and nesting marbled murrelets likely encounter only limited masking of acoustic

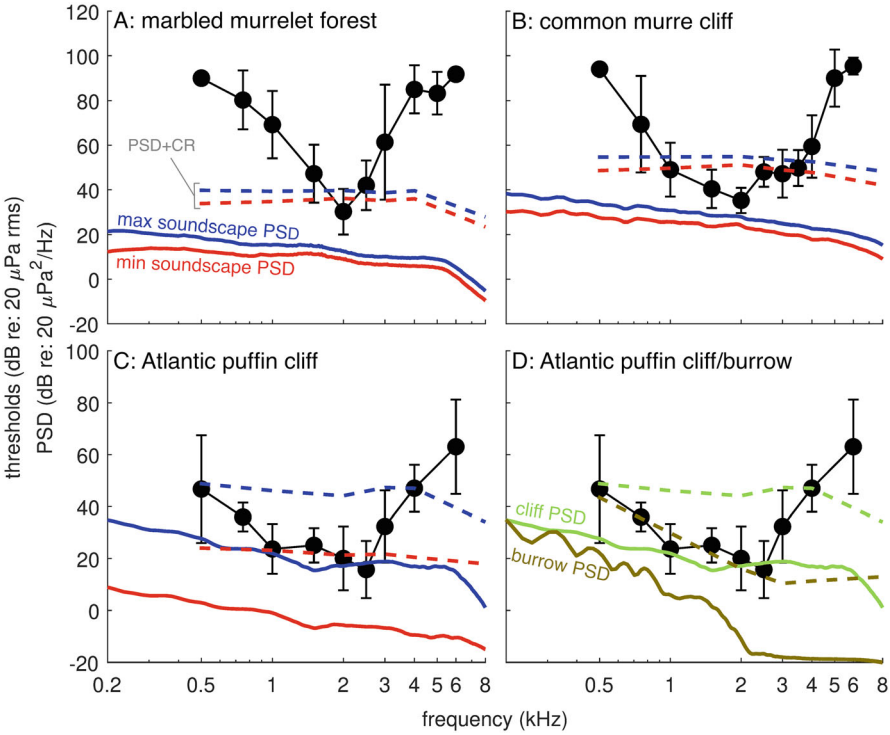

**Fig. 4** Aerial audiograms from each species (mean ± s.d., black markers) plotted with the maximum and minimum soundscape power spectral density (PSD) profiles at the species nesting site (solid red/blue lines). The dotted lines in denote estimated onset levels of auditory masking in the environment by adding mean avian critical ratios (CR) to the soundscape PSDs. In (D), the Atlantic puffin audiogram is compared to the concurrent PSDs from inside and outside the burrow

signals by the naturally occurring environmental sound levels (Fig. 4a). In general, this could suggest that anthropogenic sounds would need to be generally louder or closer to disturb the seacliff-nesting common murres and Atlantic puffins in comparison to the marbled murrelet, whose quite forest habitat and solitary-nests allow greater penetration of faraway anthropogenic noise sources (see Fig. 2a) and may result in lower thresholds for the onset of acoustic disturbance. A comparison of noise-induced disturbance relative to species and habitat type would help elucidate how sound sensitivities vary among these seabirds.

Notably, nesting soundscapes of the Atlantic puffin were also sometimes very quiet (see Fig. 2c), which might likewise increase their susceptibility to anthropogenic noise disturbance, even inside the relative safety of their burrows. Low frequencies, which dominate many anthropogenic sounds, overlap with the low-pass characteristics of the puffin burrow, and tend to attenuate less in a constant media and can propagate well through the ground. Thus, low-frequency anthropogenic noise could pose a particular problem for the burrowing Atlantic puffin when

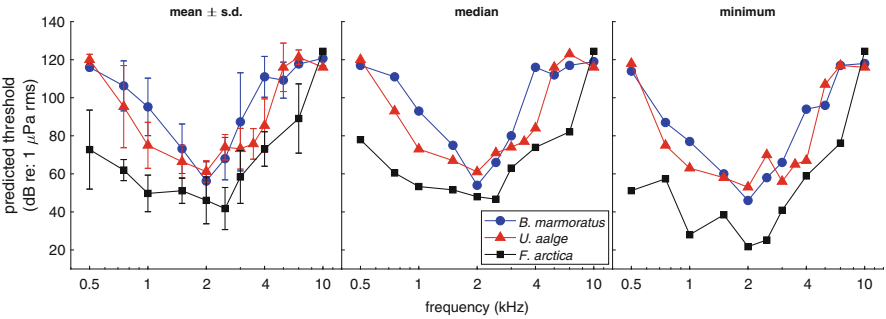

**Fig. 5** Preliminary estimates of pressure-equivalent underwater AEP audiograms compiled from the in-air audiograms presented in Fig. 1

combined with the relative sensitivity of the puffin auditory system compared to the other two alcid species presented here. Against this backdrop, additional research might investigate more specifically if the reduced noise of the burrow environment facilitates acoustic-mediated behaviors and if the relative acoustic shelter of the burrow influences their susceptibility to acoustic disturbance (Fig. 5).

## Considering Underwater Auditory Sensitivity and Use of Sound

Given these species' amphibious lifestyle, there is also a need to understand if, and how, their acoustic biology may be adapted for use underwater. Such information is a crucial for the implementation of effective underwater noise mitigation measures since diving seabirds also face potential exposure to marine anthropogenic noise (Mooney et al. 2019b). At least four species of seabird can conclusively detect underwater sound, including one alcid, the common murre (Hansen et al. 2020; Larsen et al. 2020; Therrien 2014; Sørensen et al. 2020). Of these, underwater auditory thresholds have been measured from only two: the long-tailed duck (*Clangula hyemalis,* Therrien 2014) and great cormorant (Larsen et al. 2020). Notably, the combined aerial and underwater AEP results from Larsen et al. indicated that mean hearing thresholds across all cormorant individuals were similar between the two media when compared in terms of the stimulus acoustic pressure. If this aerial-underwater threshold relationship is similar across other diving seabirds, the three alcids discussed here could be predicted to have lowest pressure-equivalent mean underwater thresholds between 42 and 61 dB re: 1 μPa at 2 kHz. While this prediction certainly represents an extrapolation, it suggests that deep-diving alcids may have sensitive hearing underwater and are therefore susceptible to impacts from underwater anthropogenic noise such as auditory injury or hearing loss. This supposition provides a hypothesis, but supporting it fully requires corroboration from robust and direct underwater threshold measurements from multiple alcid species in the future. Such data would support the needed development of appropriate underwater noise mitigation strategies.

The establishment of auditory thresholds also does not address the separate but relevant question of whether diving seabirds utilize underwater sound, even if it can be detected. Answering this separate question will provide important context for managers and regulators to assess the underwater noise impacts that are less acute than physical injury but still intrusive, such as auditory masking of potentially important acoustic signals. Thus, synergistic and interdisciplinary research projects are also needed to address what extent underwater sound is utilized by diving species.

**Acknowledgments** We are grateful to the National Park Service, Juneau, Alaska, for use of their dock and facilities during field experiments. All research was conducted under Woods Hole Oceanographic Institution IACUC permits (ID number: BI21798.01). Marbled murrelet data collection was conducted under approved permits from the US Fish and Wildlife Service (#MB68522D-0 to M.L.K.), the US Geological Survey (#23740 to M.L.K.), and Alaska Department of Fish and Game (#21-034 to T.A.M). Common murre and Atlantic puffin data collection was conducted under approved permits from the Environment Agency of Iceland and MAST (the Icelandic Food and Veterinary Authority). The findings and conclusions in this chapter are those of the authors and do not necessarily represent the views of the US Fish and Wildlife Service. The work was supported by the US Navy's Living Marine Resources Program and the Woods Hole Oceanographic Institution.

**Abstract**

Kororā (little blue penguin; *Eudyptula minor*) are a small penguin species native to New Zealand and often found nesting in man-made structures nearby ports and marinas. The species has a national conservation status of "At Risk – Declining" and is protected under New Zealand's Wildlife Act (1953). As such, development projects occurring in areas that kororā inhabit need to consider how this species may respond to construction noise and vibration. This chapter presents the noise assessment approach and on-site mitigation and management for the construction of a new marina on Auckland's Waiheke Island, which involved piling and other intensive construction activities close to kororā burrows. The project is still under construction, and monitoring of kororā will continue until its completion. The results of the monitoring to date show that kororā continue to inhabit and breed successfully in the breakwater on which the marina is being constructed, including during the noisiest phase of the works.

## Introduction

### Effect of Noise on Birds

Birds can be adversely affected by sound, and anthropogenic noise is a key source of disturbance for species that live alongside human development. There are several ways in which birds (and animals in general) could be affected by noise, depending upon the loudness and character of the noise as well as the sensitivity of the species. At the closest point to an activity where the loudest noise levels would occur, there is a potential for noise exposure to cause physiological hearing damage in the receiving animal that can be permanent (i.e., permanent threshold shift (PTS)) or temporary (i.e., temporary threshold shift (TTS)). Further away, or when the sound is quieter, masking can occur, which is when the sound source is loud enough, and in the same time and frequency window, that it disguises other sounds that are biologically important (e.g., sounds from predators, prey, or other members of the same species). Often considered the least effect, sound has the potential to elicit a behavioral response when it can be distinguished from the ambient soundscape. Behavioral responses may be context-specific (animals may exhibit disturbance differently during their breeding season, for example), and some individual animals may be

more affected than others (e.g., mothers with young may respond differently to lone males) (Southall et al. 2021).

Behavioral responses vary greatly in severity, from large-scale obvious abandonment of a noisy habitat to fine-scale changes in foraging behavior or time spent in a behavioral state (Blickley et al. 2012; Wright et al. 2010). Behavioral responses are difficult to predict and can be challenging to quantify. While some minor behavioral responses may seem trivial (e.g., turning the head to look in the direction of a sound source), regular disturbance can lead to energetic consequences for wildlife. A constant state of alertness can lead to heart rates and stress levels that are higher than normal (DeRose-Wilson et al. 2015). The impact of stress can be acute or chronic. Chronic stress can lower immune response, making an animal more susceptible to disease or predation (Siegel 1980). Moreover, when energy is expended during a disturbance event, less energy is available for other activities, such as foraging or parental investment. Accordingly, individual disturbance events can lead to population-level consequences (Pirotta et al. 2018). If courtships and breeding are interrupted by disturbance, overall breeding productivity of a population can be affected.

## New Zealand Approach to Avoid Disturbance to Avifauna

New Zealand is currently home to 429 bird species, 179 of which have a national conservation status of "Threatened" or "At Risk" as of 2021 (Robertson et al. 2021). Many of these bird species inhabit areas that can be impacted by anthropogenic noise from human development. In general, the greatest noise risk from human development occurs during the construction phase when the highest noise emissions are produced. Construction projects must therefore be carefully managed to ensure that noise emissions do not exceed a level where there could be significant disturbance to protected species.

In New Zealand, the general approach to managing noise and vibrational disturbance to avifauna has been for consenting authorities to specify a setback distance, most often 50 m, from works. However, such an approach is not site or species specific, nor are scientific rationales provided for any specific setback distances.

## The Project

A new 180 berth marina is currently being constructed in Putiki Bay on the western side of Auckland's Waiheke Island. The marina is adjacent to the existing Kennedy Point ferry terminal and includes a fixed wharf, floating carpark, piers, pontoons, and finger jetties. These structures are all supported or secured by piles driven into the seabed and existing rock wall. A plan of the development is shown on Fig. 1.

It was discovered during the consenting and design phase of the project that kororā, little blue penguins (*Eudyptula minor*), may inhabit the rock structures around the proposed development. Kororā are protected under the New Zealand

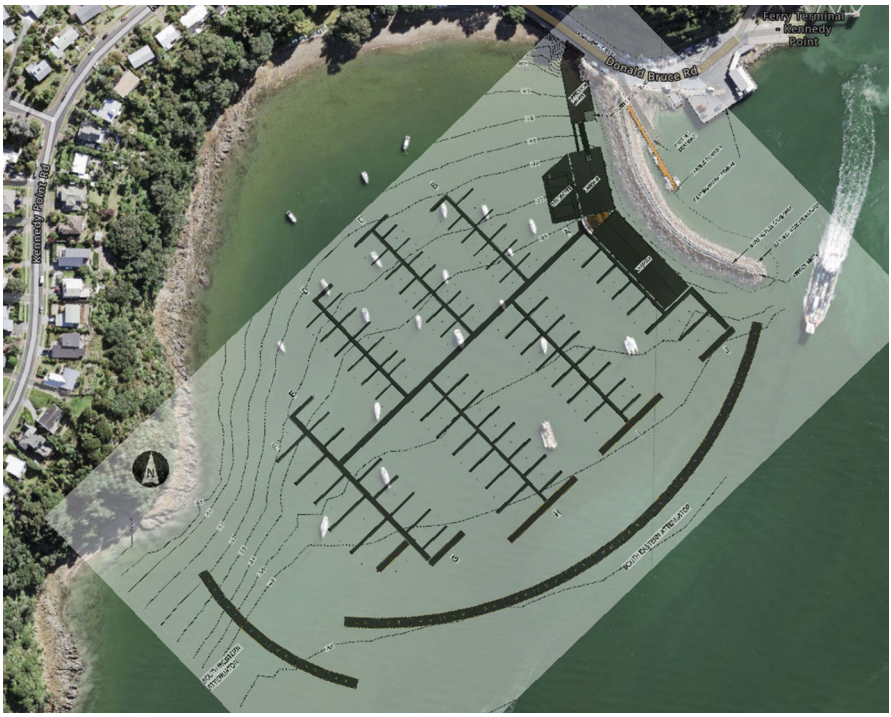

**Fig. 1** Map of the proposed marina

Wildlife Act (1953). Kororā surveys undertaken in October 2016 (DabChickNZ 2016), October 2017 (DabChickNZ 2017), and April 2021 (4Sight Consulting 2021a), using a certified conservation dog trained to detect penguins, provided data on the distribution of birds along the Kennedy Point breakwater prior to the marina construction (Fig. 2). Several detections were made close to the proposed piling works for the wharf structure.

The presence of kororā became a key factor in determining the noise management and construction methodology for the development. The management plan for the project involved setting an appropriate disturbance threshold based on available literature on kororā and similar species, and managing works on the site to keep within this limit.

## Kororā/Little Penguin

### Distribution, Habitat, and Behavior

Kororā are native to New Zealand and Australia. In New Zealand, they are widely distributed along the coastlines of the main and offshore islands (Heather and Robertson 2015; Marchant et al. 1990), with the national population estimated to

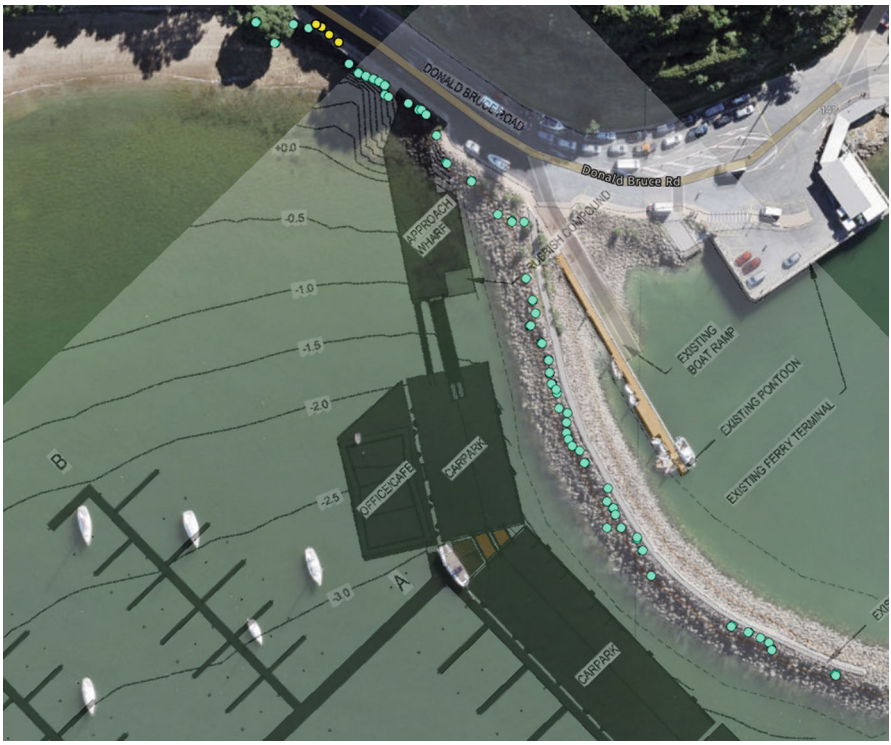

**Fig. 2** Kennedy Point Marina kororā locations (yellow circles indicate nest boxes, and blue circles indicate natural burrows)

be approximately 50,000–100,000 individuals (C. J. R. Robertson and Bell 1984; Taylor 2000). Weighing approximately 1 kg and standing 30–40 cm tall, the kororā is the smallest of all the 17 penguin species (Reilly 1994). Robertson et al. (2021) assigned an "At Risk – Declining" threat classification to kororā in New Zealand.

Kororā form loose colonies, with burrows located several meters apart (Braidwood 2009; Bull 2000a; Bullen 1997; Marker 2016). Colonies can range in size from a few to hundreds of pairs. Nests are generally situated close to the sea in burrows excavated by the birds or other species, or in caves, rock crevices, under logs, or in or under a variety of man-made structures including nest boxes, pipes, stacks of wood or timber, and buildings. Several studies have shown the ability for kororā to adapt their nesting behavior to urban environments; in response to the lack of "natural" habitats, birds successfully nest in rock crevices and human-made structures, such as breakwaters and even under rail tracks, that offer protection from the weather, tidal action, predators, and human disturbance (Bourne and Klomp 2003; Giling et al. 2008). Kororā exhibit high levels of site fidelity, generally returning to the same landing site and nest each breeding season (Bull 2000b; Pledger and Bullen 1998).

**Table 1** Indicative breeding cycle of kororā in the Hauraki Gulf

| | JAN | FEB | MAR | APR | MAY | JUN | JUL | AUG | SEP | OCT | NOV | DEC |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| Burrow occupation | | | | | | | | | | | | |
| Pair bond / nest building | | | | | | | | | | | | |
| Egg laying | | | | | | | | | | | | |
| Chick rearing / fledging | | | | | | | | | | | | |
| Moulting | | | | | | | | | | | | |

The yearly cycle of kororā comprises three overlapping stages: (1) occupation of burrows and pair formation; (2) breeding (eggs and chicks); and (3) molting (Table 1). Adults are present at colonies throughout the year, though numbers are lowest between completion of molt and start of breeding (Marchant et al. 1990). Molting birds remain on land for the entire molt period as they are unable to swim without getting waterlogged (Heather and Robertson 2015). During the nonbreeding and nonmolting season, birds are less frequently on land during the day, mostly returning to land at night. The breeding cycle of kororā in the Hauraki Gulf (Table 1) is based on Geurts (2006), van Rensburg (2010), McKenzie (2011), and Fitchett (2017).

## Response to Airborne Noise

As part of the effort to minimize the effects of noise on the kororā, a literature review was undertaken to ascertain their sensitivity to sound. There have been relatively few studies on the hearing abilities of penguins in general, and the research undertaken for this project was unable to uncover any specifics pertaining to kororā hearing. The applied noise threshold on site was therefore based on available literature on penguin or bird hearing in general, it being the best relevant information.

Hearing ability is determined by the frequencies that a species has the capability to hear, in addition to their sensitivity across those frequencies. The sensitivity curves of three Blackfooted penguins (*Spheniscus demersus*) from Wever et al. (1969) demonstrated that penguins are most sensitive to sounds between 600 Hz and 4000 Hz. These sensitivity curves are supported by the 1000–5500 Hz frequency range of in-air vocalizations, for kororā specifically (Nakagawa et al. 2001), as an animal's hearing is expected to be most sensitive at the frequencies produced by its own species. The frequency range of best sensitivity is relatively similar to the human range of 500–4000 Hz. However, birds are generally less sensitive than humans at the frequencies of best hearing, and their sensitivity falls off rapidly outside of this range (Halfwerk et al. 2018).

In air, continuous noise levels above 110 dBA SPL, or a single impulsive sound over 140 dB SPL, can lead to PTS in diving birds, while TTS can occur at continuous noise exposure levels above 90–95 dBA SPL (Dooling and Therrein 2012). Non-physiological effects such as masking and other behavioral responses are context specific and can occur at a range of noise levels. Penguins, including kororā, are vulnerable to direct masking of their sounds in air as they utilize auditory cues above water to identify other penguins.

Studies on behavioral response to noise for Fiordland penguins (tawaki, *Eudyptes pachyrhynchus*) (Fanning et al. 2020), Australian little blue penguins (Schaefer and Colombelli-Negrel 2021), and King penguins (*Aptenodytes patagonicus*) (Hughes et al. 2008) were reviewed for this project. The study from Hughes et al. (2008) on the King penguin was the only one that provided sound levels at which behavioral responses occurred. The study identified that penguins exhibited behavioral responses during aircraft overflights with maximum 1 s $L_{Aeq}$ levels ranging from 67 to 83 dB $L_{Aeq}$. The paper did not determine whether the reported behavioral responses were due to the sound levels produced by the aircraft or merely due to an object flying overhead. Moreover, the reported ambient noise levels were sometimes louder than the aircraft noise levels.

## A Species-Specific Approach to Minimize Disturbance from Anthropogenic Noise

The proposed marina construction activities were located within the typical required setback of 50 m from a kororā burrow and were scheduled to be carried out in August when breeding activity is generally occurring. The project's acoustic consultants, in collaboration with the project ecologist, were therefore asked to provide specific advice regarding the effect of the works on the local penguin population. Addressing noise effects on the behavior of wild species is difficult as very little is known about how free-ranging animals, and kororā in particular, respond to noise, and it is challenging to quantify behavioral responses. There is anecdotal evidence that kororā may be reasonably tolerant to noise and/or disturbance as many burrow locations are adjacent to ports, roads, and rail lines. However, this does not mean that they are unaffected by noise, and moreover, construction noise features a different character of sound to day-to-day activities.

Based on the best available evidence described above, the construction activities on site were not expected to cause PTS or TTS in the penguins, and a threshold of 80 dB $L_{Aeq(1s)}$ at the penguin burrows was recommended to minimize behavioral disturbance to the penguin population. The threshold incorporated an A-weighting (human auditory weighting) (Houser et al. 2017) to account for frequency-based hearing sensitivity of the kororā. As noted earlier, birds are generally sensitive over a narrower frequency range than humans, so the human A-weighting is considered to be a conservative assumption. Furthermore, it is convenient to measure using the A-weighting as it is widely used and is the default weighting for most sound-level meters. The 80 dB $L_{Aeq(1s)}$ threshold was accepted and certified by Auckland Council.

This chapter presents validation measurements made on site around and within the penguin burrows, which were undertaken to check the feasibility of adhering to the threshold. The findings are supported by results from ecological surveys throughout the construction works to investigate the effectiveness of the established threshold. The focus is on airborne noise received from construction activities adjacent to the identified kororā burrows in the rock wall and breakwater. Specifically, it

addresses the issue of undertaking noisy works during ecologically sensitive periods (i.e., breeding season) while the penguins are in their burrows.

## Method

### Acoustic Monitoring Methodology

A Bruel and Kjaer 2250 sound-level meter (https://www.bksv.com/en/instruments/handheld/sound-level-meters/2250-series) was used to measure noise levels from the piling on-site. The sound level meter was calibrated before and after each noise survey. The monitoring was carried out in air at 1 m above the rock face, and generally at the closest point along mean high water springs (MHWS) to the piling. Noise levels were monitored for a representative duration to capture each construction activity. Acoustic measurements were undertaken in August, October, November, and December 2021. The measurement durations are presented in detail in the results section of this chapter.

A map of the piling area and acoustic measurement locations on site is shown on Fig. 3. The acoustic measurement sites correspond to the results presented in Table 2.

The purpose of the noise monitoring was to assess the construction works against the 80 dB $L_{Aeq(1s)}$ A-weighted threshold. When an exceedance was identified, the construction methodology was reviewed to identify lower noise methods and to implement additional mitigation measures. Further monitoring was then carried out to confirm that the revised methods were sufficient to avoid exceeding the threshold.

Additional measurements were carried out on-site in April 2022 inside a representative kororā burrow to determine the noise reduction provided by the rock wall of the breakwater. One Wildlife Acoustics Song Meter Mini recorder (https://www.wildlifeacoustics.com/products/song-meter-mini) was installed inside "Burrow 13," after it was confirmed that no kororā were present inside, and a second unit was attached to a nearby tree branch approximately 1 m above the rocks. Burrow 13 is depicted in Fig. 6c. Both devices were calibrated by recording a tone from a calibrator before and after the survey, which was used to adjust the processed data to the correct level. The monitors were left on site from 1 to 6 April 2022 and recorded continuous audio between 7 am and 5 pm each day. The data was analyzed based on construction timings provided by the project team and by listening to the recordings to identify noise sources. The purpose of this monitoring was to compare the noise levels inside the burrows to the corresponding free-field levels at 1 m from the burrow entrance.

### Penguin-Monitoring Methodology

In order to determine the effectiveness of noise management efforts, as well as other disturbance reduction efforts, the kororā on-site were monitored by qualified and permitted ecologists.

**Fig. 3** Map of acoustic measurement locations (pink), and pile locations (red)

The ability to monitor kororā activity within a burrow is in part dependent on the ability to access the "chamber," which can be located at the end of a tunnel (in some cases >1 m long). Furthermore, due to the nature of the substrate in which a burrow is located, the tunnel is not always straight and therefore a direct line of sight into the chamber is not always possible. Thus, due to the difficulties in being able to observe kororā behavior directly, the objective of the kororā monitoring was to confirm the ongoing habitation of the breakwater by kororā during the construction phase of the marina.

Monthly monitoring of kororā activity has been undertaken since July 2021, except for August 2021 due to New Zealand Covid Alert Level restrictions. At the beginning (July 2021), 40 locations were monitored along the Kennedy Point breakwater. However, the number of monitoring sites increased over time due to the detection of new locations. The locations are shown on the map in Fig. 2. Burrows were numbered by the ecology team so activity within each burrow could be tracked over time. During each monitoring session, the locations of all previous kororā detections were inspected first by way of a visual check for the presence of any penguins or their sign (e.g., feathers or guano/excrement), and then using a burrowscope and/or video camera on a mobile device if possible. The following information was recorded at each monitoring location: the presence of any sign (feathers or guano), birds, or nest contents (eggs and / or chicks).

**Table 2** Noise-producing activities on-site and results from acoustic measurements, as measured from the breakwater

| Activity | Pile # and distance from measurement location | Measurement position (see Fig. 3) | Highest 1 second level (dB $L_{Aeq(1s)}$) | Cumulative duration and number of events |
|---|---|---|---|---|
| **Survey 1, 5 August 2021** | | | | |
| Vibro piling and excavator drill rig engine (pile free standing) | Test pile, 12 m | MP1 | 79 | 1 minute, 1 event |
| Vibro piling only (pile free standing) | Test pile, 12 m | MP1 | 79 | 1 minute, 1 event |
| Drilling (including mechanical component banging) | Pile 15, 12 m | MP2 | 88–95 | 11 minutes, 2 events |
| Drilling with banging avoided through careful operation | Pile 15, 12 m | MP2 | 79 | 3 minutes, 1 event |

## Results

### Noise Levels Outside the Burrow, per Activity

Noise levels were measured for the two main noise-producing construction activities on-site: vibratory piling and drilling. The measured levels are shown in Table 2, and the results for each activity are discussed in the following sections.

## Noise Measurements: Vibro Piling

A vibratory hammer suspended from a crane was used to drive the piles which were contained within pile gates. The activity consisted of 30 s to 5 min long periods of vibro driving, with quiet periods in between while the alignment of the pile was checked. Noise from the vibro hammer itself was primarily low-frequency noise but included a noticeable high-frequency rattle. The piling noise was relatively constant with levels between 74 and 79 dB $L_{Aeq(1s)}$. However, spikes in noise level of up to 89 dB $L_{Aeq(1s)}$ were caused when the steel pile came into contact with the steel pile gate as shown on Fig. 4. This issue was addressed by increasing the clearance between the gate and pile, and by careful control from the crane operator. These measures significantly reduced the problematic noise to a maximum of 81 dB $L_{Aeq(1sec)}$.

## Noise Measurements: Drilling

Drilling was carried out by a large excavator with a drill attachment and auger. The main noise from the activity was a high-frequency whine of the drill attachment turning. The low-frequency rumble from the excavator engine was audible but at a much lower level. It is common for drill rig operators to shake or counter-rotate the drill attachment to remove the spoil into the bin, but in this case a worker was using a shovel to remove spoil stuck to the auger to minimize noise emissions.

In general, the drilling was relatively quiet (75–79 dB $L_{Aeq(1s)}$ at 12 m, see Table 2). However, a mechanical component occasionally slipped during drilling resulting in loud bangs of up to 20 decibels above typical drilling (88–95 dB $L_{Aeq(1sec)}$ at 12 m, see Table 2). The banging was mitigated by training the rig operator in quiet operation techniques. Once the issue was resolved, the drilling was below the 80 dB $L_{Aeq(1sec)}$ threshold.

**Fig. 4** Photo of pile gate

## Other Noise-Producing Activities

It is important to note that other activities such as tracking of the excavator and moving/placing materials with a crane would have likely generated intermittent high noise events. This is common on most construction projects involving heavy machinery. While these intermittent events can be minimized through operator care, they are difficult to anticipate, predict, and mitigate and therefore cannot be avoided completely.

## Noise Reduction from Outside to Inside a Burrow

The data from the two Wildlife Acoustics Song Meter Mini sound level meters recorded three separate occurrences of vibro piling associated with the marina construction. The measured noise levels inside and outside the burrow are shown in Table 3 and illustrated in Fig. 5. The levels shown are an average across each vibro piling period.

The results show that the burrow provided an overall noise reduction of 8 dB, with the biggest reduction being at frequencies above 8 kHz. There was an amplification of 2–10 decibels at low frequencies (40–100 Hz). However, as identified in the literature review, kororā hearing is likely to be most sensitive in the range of 600–4000 Hz or 5000 Hz as per other penguin species, which is outside of the frequencies where the amplification occurs. Noise reduction provided by the breakwater rock wall is likely to vary depending on factors such as the position/orientation, material, and depth of the burrows but is expected to be at least 5 decibels for burrows in rock walls. Accordingly, kororā inside the burrows were not exposed to sound levels exceeding the 80 dB $L_{Aeq(1sec)}$ threshold once appropriate mitigation and methods were in place on site.

## Korora Activity

The monitoring undertaken to date has confirmed that the pattern of kororā activity recorded over a year at Kennedy Point is consistent with that of the typical annual cycle, including egg laying, incubation, chick rearing, and molting (Table 4). The birds have continued to inhabit the breakwater, and birds have been recorded present in their burrows during the day throughout the breeding and molting periods, as well as during the nonbreeding and nonmolting period (Fig. 6). These observations confirmed that the noise levels experienced by the birds during the piling activities at Kennedy Point did not stop their normal patterns of behavior.

Furthermore, comparison with kororā activity recorded in previous surveys during the same months showed that there was in fact increased kororā activity during the construction period. The numbers of kororā sign at the monitoring locations and active

burrows recorded over the course of the monitoring sessions to date are provided in Figs. 7 and 8, respectively. To date, there are 5 calendar months (July, September, October, November, and December) in which monitoring sessions have been conducted in both 2021 and 2022, enabling comparison. While it is important to note that there will likely be variation in the timing of annual activity due to external factors (e.g., sea-surface temperatures and food supply), the data does indicate that the numbers of kororā sign and active burrows recorded were in general higher in 2022 months than 2021. Most importantly, increased numbers of sign and active burrows were recorded during the 2022 breeding months (September through November) postbreakwater piling compared to the same months in 2021 (Figs. 7 and 8).

**Table 4** Kennedy Point kororā monitoring results

| Monitoring session | No. of burrows monitored | Korora sign | Burrow activity | Comparison with preconstruction surveys in the same months |
|---|---|---|---|---|
| July 2021 | 40 | 21 | Burrow 10 – adult incubating egg<br>Burrow 13 – adult incubating egg | July survey not previously conducted |
| September 2021 | 40 | 17 | Burrow 10 – adult with chick | September survey not previously conducted |
| October 2021 | 26 *(Full monitoring session could not be completed due to interference by members of the public)* | 11 | Burrow 5 – two adults incubating egg<br>Burrow 10 – chick<br>Burrow 13 – adult incubating egg | The October 2016 and 2017 surveys reported potentially five and nine kororā burrows, respectively, based on positive indications by the dog, although no birds were observed, nor was breeding confirmed (DabChickNZ 2016, 2017). In comparison, the October 2021 results reported 11 locations where kororā sign was observed as well as breeding activity at three burrows |
| November 2021 | 40 | 14 | Burrow 5 – adult with chick<br>Burrow 10 – adult with chick | A kororā survey previously conducted along the Kennedy Point Breakwater in November 2020 (4Sight Consulting 2020) recorded some evidence (including small patches of guano and a feather) of potential penguin use but no active burrows. In comparison, the November 2021 results confirmed the presence of two |

| October 2022 | 55 | 29 | Four burrows (10, 13, 23, and 26) were active, containing or suspected to contain chicks | Similar number of active burrows compared to October 2021. Burrows 10 and 13 were active in both years |
| November 2022 | 55 | 25 | Seven burrows (10, 18, 20, 21, 22, 23, and 26) were considered active, containing or suspected to contain chick | Increased number of sign and active burrows compared to November 2021 |
| December 2022 | 55 | 25 | Five burrows (20, 21, 23, 25, and 26) were considered active | Increased number of sign and active burrows compared to December 2021 |

## Discussion

Construction noise is a key source of anthropogenic noise for wild species that live close to human development. In New Zealand, consenting authorities commonly specify a generic distance (often 50 m) that works must be separated from the

**Fig. 6** (**a**) Adult kororā with chick in Burrow 10 (24 September 2021, breeding/molting period); (**b**) adult kororā in Burrow 10 (12 April 2022, nonbreeding/nonmolting period); and c) pink dot on rock (right) indicated location of Burrow 13 (containing bird) relative to the construction works area (12 April 2022, nonbreeding/nonmolting period). *Top two photographs taken by 4Sight Consulting Ltd*

location of protected species in order to minimize the effects of noise disturbance or hearing injury. However, these generic setback distances are not context, site, or species specific and are not based on scientific evidence.

The aim of this work was to minimize the effect of nearby construction noise on nesting kororā during an ecologically sensitive period. The study measured the sound levels on site, assessed their adherence to an ecologically informed noise threshold, and considered the results from ecological surveys throughout the construction works to investigate the effectiveness of the established threshold.

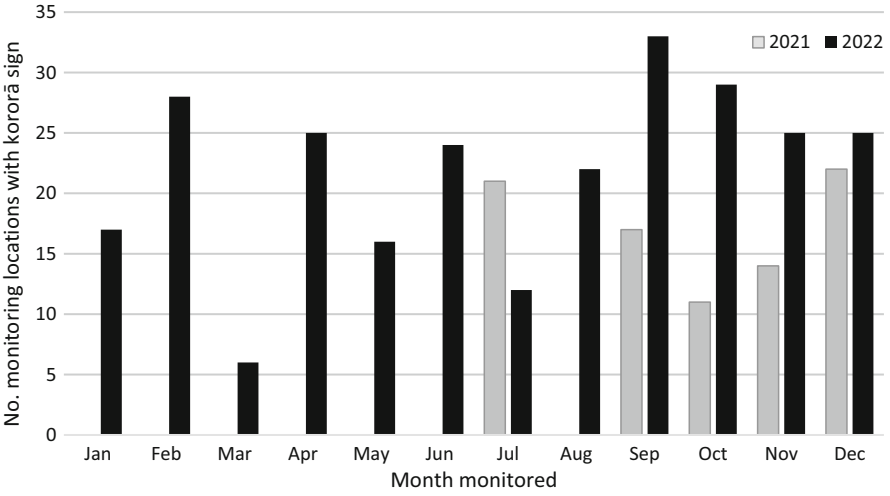

**Fig. 7** Number of monitoring locations at which kororā sign was observed during each monitoring session. Monitoring sessions began in July 2021; no monitoring was undertaken in August 2021 due to Covid-19 restrictions; and October 2021 monitoring session was incomplete due to public harassment

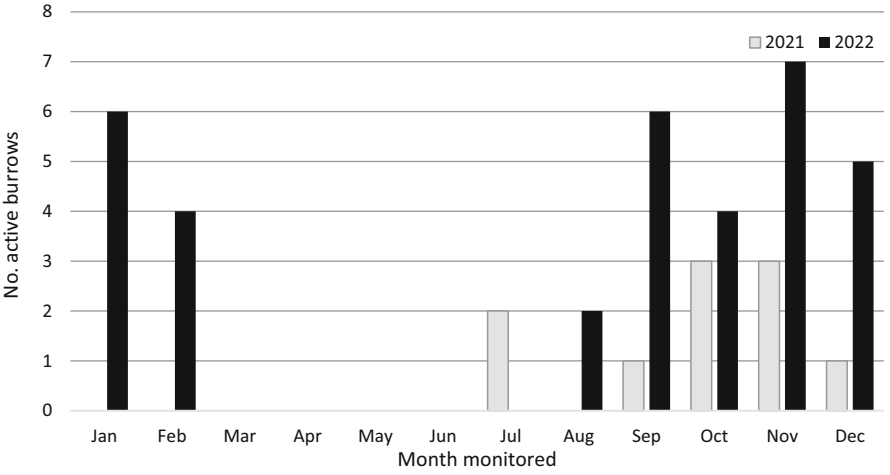

**Fig. 8** Number of active burrows recorded during each monitoring session. Monitoring sessions began in July 2021; no monitoring was undertaken in August 2021 due to Covid-19 restrictions; and October 2021 monitoring session was incomplete due to public harassment

## Feasibility of an 80 dB $L_{Aeq(1s)}$ Threshold for Construction Works

Based on verification measurements, the construction works associated with vibro piling and drilling were generally below the 80 dB $L_{Aeq(1s)}$ threshold at the location of the kororā burrows. Short periods of higher noise due to mechanical banging on

the drill rig and the pile touching the pile gate during vibro piling were resolved by providing additional training to the operators. At a representative burrow, which was known to support breeding activity, the rock wall of the breakwater was measured to provide an additional 8 dBA reduction in noise level from outside to inside, so the construction noise levels received by the kororā inside the burrows on site would have been lower than the in-air reported levels.

While the outcome of this project is satisfactory in that the noise emissions were generally able to be kept below the 80 dB $L_{Aeq(1s)}$ threshold and the kororā remained in the burrows, quieter piling methodologies, such as screw piling, are still preferable over the vibro piling and drilling methodologies and should be used where practicable. Impact piling was not used, but it is noted that this activity can produce significantly higher noise and vibration levels than the methodology used for this project and should therefore be avoided close to kororā burrows.

### Kororā Responses to Construction Activities

Kororā exhibit considerable variability in regard to reproductive success rates. A number of factors have been shown to affect kororā reproductive success, including breeding habitat (Braidwood et al. 2011; Bull 2000a; Colombelli-Négrel 2015; Perriman and Steen 2000), age and experience of birds (Nisbet and Dann 2009; Ramírez et al. 2021; Robinson et al. 2005), disturbance (Vertigan et al. 2012), sea surface temperature, and food availability (Cullen et al. 2009; Dann et al. 2000; Geurts 2006; Kowalczyk et al. 2014; Perriman et al. 2000). These factors can make it difficult to identify the specific cause of reproductive failures. For these reasons, changes to the habitation of the Kennedy Point breakwater by kororā were determined to be the only variable that could be measured in a meaningful way.

Kororā are confined to land during the day during the egg incubation phase, chick guard period, and molting period of their annual cycle; at all other times, kororā are not confined to land and can spend the day at sea. During the sensitive land-based phases, kororā were still recorded on land in their burrows while piling and construction works were occurring. Furthermore, adults in burrows (5, 10, and 13) located closest to the works did not abandon their clutch but in fact successfully fledged chicks, and comparison with kororā activity recorded in previous surveys during the same months showed that there was actually increased kororā activity during the 2021/22 construction period.

Overall, based on the kororā activity data collected, it appears that the birds did not alter their general patterns of behavior, and were able to successfully raise clutches and molt during and after the marina piling and construction works.

## Further Research

This chapter has focused on airborne noise effects on kororā in burrows. However, underwater noise and vibration also have the potential to affect kororā:

- Underwater noise can affect kororā in the same way as airborne noise (physiological effects, masking, and behavioral effects). While the vibro piling and drilling for this project were measured to have relatively low underwater noise levels, other noisier methodologies, such as impact piling, may affect kororā behavior underwater, even at relatively large distances.
- Vibration has the potential to affect kororā on land. Drilling produces negligible vibration, but vibro piling can result in relatively high vibration levels at close distances, depending on the ground conditions. No vibration measurements were carried out for this project as airborne noise was the key concern, and furthermore there is little available published literature on vibration effects on penguins to determine a suitable threshold. Nonetheless, this is an area that needs further research.

There is also limited data on the ambient noise and vibration levels that kororā are exposed to outside of construction settings. Anecdotal evidence suggests that the species is tolerant of high levels of anthropogenic noise based on the burrow locations of some free-ranging penguins (e.g., nearby busy roads, port areas, or rail lines), but ambient acoustic data has not been obtained to quantify the noise levels that these animals choose to inhabit. Teasing out the relationship between preferred foraging and nesting sites from their overlap with anthropogenic noise is likely to be extremely difficult; some individuals may persist in areas of high noise due to productive feeding opportunities or preferred nesting areas, for example. Further research into real-world received levels would help to set appropriate thresholds for minimizing disturbance in areas affected by anthropogenic noise.

## Conclusion

Although the results of this study are positive as the kororā continued to inhabit the rock wall of the marina and successfully fledged chicks, this project does not provide certainty that the 80 dB $L_{Aeq(1s)}$ threshold is appropriate for all kororā habitats. Nonetheless, it does provide evidence that this may be a suitable threshold for environments influenced by anthropogenic noise, and that intensive construction works can generally be constrained to meet the threshold. The results of this study provide a foundation for minimizing noise effects on wild species, and highlight the benefits of collaboration between technical experts and industry.

**Abstract**

Many anthropogenic activities in the ocean involve direct contact with the seabed. These benthic interactions can potentially be harmful to marine fauna. For example, pile driving is commonly used for coastal and offshore

constructions, including wind farms that overlap with vital marine habitats. The sound from pile driving is a major pollutant of international concern, although studies on substrate-borne vibrations arising from these activities are scarce, particularly those which address impacts to key benthic invertebrates. In a field-based study, the impacts of substrate-borne vibrations from pile driving were quantified on the giant scallop (*Placopecten magellanicus*), an ecologically and commercially important bivalve. Behavioral responses of tagged scallops to pile driving were assessed at two spatial scales (< 10 and 50 m from the source). Pile driving induced valve closures in scallops at substrate-borne vibration levels similar to those measured hundreds of meters from wind turbine constructions. These responses could have long-term energetic consequences on scallops, rending them more vulnerable to predation. The results suggest offshore wind farm constructions have the potential to impact scallop populations.

## Introduction

Offshore wind farms (OSW) are proliferating dramatically worldwide, often overlapping with important ecological habitats and fisheries, consequently raising concerns about their potential impacts on marine species. Pile driving (PD) used to build OSW generates high-intensity impulsive sounds that have various impacts on marine fauna (Mooney et al. 2020). However, the impacts of associated substrate-borne vibrations on benthic invertebrates from PD are not known (Popper et al. 2022).

Bivalves can detect substrate-borne vibrations through their abdominal sense organs and statocysts (Roberts and Elliot 2017). A previous study showed mussels and scallops respond to low-frequency vibrations (i.e., < 1 kHz) in tanks by closing their valves (Roberts et al. 2015; Jézéquel et al. 2023), which is a common anti-predatory response with likely energetic consequences (Robson et al. 2012). However, there are needs now to scale up these experimental studies into the field to better understand the impacts from OSW constructions.

Bivalves are both a key taxonomic group for many marine ecosystems and represent a commercially important taxon (Newell 2004; Wijsman et al. 2019). Given the rapid proliferation of planned OSW projects overlapping in vital bivalve habitats and fishing zones, it is necessary to quantify the construction impacts on these species. The purpose of this field-based study was to measure the behavioral responses of the giant scallop (*Placopecten magellanicus*) to real-time PD using biologging tags.

## Materials and Methods

### Data Collection

This study was performed using 14 scallops (8.2 ± 0.5 cm) that were acclimatized in tanks at the facilities of the Woods Hole Oceanographic Institution (WHOI). Before the PD experiment started, scallops were tagged with Axy 5 XS bio-loggers (Technosmart Europe Srl, www.technosmart.eu) using the same technic described in Jézéquel et al. (2022). Basically, these tags measured the valve angle of bivalves using the strength of the magnetic field (in mV; sampling frequency = 2 Hz) between a magnetometer placed on the dorsal valve and a magnet located on the ventral valve. In addition, this tag contains an accelerometer that was used to detect the substrate-borne vibrations (sampling frequency = 25 Hz) arising from PD exposure. Substrate-borne vibrations were also monitored using a calibrated geophone (model GS-11D from Geospace®; sampling frequency = 200 Hz) placed at 8 and 50 m from the PD. Overall, these data were recorded for a period of 2 weeks of PD exposure.

### Experimental Procedure

Pile driving exposures occurred from the 14th to 29th of September 2021 in a shallow water area (41.52° N, 70.67° W; Fig. 1A). A cylindrical steel monopile (length, 10.0 m; diameter, 0.3 m; thickness, 0.02 m) was hammered into the seabed each day using an impact hammer (weight, 1500 kg; Fig. 1B) at a rate of 10 strikes per min, generating 16 kJ per strike. Tagged scallops were placed in cages located at a near (< 10 m) and far (50 m) site from the PD (Fig. 1A). Scallops were exposed daily to 2-hour-long PD events.

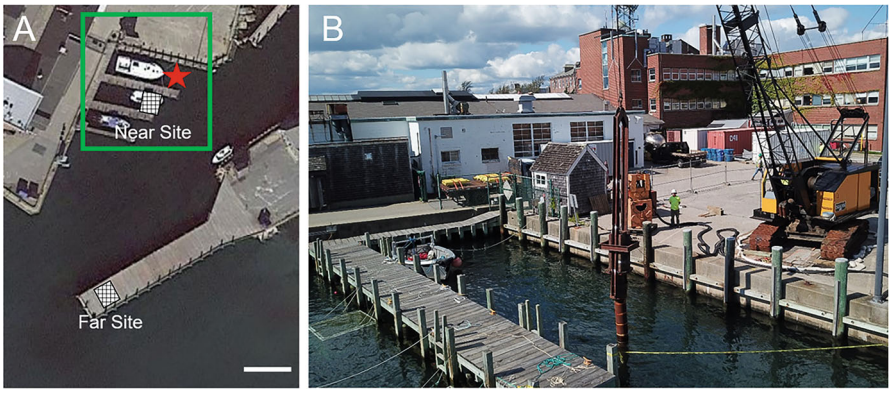

**Fig. 1** A) Top view of the experiment site at Woods Hole harbor (Massachusetts, US). Near site is located within 10 m from PD while far site is at 50 m. White bar is 10 m and red star denotes PD location. B) Picture of the PD setup at the green square shown in A

## Statistical Analyses

Linear mixed-effects analyses were conducted between scallop valve angle and different fixed effects. Individual and date were used as random effects, while fixed effects included exposure type (pre-exposure vs. exposure). Pairwise tests were also performed using post hoc Tukey tests.

## Results

Substrate-borne vibrations recorded without PD were low at both distances (Fig. 2A, D). The PD generated transient substrate-borne vibrations with calculated peak-to-peak levels ranging from 87.08 ± 2.88 to 109.95 ± 1.25 dB re 1 µm.s$^{-2}$ at 50 and 8 m, respectively (Fig. 2B, E). Single strike exposure levels were 94.39 ± 1.34 dB re (1 µm·s$^{-2}$)$^2$.s at 8 m and 72.48 ± 2.51 dB re (1 µm·s$^{-2}$)$^2$.s at 50 m. The spectra peaked at low frequencies around 10 Hz (Fig. 2C, F).

Scallops located within 10 m from the PD showed valve closures in synchronicity with PD substrate-borne vibrations (Fig. 3). This resulted in a significant diminution of 30% in valve angle during PD exposure compared to pre-exposure (Tukey test, $p < 0.001$, Fig. 4). Interestingly, no reactions were found in scallops placed at 50 m, and there were no significant differences in valve angles between pre- and PD exposure (Tukey test, $p = 0.864$, Fig. 4). These results show that scallops were not behaviorally affected by substrate-borne vibrations at 50 m from the PD.

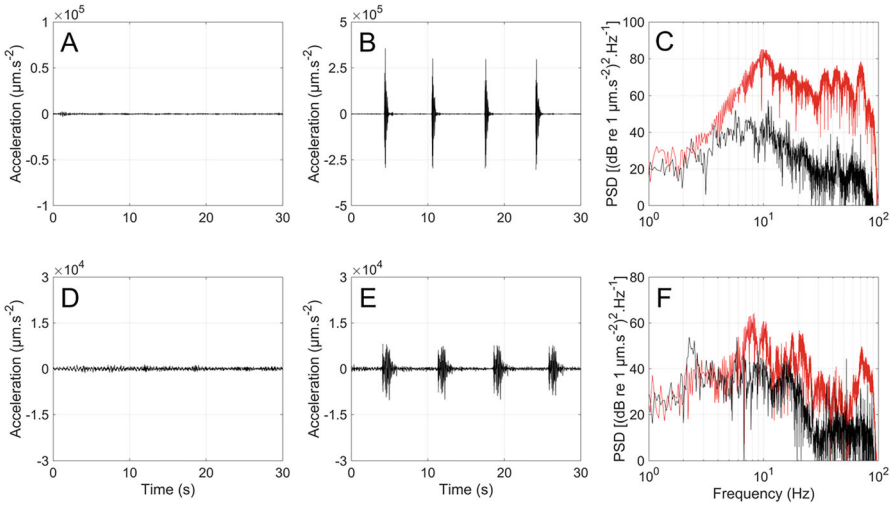

**Fig. 2** Example of recorded substrate-borne vibrations recorded by the geophone (x-axis) at 8 m (top) and 50 m (bottom) without (A and D) and during PD (B and E). Power spectral densities (PSD) of the temporal signals are presented in C and F (red: PD; black: ambient)

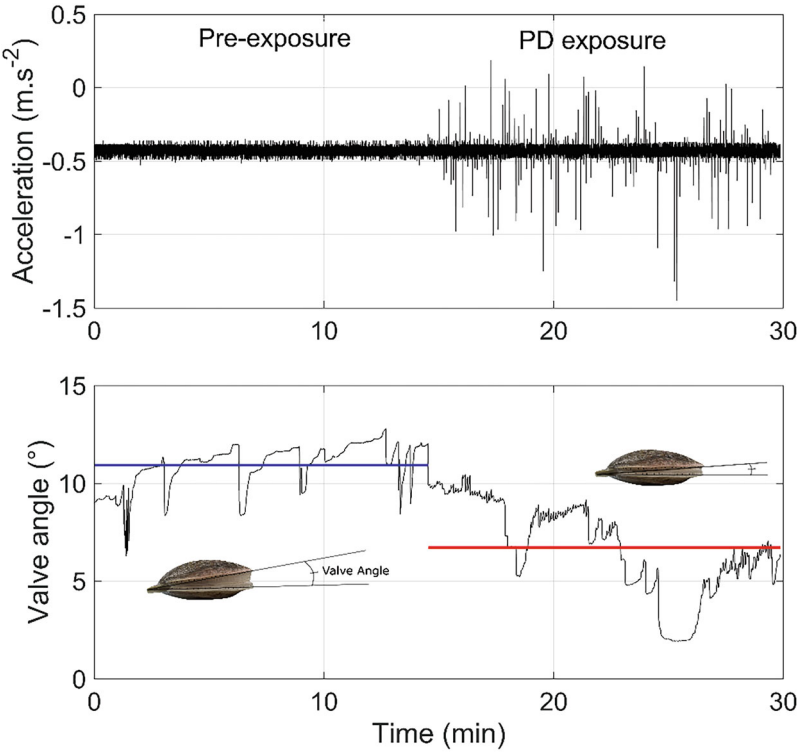

**Fig. 3** Synchronized data from one tagged scallop located in the vicinity of the PD (< 10 m), with the accelerometer (top) and magnetometer (bottom). Substrate-borne vibrations from the PD (vertical bars) were detected by the scallop, which responded by closing its valves. Horizontal bars highlight mean valve angle measured before (blue) and during (red) pile driving

## Discussion

This field-based study showed that substrate-borne vibrations arising from PD impacted scallop behaviors. While strong valve closures were found in the vicinity (< 10 m) of the PD, scallops showed no behavioral responses at 50 m despite PD substrate-borne vibrations were still detected. These data raise concerns about the potential impacts from OSW constructions on scallops.

Scallops exposed to PD responded to substrate-borne vibrations by closing their valves (Fig. 3), which is a common antipredatory response (Thomas and Gruffydd 1971). Similar results were found by Day et al. (2017) with scallops (*P. fumatus*) exposed to seismic air gun. The energy cost and ecological consequences associated with these behaviors are not known. Robson et al. (2012) showed that scallop valve closures result in large expenditures of energy, and an oxygen debt has to be paid off

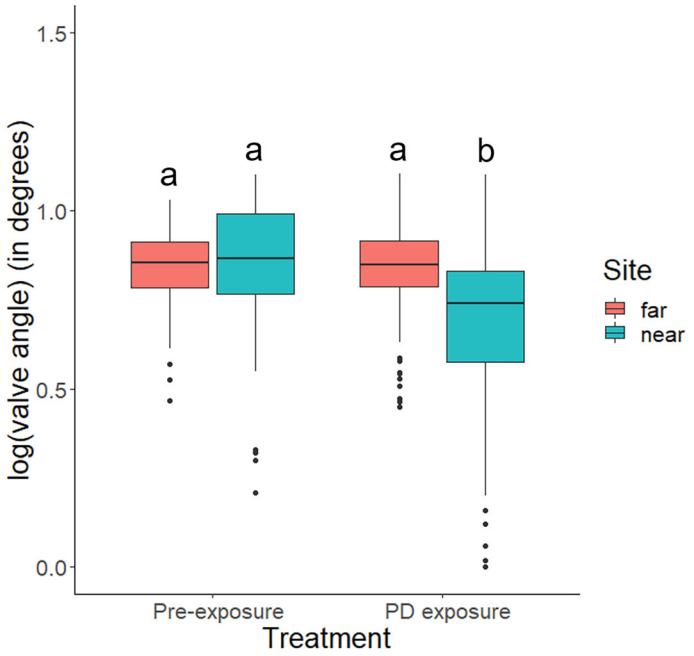

**Fig. 4** Boxplot showing the mean valve angles (log transformed) measured from tagged scallops at the far (red) and near (green) sites before and during pile driving exposure. Results of the post hoc Tukey test are shown with the letters

over long periods of time that limit further movement, including predator escapes. Hence, scallops exposed to PD could be more vulnerable to predation.

Most previous studies with marine invertebrates exposed to PD occurred in tanks at unrealistic sound exposure levels, which rend these results difficult to translate to wild populations (Popper et al. 2022). To fill this gap, scallops in this study were exposed to substrate-borne vibrations from real-time PD in an open water environment (Fig. 1). While such study remains scarce, it is to note that OSW foundations are much larger compared to the PD setup used here (Kallehave et al. 2015). Physical parameters such as bottom type also need to be considered when assessing substrate-borne vibration impacts. Taken together, the spatial range of impacts found in this study is likely to increase during OSW constructions, potentially impacting scallops at the population level.

## Conclusion

The efforts developed in this field study are an important step in understanding the impacts of substrate-borne vibrations from PD in marine benthic invertebrates. The results indicate that scallops behaviorally responded to PD with potential ecological consequences. Further studies are now required to measure the responses of wild scallop populations to OSW constructions (Popper et al. 2022).

**Acknowledgments** We thank Nate Perry for providing us with the scallops. We thank the Shultz Company for the pile driving support. We thank Ed O'Brien and Kim Malkoski for assisting with Scuba operations and Rick Galat and Kerry Strome for coordinating dock space. **Abstract**

Anthropogenic low-frequency noise (LFN) is a continuously growing stressor in our oceans. How this noise affects most groups of marine animals is understudied especially in the case of benthic invertebrates, important ecosystem engineers that rework the sediment in which they live. Here, the effects of acute, continuous LFN on the bioirrigation behavior of *Lanice conchilega*, a tube-building worm

abundant on the North Atlantic coasts, were investigated by tracking sediment oxygen concentrations via microsensor pre- and during exposure. Individuals exhibited lower pumping (tube ventilation) rates when exposed to LFN than when under control conditions. This may signify repercussions for both *L. conchilega* and the ecosystems it helps maintain. Thus, more research is urgently needed to predict and circumvent potentially adverse scenarios brought about by underwater anthropogenic noise.

## Introduction

Anthropogenic low-frequency noise (LFN), or sounds emitted by human activities with frequencies between 10 and 500 Hz (Carey and Evans 2011), is a rising pollutant in our oceans since recent decades. Emitted by sources such as cargo shipping, pile driving, and wind farm operation, these sounds have seeped into natural underwater soundscapes and only continue to increase in prevalence and intensity. Despite this, not much is known about how LFN affects most groups of marine animals, with its effects on benthic invertebrates being especially understudied.

Benthic invertebrates such as worms and bivalves rework the seafloor they live in or on through everyday activities such as burrowing, defecating, and ventilating. This process, known as "bioturbation," is a driver of resource exchange between different sediment layers and the sediment-water interface. Bioturbation also drives local sediment dynamics and biogeochemical cycles, deeming bioturbators crucial ecosystem engineers (Aller 1994; Aller and Cochran 2019; Kristensen et al. 2012). Almost nothing is known about how these organisms respond to LFN, and even the way most marine invertebrates perceive noise is only poorly understood.

While a few studies in very recent years have shown deleterious or no effects on invertebrates (Carter et al. 2020; de Soto et al. 2013; Fitzgibbon et al. 2017; Hudson et al. 2022; Leiva et al. 2021; Zhao et al. 2021), less than a handful of these have focused on bioturbation. A laboratory experiment by Solan et al. (2016) showed that the burrowing behaviors of a bivalve (*Ruditapes philippinarum*) and a commercially important lobster (*Nephrops norvegicus*) were reduced by anthropogenic noise. Similar results were seen in the previous work of Wang et al. (2022): the average sediment reworking rate and depth of the amphipod *Corophium volutator* were reduced in the presence of LFN. While not statistically significant, a potential anti-burrowing stress response was seen in the bivalve *Limecola balthica*, and an increase in bioirrigation (the water exchange component of bioturbation) variability was detected in the polychaete *Arenicola marina.*

To continue filling this immense knowledge gap, this study investigated how the bioirrigation behavior of the tube-building worm *Lanice conchilega* may be affected by LFN in a controlled laboratory setup. *Lanice conchilega* is an abundant polychaete on the North Atlantic coasts; its bioturbation activities facilitate biogeochemical cycles, stabilize sediment via its erect tubes built into the seafloor, and help determine ecosystem structure (De Smet et al. 2015; De Smet et al. 2016; Van Hoey et al. 2008). If, and if so, how added LFN alters the piston-pumping (tube ventilation) rate of *L. conchilega* were tested here, which might then hold potential implications for local sediment characteristics. The LFN employed in this study does not simulate that of a specific source; rather, the frequency produced falls within the range of those emitted by sources such as wind farm operation and ships. The results are intended to explore potential first cause-effect relationships to serve as a pilot for future field- or upscaled laboratory experiments.

## Methods

### Animal Collection

Individuals of *Lanice conchilega* were unearthed by shovel and collected in the Bay of Heist, Belgium (51°20′38.5″N, 3°14′04.0″E). The animals were immediately transported to the lab, planted in cores as mentioned below, and then left to acclimate for 60 h.

### Experimental Setup

Eight 200-L replicate tanks made out of polyisocyanurate plates (inner dimensions: 90 cm length, 60 cm width, 39 cm height) were placed in a temperature-controlled chamber at 13 °C. Each tank was paired with its own aerated seawater tank and pump to form a cyclical water system; filtered seawater was sourced from the facilities at Ghent University in Ghent, Belgium. Within each tank, three cylindrical plexiglass cores (5.4 cm diameter, 15.7 cm height, plugged on one end) were placed after being filled with approximately 14 cm of sieved and settled sediment from the *L. conchilega* sampling site. One individual of *L. conchilega* was planted using a glass straw as described by Ziegelmeier (1969) in a random core until all cores were occupied.

### Added Noise Treatment and Measurement

A small battery-powered submergible vibrator designed by de Jong et al. (2017), or the "noise egg," was employed to generate continuous low-frequency noise at approximately 160 Hz. The egg was attached to a PVC pipe fastened to two perpendicular rods; sandbags were fastened to the ends of the rods to weigh down the apparatus and mitigate vibration transfer from the vibrator to the tank wall. The

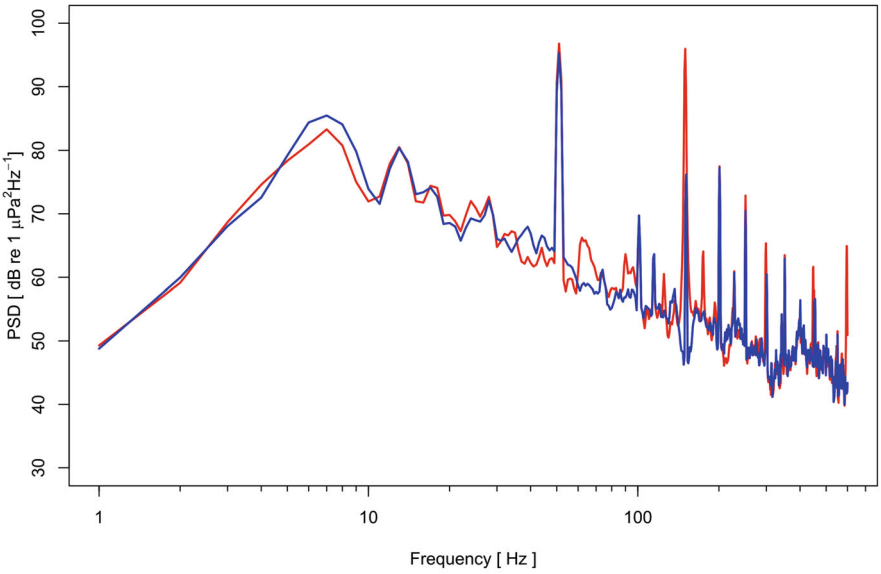

**Fig. 1** Power spectral density comparison of the added noise (red) and control (blue) conditions. The lines depict the root mean square levels. A 10 dB increase on the decibel scale signifies a tenfold increase in power. The red peak at approximately 160 Hz represents the added noise produced by the noise egg, while the red and blue peaks at approximately 50 Hz are likely ambient climate chamber noise

egg was then deployed just below the water surface, positioned between the three cores in the tank. Each replicate tank was exposed first to 1 h of ambient noise with an inactive egg and then to 1 h of added low-frequency noise with an active egg.

A calibrated hydrophone (Aquarian Scientific AS-1, −208 dBV re 1 µPa sensitivity, paired with a PA4 preamplifier and connected to a Zoom UAC-2 audio interface) was positioned 2 cm from the sediment surface of one core from each tank to monitor the frequencies produced by the noise egg. Thirty-second sound recordings of the control and noise treatments were taken in WAV format and analyzed using PAMGuide code (Merchant et al. 2015) in R (3.5.1) (R Core Team 2018) to produce power spectral density (PSD) graphs (Fig. 1) for comparison. As described in Wang et al. (2022), the following settings were used for PSD generation: Fs(Hz), 44,100; window, Hann 50%; and average, 1 s. The correction factor for calibration was calculated using manufacturer technical specifications, gain values from the preamplifier and audio interface, and the zero-to-peak voltage of the audio interface.

## Pumping Rate Measurement

Porewater oxygen concentrations (µmol/L) were measured using an oxygen microsensor (Unisense OX-25) connected to a Unisense Field Microsensor Multimeter

and recorded using the Unisense Logger software. The microsensor was calibrated using freshly oxygenated seawater as the 100% oxygen point and sodium ascorbate as the 0% oxygen point and then inserted into a motorized arm mounted on a steel frame. The microsensor was then inched approximately 1.5 mm into the sediment next to the *L. conchilega* tube until a consistent pumping signal was acquired on the logger software. For each tank, continuous oxygen concentration measurements were taken for one *L. conchilega* individual under control and added noise conditions. Pumping rates were then calculated by plotting the data in GraphPad Prism 8.0.2 and counting the number of peaks per hour; these rates were afterward statistically analyzed using the same program.

## First Results and Discussion

The added noise treatment had a significant effect on the pumping rates of *Lanice conchilega* (paired t-test, $t = 2.646$, $df = 6$, $p = 0.0382$). Individuals pumped less often when exposed to low-frequency noise (LFN) than they did when under control conditions (Fig. 2).

In five of seven replicates, the pumping pattern of the worm was visibly influenced by the LFN; apparent effects on pumping included significant changes in regularity, slight shifts in peak amplitudes, and changes in overall signature (Fig. 3).

These results, along with those from the previous study (Wang et al. 2022), provide some first indications as to how LFN might affect polychaetes. Wang et al. (2022) showed that the lugworm *Arenicola marina,* an abundant burrowing worm along North Atlantic coasts, exhibited great variability in its bioirrigation rates

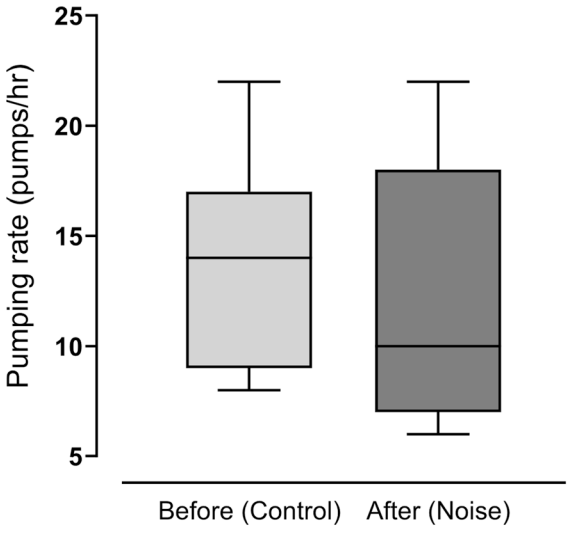

**Fig. 2** Pumping rates of *L. conchilega* before and after exposure to added low-frequency noise

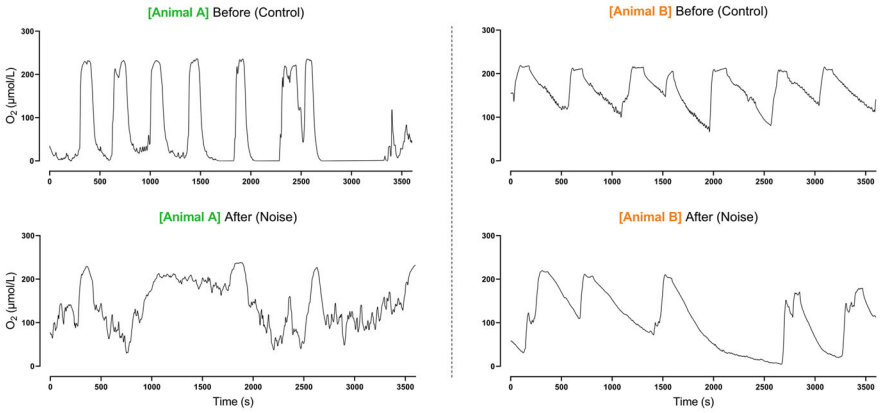

**Fig. 3** Example before-and-after pumping pattern comparisons within two replicates (**a** and **b**). The top graphs show pumping under control conditions (before), while the bottom graphs show pumping under added noise conditions (after)

when exposed to continuous LFN produced by the same source. This was done by periodically sampling sodium bromide tracer concentrations in the overlying water column, contrasting with the current study in which local sediment oxygen concentrations were measured using a microsensor. Both methods, however, ultimately quantified bioirrigation in different ways. It is then plausible that the aforementioned large variabilities might be reflections of the changed pumping characteristics seen in the current results, assuming that both *A. marina* and *L. conchilega* reacted to LFN in a similar way. Both polychaetes are infaunal facilitators of the nitrogen cycle (Braeckman et al. 2010; Volkenborn et al. 2007), and therefore, changes in their bioirrigation behaviors (rate, depth, regularity) will affect the local biogeochemistry. Yazdani Foshtomi et al. (2018) showed that *L. conchilega* in *L. conchilega* reefs, through their bioirrigation activity, had significant influence on the composition and diversity of the *nosZ* gene (a crucial gene in the microbial denitrification pathway) and, by association, the local denitrifying microbiota. *Arenicola marina*, in addition to having similar influence at depth, has also been shown to fuel microphytobenthos growth on typically low-nutrient sediment surfaces via nutrient advection when they ventilate their burrows (Chennu et al. 2015). A decrease in bioirrigation due to LFN might therefore bring about serious repercussions in terms of benthic-pelagic coupling and ecosystem functioning. Low-frequency noise may affect different life stages of the bioirrigators as well as the microbiota themselves. A more detailed understanding of how LFN affects all parts of a benthic ecosystem will be crucial in predicting and avoiding critical scenarios in our increasingly noisy oceans.

studies only focus on the effects of the sound onset or on the effects of the sound exposure as a whole. However, the impact over time of an exposure or over repeated exposures may also reveal relevant information on how bivalves respond to sound and what mechanisms may explain variation in their responsiveness. This chapter analyzes the combined results of four published experiments on the effects of sound on mussels (*Mytilus* spp.) to reveal generalities in their valve gape behavior throughout the trials of all studies. Across studies, mussels responded to sound by partial valve closure and also returned to pre-exposure valve gape levels within the exposure periods. Furthermore, the closing response decayed over sequential sound exposures. These results provide insight into the initial and long-term effects of sound on mussels. Future studies should examine effect of sound in situ and link this to fitness and population consequences.

## Introduction

Increasing amounts of human activity at sea have changed the acoustic scene underwater (Andrew et al. 2002; Duarte et al. 2021). Activities like shipping, seismic surveys, and pile driving produce high levels of sound and are audible to marine life (Morley et al. 2014; Richardson et al. 1995; Slabbekoorn et al. 2010). Marine animals are probably exposed to anthropogenic sound continuously due to the omnipresence of sources and the far-reaching propagation of underwater sound. Human-made sound has been shown to cause stress and hearing damage and disrupt vital behavior (Nichols et al. 2015; Popper et al. 2005; van der Knaap et al. 2021). Most studies focused on marine mammals and fishes, while invertebrates including bivalves received limited attention (Williams et al. 2015). Bivalves fulfill an important role in the ecosystem as filter feeders, reef builders, and prey species (Borthagaray and Carranza 2007; Jørgensen 1990; Kautsky 1981). Most bivalves adopt a sessile or sedentary lifestyle, making it difficult or impossible to move away from a sound source, and are therefore likely to be exposed to the same sound for long periods or repeatedly.

Bivalves have been shown to detect and respond to natural and anthropogenic sound. Planktonic larvae of bivalves have, for example, been shown to increase settlement in response to playbacks of recordings from reefs with conspecifics (Jolivet et al. 2016; Lillis et al. 2013; Wilkens et al. 2012). Anthropogenic sound has been shown to impact bivalve behavior, physiology, and survival (Day et al. 2017; Jézéquel et al. 2022; Spiga et al. 2016; Vazzana et al. 2016; Wale et al. 2019).

The mechanism of sound detection in bivalves is not yet fully understood. Bivalves lack gas-filled cavities and are therefore not expected to detect sound pressure but are rather expected to detect particle motion through mechanoreceptor cells (Ellers 1995; Zhadan 2005). Nineteen bivalve families possess an abdominal

sense organ which is shown to be involved in sound detection (Haszprunar 1985; Zhadan 2005). Bivalve lineages that lack this specific sense organ possess structurally similar organs, possibly also to detect sound (Haszprunar 1983). Hair cells and statocysts have also been suggested to be involved in sound detection (Charifi et al. 2017; Roberts et al. 2015; Zhadan 2005). However, despite the reports on impact of noise pollution on bivalves and their widespread sensitivity to sound, insights into effects from continuous or repeated sound exposures are scarce.

This chapter replots the results of four experiments from three published studies on the effects of sound on mussels (*Mytilus* spp.). The valve gape behavior of mussels from all experiments was plotted in the very same way and scale to allow better comparison of general patterns, which are addressed by integrating the results of all four experiments. This chapter also explored whether the time allowed for acclimation before sound exposure in each experiment had been long enough by examining data from nonexposed control mussels from two of the experiments.

## Methods

All valve gape data from four previous sound exposure experiments on mussels (*Mytilus* spp.) in the lab was used (Hubert et al. 2022a (two experiments); b, 2023). In these experiments, individual mussels were independently tested in separate containers, and their valve gape was measured using a valve gape monitor. Mussels' valve gape has been linked to filter-feeding rate and is therefore a relevant measure related to fitness. The valve gape monitor consists of pairs of electromagnetic coils which were glued on to opposite valves of a mussel. The active coil generated an electromagnetic field, which was measured by the responsive coil and translated to a distance between the coils. To determine the valve gape, rather than the distance between coils, the minimum distance between the coils was deducted from the distance fluctuations over time. The location of the coils on the mussel and the size of the mussels also affected the measured valve gape. For this reason, the valve gape was translated to the fraction of the maximum opening (Fig. 1). The trials typically started with 25 min of silence playback to allow the mussels to recover from handling and to acclimate to the experimental setup. This was followed by a

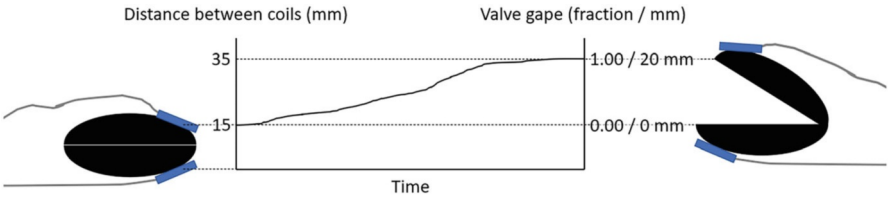

**Fig. 1** Schematic on how valve gape monitors were used to determine the valve gape of mussels. The electromagnetic coils (blue rectangles) of a pair were glued on the valves of a mussel (black half ovals). The distance between the coils was measured, and the minimum and maximum distance between the coils was used to determine the valve gape. The plot is not based on actual data

**Table 1** Description of the sound treatments, sound levels, and sample sizes (N) for all experiments discussed (I and II, Hubert et al. 2022a; III, b; IV, 2023). Sample sizes may differ slightly from the original papers as identical inclusion criteria across studies were used here

sound treatment (or silent control) which varied per experiment and was designed to answer specific research questions (Table 1). The mussels were hung in the water column and did not touch the container they were in and are therefore expected to respond to in-water particle motion, rather than substrate vibration.

This chapter uses the mussels' valve gapes over time as fraction of the individual's maximum opening and plotted the median and first and third quartiles of all individuals. Mussels with a maximum valve gape of less than 0.5 mm or less than 10% of their maximum valve gape 23 min after the start of the trial were excluded because this indicated poor recovery from handling and limited or no acclimation to the experimental setup.

## Results

### Experiment I

Hubert et al. (2022a) examined whether the response of mussels to repeated sound exposures decreased over time. To test this, mussels were exposed to ten 1-min tonal sound exposures of 150 or 300 Hz (with unintentional presence of harmonics), and an 11th sound exposure with the tone this mussel had not heard before (300 or 150 Hz, respectively). Each 1-min sound exposure was followed by 5 min of silence. Mussels in the control condition were only exposed to the tenth and 11th exposure.

The figure of this chapter shows that the mussels' valves were closed at the start of the trial, probably because of the handling by the experimenter (Fig. 2). The mussels opened their valves in about 10 min to a relatively stable level of about 60–80% of their maximum observed valve gape. Upon the first sound exposure, the mussels rapidly closed their valves partially. Interestingly, the interindividual variation in valve gape clearly decreased after sound onset (based on Q1 and Q3).

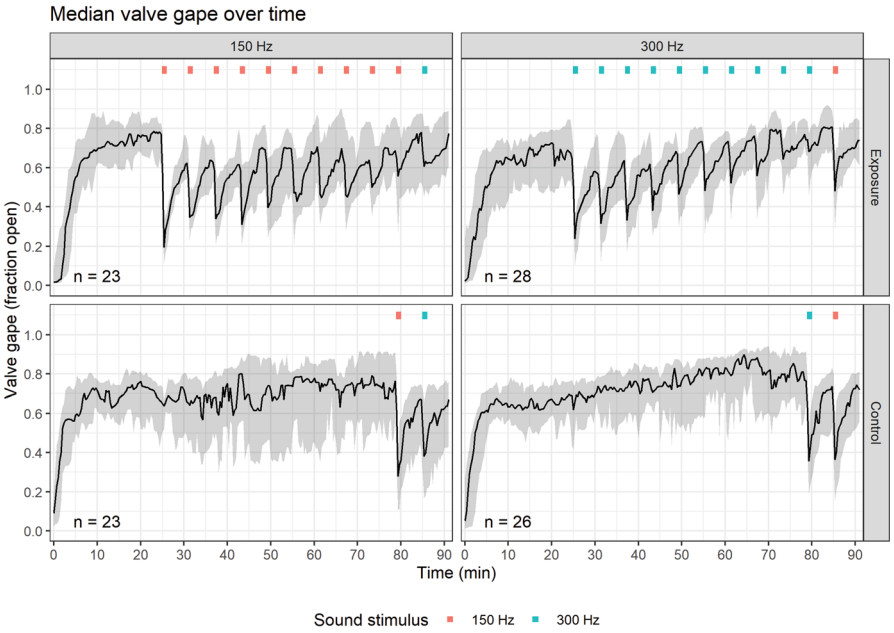

**Fig. 2** The median (solid line) and interquartile range between the first and third quartile (shaded area) of the mussels' valve gape over time. The colored blocks at the top of the panels indicate the timing and type of sound that was played back. The four panels show the four treatments in a 2 × 2 design, with the exposure treatments (top) consisting of 10 identical sound exposures followed by a single novel exposure and control treatments (bottom) consisting of the last two sounds of the exposure condition only. The treatments started with 150 Hz sound(s) (left) or 300 Hz sound(s) (right). The mussels clearly responded to the sound exposures by closing their valves, and the response magnitude decreased over sequential exposures

Moreover, during the 1-min sound exposures, the mussels started to increase their valve gape again. During recovery, the variation in valve gape among individuals increased, indicating variation in recovery speed. The response magnitude to repeated sound exposures decreased over time, and the variation in response seemed to increase.

The mussels were exposed to an 11th novel sound stimulus (with a different spectrum) to examine whether the decay in responsiveness could be attributed to habituation. Habituation is specific to a particular stimulus, while motor fatigue (muscle exhaustion) and sensory adaptation (e.g., increased sound detection threshold) are not. A stronger response to the novel stimulus therefore proves habituation; however, this was only present in one of the two exposure conditions.

## Experiment II

Hubert et al. (2022a) examined whether mussels' responses in valve gape were mostly determined by the sound onset or was also affected by the continuation of sound treatments. To test this, mussels were exposed to three 15-min pulse trains, consisting

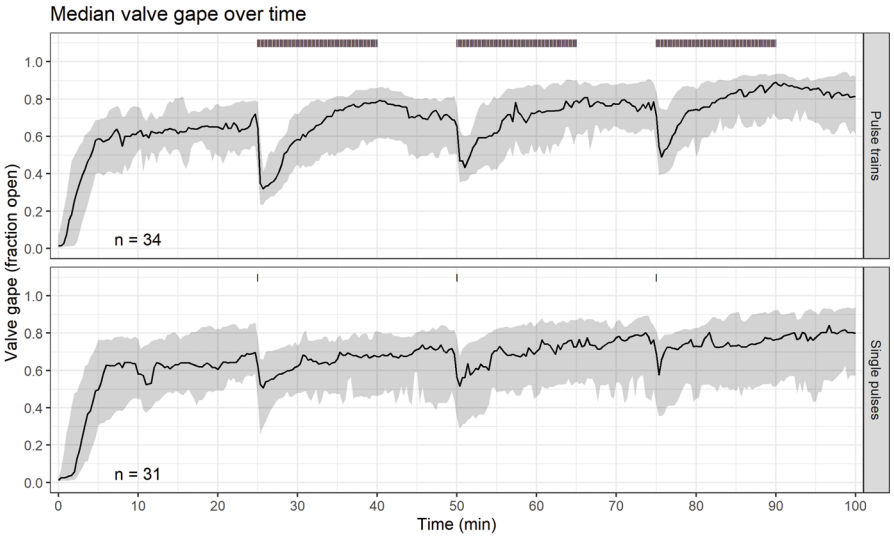

**Fig. 3** The median (solid line) and interquartile range between the first and third quartile (shaded area) of the mussels' valve gape over time. The black vertical bars at the top of the panels indicate the timing of the sound pulses that were played back. The mussels responded to both the pulse train and single pulses and returned to pre-exposure baseline levels already during the pulse train or after the single pulse

of 1-s pulses followed by 9 s of silence; each 15-min pulse train was followed by 10 min of silence. In another condition, mussels were only exposed to the first 1-s pulse for each pulse train, and the rest of the pulses were replaced with silence.

The figure of this chapter shows that the mussels in both treatments responded to the sound by decreasing their valve gape and recovered soon after, either during the pulse train or after the single pulse (Fig. 3). The response magnitude and recovery time decreased over the three sequential pulse trains or single pulses. Statistical analyses from the paper did not reveal statistically significant differences in initial response magnitude and recovery time (time to return to pre-exposure level) between pulse trains and single pulses. Based on visual observation of the valve gape data over time (Fig. 3), it seems that – if anything – the response magnitude was higher during the pulse trains, and recovery times between conditions were similar due to a steeper recovery during pulse trains. Additionally, after recovery during the pulse trains, mussels had a larger valve gape than prior to the first pulse train, perhaps to compensate lower filtering rates or higher oxygen demand during the initial response.

## Experiment III

Hubert et al. (2022b) examined whether the response of mussels to pulse trains was affected by the pulse rate. To test this, mussels were exposed to a 55-min pulse train with consistent pulse intervals ranging from 5 s to 160 s or a silent control with only a single

pulse at the end of the trial. The effect of sound on the phytoplankton clearance rates of the mussels was also explored by taking water samples at the start, after 60 min, and at the end of the trial and analyzing the water samples using a spectrophotometer.

The figure of this chapter shows that mussels responded to the start of the sound treatments by partial valve closure and that most mussels returned to pre-exposure valve gape levels during the pulse train exposure (Fig. 4). The statistical analysis from the paper revealed that recovery was fastest during faster pulse rates (Hubert et al. 2022b). The figure of this chapter reveals that, at relatively fast pulse rates ($\leq$40 s), mussels seem to respond quite strongly at the start of the pulse train, with no additional closure directly after sequential individual pulses. During the slower pulse rates ($\geq$80 s), the initial reaction seems less strong, and mussels already recovered a bit before the subsequent pulse and then respond again. For the 80-s interval, this pattern seemed to fade relatively quickly, while for the 160-s interval, responses to the individual pulses remained clearly visible at the median and Q1. At the Q3, the responses also faded fairly quickly. Around 60 min (and directly before and after the trial), an experimenter entered the experimental room to take some water samples to determine the mussels' clearance rates (cf. Hubert et al. 2022b). Here, it seems that the experimental groups that already returned to pre-exposure valve gape levels (or were not exposed in the control) responded more strongly to the disturbance from the experimenter. Lastly, the paper also analyzed the phytoplankton clearance rate and found a link with valve gape but did not find a sound-induced effect on mussels' clearance rate (cf. Hubert et al. 2022a).

## Experiment IV

Hubert et al. (2023) examined whether mussels responded to sound exposures of boat sound. To test this, mussels' valve gape behavior during one of various ambient or boat sound treatments were compared. The effects of a crab predator and potential interactions with the sound treatment were also explored by exposing the mussels to a live crab predator (either chemical cues or a free-ranging crab) or a control.

The figure of this chapter shows that the mussels strongly responded to the introduction of a live crab stimulus – or sham control – by partial valve closure. The boat sound exposure started before the mussels were fully recovered from the (sham) crab introduction. Nevertheless, and despite a 10-s linearly increasing transition (fade in) to the boat sound, the mussels responded again by closing their valves a bit more again but also recovered and caught up with the ambient control mussels (Fig. 5). The analysis from the paper showed that mussels had a lower valve gape when exposed to a live crab in the same enclosure, but not when only chemical cues were present (cf. Hubert et al. 2023).

## Pre-exposure Baseline

The control conditions of experiment I and III were used to evaluate the duration of the recovery period prior to the sound treatments in the exposure conditions.

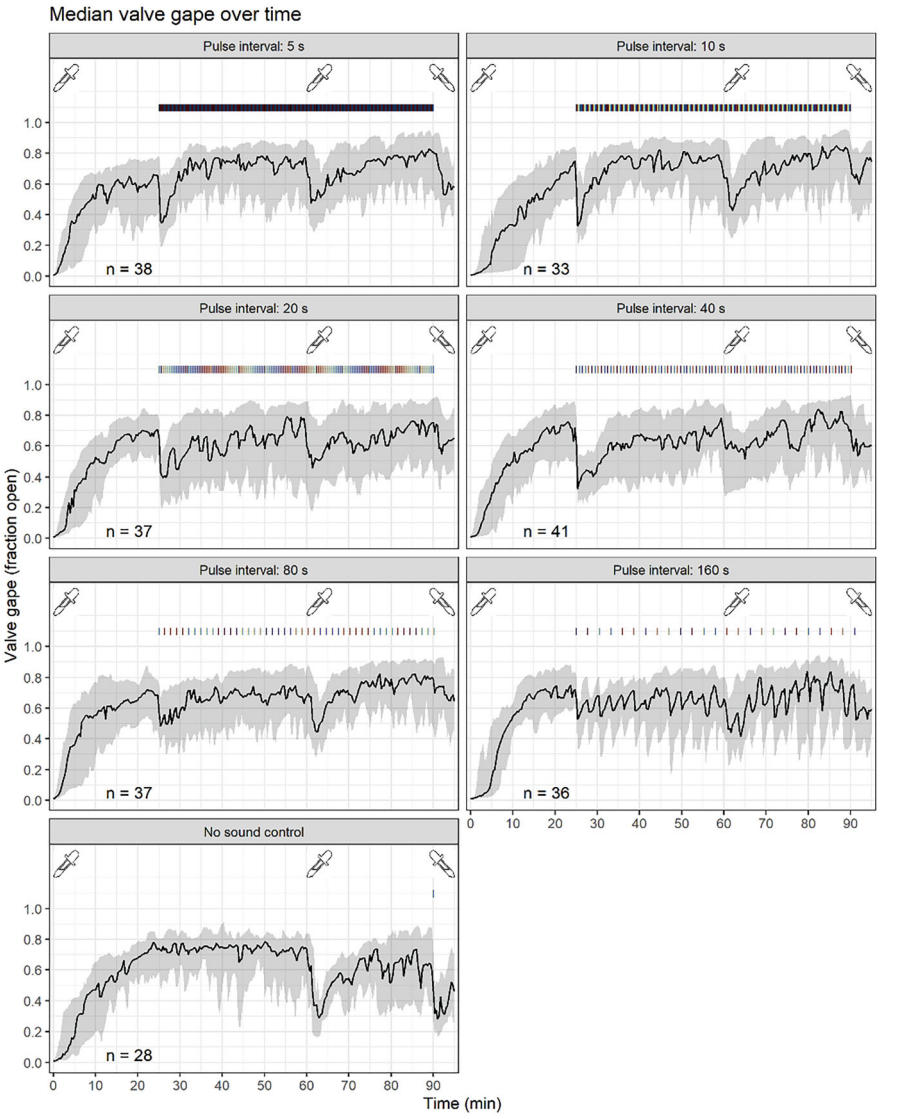

**Fig. 4** The median (solid line) and interquartile range between the first and third quartile (shaded area) of the mussels' valve gape over time. The pipets and vertical bars at the top of the panels indicate water sampling and the timing of the sound pulses that were played back. The interval between the pulses ranged from 5 to 160 s. At around 60 min, a water sample was taken to determine the mussels' clearance rates. The mussels closed their valves upon pulse train onset and mostly return to pre-exposure baseline levels during the pulse train. The recovery time was positively correlated with the pulse interval (Hubert et al. 2022b)

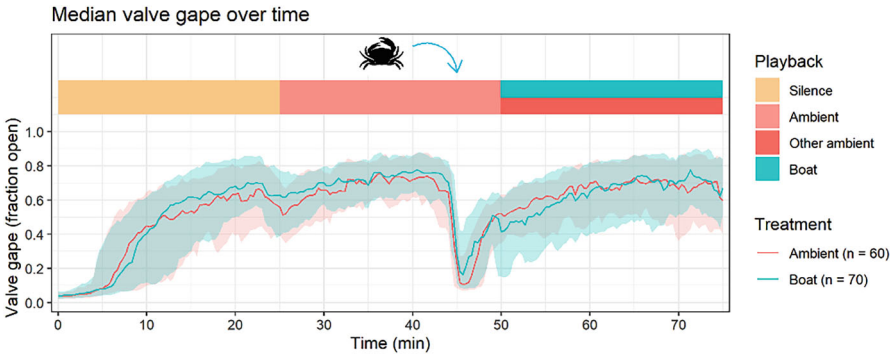

**Fig. 5** The top part of the panel shows that all mussels were first exposed to silence, followed by ambient sound (from 25 min) during which a (sham) crab introduction took place (at 45 min), followed by either another ambient sound or a boat sound playback (from 50 min). The bottom part shows the median (solid lines) and interquartile range between the first and third quartile (shaded areas) of the mussels' valve gape over time. The mussels closed their valves upon the (sham) crab introduction and again at the boat sound onset and caught up with the ambient exposed mussels after about 10 min

The sound exposure typically started after 25 min, but the control mussels in experiment I and III remained undisturbed until, respectively, 79 and 60 min after the start of the trials (Fig. 6a). A 1-min moving median was used to determine when mussels reached or exceeded the median valve gape of the last 5 undisturbed minutes. This analysis showed that a small majority reached this level before 25 min, when mussels in the exposure condition were exposed to sound (Fig. 6b).

## Discussion

Throughout all four experiments, mussels responded to the start of sound exposures by partial valve closure, and this response decayed over sequential exposures. Most of the mussels returned to pre-exposure valve gape levels during the sound exposures, and this recovery took longer during low pulse rates than during fast pulse rates. The mussels not only responded and recovered during pure tones with harmonics but also during boat playbacks with a soft start.

### Initial Valve Gape Closure

The mussels responded to sound by closing their valves. Valve closure is a general defensive reaction by bivalves and has been found in response to all kinds of changes in the environmental (Bayne et al. 1976; Carroll and Clements 2019; Curtis et al. 2000; Robson et al. 2010). Valve closure in response to tonal sound is in line with an earlier study (Roberts et al. 2015) but potentially contrasts with a study that found a larger mean valve gape in response to boat sound playbacks over a 1-h period (Wale et al. 2019),

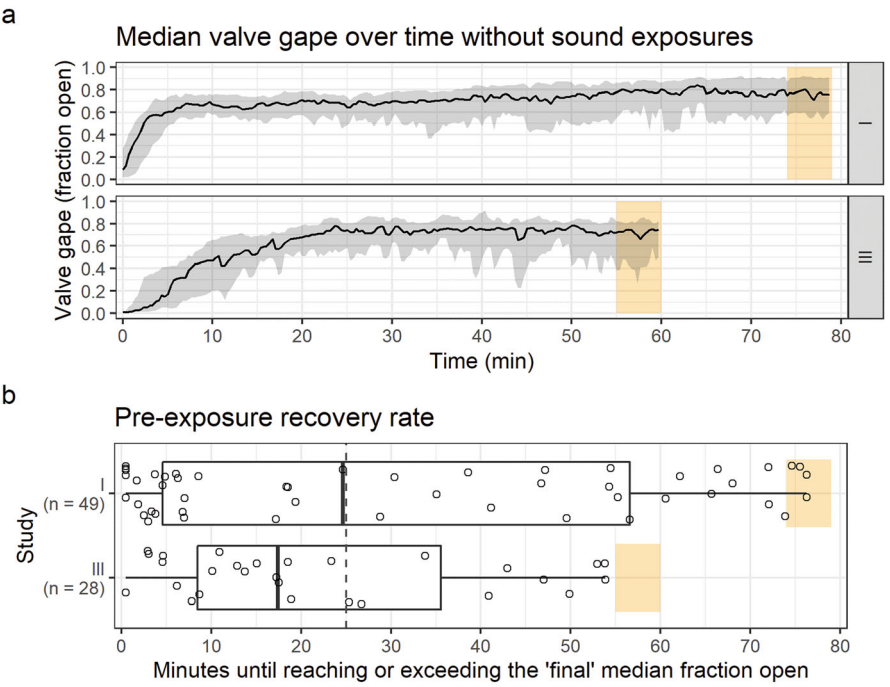

**Fig. 6** (**a**) The median (solid line) and interquartile range between the first and third quartile (shaded area) of the valve gape over time of mussels in the control conditions in experiment I and III. The yellow rectangle indicates the last undisturbed 5 min, from which the individuals' median valve gape was used as a "final" valve gape. (**b**) Time until mussels first reached or exceeded their "final" median valve gape. Most mussels reached this level before 25 min, when the sound started in exposure conditions. The open circles indicate the individuals, and the box-and-whisker plots indicate the median, first and third quartile, and minimum and maximum excluding outliers

although a larger mean valve gape does not exclude initial closure at the sound onset. Mussels' valve gape has been linked to filter-feeding rate (Hubert et al. 2022b; Jørgensen et al. 1988), but dissociation also occurs (Maire et al. 2007). Despite the link, no evidence was found for a sound-induced reduced clearance rate in experiment III, probably because sound-induced valve gape effects over the entire trial were limited (Hubert et al. 2022b). Further, the rapid closing movements in response to sound might be energetically costly (Galler et al. 2010; Robson et al. 2010). Overall, valve closure in response to sound may limit energy intake or increase energy use; future studies should examine to what extent these impacts also affect mussels in situ.

## Long-Term Effects

The mussels returned to pre-exposure baseline valve gape levels during or quickly after the exposures and responded less strong to sequential sound exposures. The decay in responsiveness to sound is in line with earlier studies on bivalves that

reported this for visual and tactile stimuli (Clements et al. 2021; Dehaudt et al. 2019; Wilkens 1986). A reduction in responsiveness can generally be explained by motor fatigue, sensory adaptation, habituation, or a combination of these (Netser et al. 2011; Rankin et al. 2009). Habituation is probably the most likely explanation for the decay in responsiveness to sound as mussels responded stronger again to a novel stimulus, at least in one condition (experiment I, ten 300 Hz exposures followed by one 150 Hz exposure). However, this result was not ambiguous across conditions, making it unable to exclude sensory adaptation (increase in sound detection threshold) (cf. Hubert et al. 2022a). The mechanisms underlying the decay in responsiveness are relevant for determining the impact of sound. If the responsiveness decays due to sensory adaptation or motor fatigue, it means that mussels may also not be sensitive or able to respond to other – potentially relevant – stimuli (Bejder et al. 2009; Domjan 2010), while habituation means that an animal is still able to detect and respond to a cue but ceases to do so as a result of nonassociative learning (Bejder et al. 2009; Rankin et al. 2009). Nevertheless, habituation of one response does not necessarily mean habituation of all responses and absence of all impacts of sound (e.g., masking of relevant cues) (Neo et al. 2018).

## Evaluation of the Pre-exposure Baseline

A small majority of the mussels in the control conditions first reached or exceeded their final median valve gape in the first 25 min of the trial, after which the sound treatment started in the exposure conditions. This measure is a proxy for recovery of handling and acclimation to the experimental setup. For this proxy, it is assumed that mussels had stable baseline valve gape at the end of the undisturbed period of these trials, as this period acted as a reference. Secondly, it was assumed that the first time reaching this valve gape level meant that the mussels had indeed reached this stable baseline level. While accepting these uncertainties, it can be concluded that a relatively large group (even thought a minority) did not reach the final valve gape before the start of the exposures at 25 min. So, for studies that require to manipulate mussels at stable valve gape levels, it is recommended to use a longer recovery and acclimation time than the experiments from this chapter.

## Future Research

Future sound impact research should be a combination of lab and field studies focusing on mechanisms that underly impact the actual effects of anthropogenic sound sources in the field and linking these effects to fitness consequences. The current lab experiments yielded insight into mechanisms underlying sound impact on mussels. This will help to understand impacts in the field. Insights into contribution of acoustic features, such as pulse rate, may help to mitigate effects. Future studies could focus on spectral and temporal components and the amplitude of boat sound to predict mitigation efficacy of boat motor design changes and slowdown measures. Lab studies are useful for such fundamental insights because they allow to

efficiently collect high-resolution data in controlled trials. However, the acoustic conditions, behavior of the mussels, and ecological conditions are likely different from the field (Slabbekoorn 2016). So, to gain insight into the actual effects of sound on behavior and physiology of mussels in situ, field experiments with actual anthropogenic sound sources should be conducted. Lastly, efforts should be made to link the found effects to changes in energy budgets of mussels and ultimately to fitness consequences (Hubert et al. 2020; Van Leeuwen et al. 2013).

## Conclusions

This chapter examined the behavioral response of mussels to short, long, and repeated sound exposures. Mussels responded to sound by partial valve closure, and they returned to pre-exposure valve gape levels during or after sound exposures, and the closing response decayed over sequential sound exposures. The mussels mostly responded to the onset of the sound treatments, but a slower recovery to pre-exposure baseline levels during pulse trains with slower pulse rates shows that mussels are still sensitive to acoustic traits beyond the onset. These new insights into the contribution of acoustic features to impact of sound on mussels should be considered in impact assessments of anthropogenic activities and are essential for designing future mitigation measures. Future research should expand the knowledge on the contribution of various acoustic features to guide mitigation measures and should examine the impact of sound on mussels in situ.

## Ethical Statement

The guidelines for the treatment of animals in behavioral research and teaching (ASAB 2018) were followed. There are no legal requirements for studies involving mussels (and crabs) in the Netherlands.

**Abstract**

Bivalves are an abundant and diverse taxon that serve many important ecological roles including ecosystem engineers and biofilters. As largely sessile animals, bivalves have evolved remarkable sensory systems to perceive their mobile and dynamic surroundings, including acoustic stimuli. Yet, the growing presence of human-generated ocean noise may have adverse effects on their sensory abilities, potentially resulting in physiological and fitness consequences. Recent studies have explored how bivalves detect sound and the impact of human-generated noise on their ecology and physiology. However, the vast variety of noise sources and characteristics, along with the limitation of experiments being primarily conducted in tanks, make it challenging to understand the overall impact of noise pollution on marine bivalves in situ. This work provides a brief review of the understanding of bivalve sound detection mechanisms, followed by a

collation of noise impact studies to assess trends in noise impact severity relative to amplitudes of sound received by animal subjects. Data from comparable studies of similar sound types and characterizations provide evidence that acoustic impacts tend to be more severe with increasing received levels for both zero to peak particle acceleration (water and substrate) levels (dB re 1 $\mu ms^{-2}$) and root mean square sound pressure levels (dB re 1 μPa). This suggests that animals closer to a noise source face greater impact severity. Though, more research is needed to clarify these trends, and such data may aid in identifying more robust noise level thresholds among differing impact severities.

## Introduction

Bivalves (class: Bivalvia, phylum: Mollusca) are an extremely diverse and abundant taxon that serve important roles in marine ecosystems. Ecologically, bivalves are a key energy source for a myriad of species from myriad of species from rays (Ajemian and Powers 2012), marine mammals (Kvitek et al. 1988), and other mollusks (Kabat 1990). Bivalve aggregations provide complex habitats for other species (Tolley and Volety 2005), and they transport nutrients from the water column into benthic sediments (Newell 2004). Economically, global bivalve harvest nears 14 million tons and USD $16 billion (Wijsman et al. 2019). Despite their significant contributions to human and marine health, data on the auditory sensory capabilities of marine bivalves falls behind that of taxa such as fishes and marine mammals (Sole et al. 2023). This knowledge gap is concerning due to the increase and prevalence of man-made noise in coastal and offshore waters (Duarte et al. 2021).

There is mounting evidence that water and substrate-borne vibration detection is widespread within marine bivalves (see Table 1). Specific uses of sound may be vital ecologically; for example, detection of substrate-borne vibrations may aid in the perception of mobile benthic predators as seen in other taxa (Barth et al. 1988). However, sound detection capabilities can also lead to adverse impacts of anthropogenic noise (water and substrate borne). Noise impacts to mollusks can include behavioral changes (Cones et al. 2022), temporary threshold shifts in hearing sensitivity (Putland et al. 2023), and physical damage (De Soto et al. 2013). Bivalve sound detection and associated noise impacts were last reviewed by Roberts and Elliott (2017), and since then 12 new publications have become available in this emerging research area, potentially allowing for integration of these data to begin estimating thresholds of noise impacts on bivalves.

In this chapter, the potential mechanisms of sound detection capabilities in bivalves are described. Then, existing acoustic impact studies are collated. Finally, results from noise impact studies with similar methods and sound characterizations are amalgamated to describe noise impacts at various received sound levels. This

**Table 1** A summary of all studies examining the effects of noise on marine bivalves

| Study | Model species | Life stage | Tank versus field | Sound type | Sound intensity | Sound units | Frequency (Hz) | Impact | Effect category |
|---|---|---|---|---|---|---|---|---|---|
| Aguliar de Soto et al. (2013) | New Zealand scallop (*Pecten novaezelandiae*) | Larval | Tank | Seismic pulses | 164<br>165<br>3–4 | SPLrms re 1 μPa<br>SEL re 1 $\mu Pa^2s$<br>PAL $ms^{-2}$ | <1000 | Body malformations | Physical damage |

provides a novel, empirically based, initial model of distance and potential dose-dependent responses to noise.

## Sound Detection and Mechanisms

All bivalves tested to date have been shown to behaviorally respond to sound, with responses in the frequency bandwidth of roughly 10–1000 Hz (Roberts et al. 2015; Charifi et al. 2017; Jézéquel et al. 2023, Table 1). Bivalves do not contain gas cavities, and so are not thought to detect the sound pressure component of the sound field (Budelmann 1992). Instead, there is evidence bivalves sense particle motion (Ellers 1995) and ground vibration (Mosher 1972) through three potential auditory sensory systems: paired statocyst, cilia-lined tentacles, and the abdominal sense organ (ASO).

Many invertebrates have an internal statocyst sensory system, which is analogous to the inner ear otoliths of many vertebrates and is thought to aid in sound detection (Young 1960). Statocysts are closely associated with the pedal ganglia, often located near the muscular foot (Morton 1985). Bivalve statocysts are paired (Wiederhold et al. 1986), and anatomically they are fluid-filled spheres lined with hair cells (Budelmann 1992). The hair cells function to detect movement of the statolith or statoconia, which are a singular or multiple calcium carbonate structures that reside within the fluid-filled chamber, in response to gravity and sound (Morton 1985). This auditory sensory mechanism has been demonstrated in squid (Mooney et al. 2010).

Secondly, bivalve tentacles are ciliated, and may be able to detect water motions and pressure gradients similar to the fish lateral line system (Bleckmann and Zelick 2009). Cilia tufts that line tentacles along the peripheral mantle contain a high density of nerves in numerous bivalve clads, increasing the evidence of a sensory role (Audino et al. 2021). Lastly, the ASO is an asymmetrical organ postulated to regulate water flow into the mantle cavity (Haszprunar 1985). The ASO surface is also lined with cilia, again potentially used for detecting particle motion.

The mechanisms underlying these systems are not mutually exclusive, and a combination of some or all could aid in detection of sound, or they may be differentially used for water-borne and substrate-borne vibrations. It is currently unknown which mechanism or combination of mechanisms are ultimately responsible for sound detection in bivalves.

## Noise-Induced Impacts

Man-made noise can have varying impacts on marine bivalves, including physical damage (De Soto et al. 2013), physiological changes (Day et al. 2017), and behavioral changes (Jézéquel et al. 2022b). Reponses are often a function of received level and, in a related manner, distance from the sound source (Jézéquel et al. 2022b). Unlike marine mammals and most fishes, bivalves are potentially more vulnerable to anthropogenic noise because animals are either sessile or have very limited mobility

and therefore are unable to move away from the sound source. Thus, they must incur the received levels at a given location for the extent of the noise activity.

To summarize the current state of the literature, all bivalve sound detection or noise impact studies to our knowledge are present in Table 1. Note that this work has mostly been conducted within the last decade and most studies were conducted in enclosed tanks where the acoustic field is not representative of in situ conditions (Jézéquel et al. 2022a). Tanks distort the temporal, power, and spectral characteristics of sounds, and this requires a strong understanding of the physical impacts tanks cause and how to account for them in an experimental design and data interpretations (Jézéquel et al. 2022a). It also requires careful calibration of the acoustic field within the tank for both pressure and particle motion measurements (Jones et al. 2019).

## Aggregating Noise Impact Studies

The severity of noise impact on marine species is often a function of multiple factors such as frequency, rise time, and dose parameters including duration and received sound level, which often correlate with distance. This spatial phenomenon is frequently visually depicted as linear (see Fig. 1 Mooney et al. 2020) or two dimensional (Fig. 1, Richardson et al. 2017) where there are discrete regions around a source that transition from physical damage to audible. Here, noise impact studies were aggregated to map effects within this framework and identify potential thresholds between impact types. The goal was to create a received level-based predictive zone of impacts for bivalves. In doing so, two related challenges are addressed, which should be acknowledged as this framework is assessed.

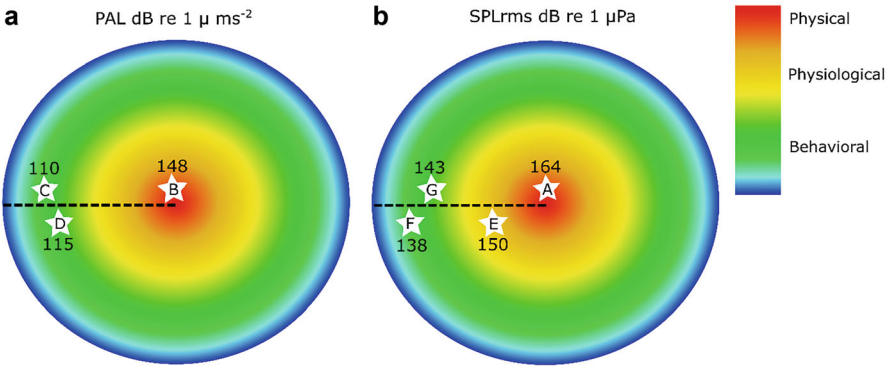

**Fig. 1** Two-dimensional noise impact maps in both particle acceleration level in zero-to-peak (**a**) and root mean square sound pressure level (**b**). The colors denote the severity of impact ranging from physical harm (red) to behavioral impacts (green). The numbered stars denote the referenced study while the adjacent number is the dB intensity reported. The location of the stars is representative of the associated impact at the reported noise level. ([A]De Soto et al. 2013, [B]Day et al. 2017, [C]Jézéquel et al. 2022b, [D]Roberts et al. 2015, [E]Spiga et al. 2016, [F]Hubert et al. 2022a, [G]Hubert et al. 2022b)

## Scant Literature on Bivalve Sound Detection and Noise Impacts

First, there were limited publications on noise impacts on marine bivalves. In total, we found 25 publications on the topic of bivalve sound detection. Of the 25 studies, 15 were experimental examinations of the effects of anthropogenic noise on bivalve behavior or physiology (Table 1). Only 3 of the 15 studies were conducted in situ using real sound sources (Spiga et al. 2016; Day et al. 2017; Jézéquel et al. 2022b). Eleven of the fifteen reported noise levels in sound pressure (SPL), while only seven of the fifteen reported either water- or substrate-borne acceleration levels (PAL) received by the animal. Given that animals detect particle acceleration and that PALs are not predictable from SPLs near the inherent (benthic) boundaries which bivalves inhabit or in tanks where many studies were conducted, this reporting limits our understanding, and predictions, of noise impacts on these taxa. Further, of the studies reporting noise in SPL, three studies reported $SPL_{rms}$ dB re 1 μPa (root mean square), two studies reported peak to peak SPL dB re 1 μPa, and two reported sound exposure levels (SEL in dB re 1 $\mu Pa^2 s$). Lastly, there were diverse sound types used in the reviewed experiments, including, pulses pulse trains, sweep tones, flat tones, and white noise.

## Lack of Audiograms

Another challenge faced when addressing sound sensitivities was the knowledge gap on hearing thresholds. Roberts et al. (2015), Charifi et al. (2017), and Jézéquel et al. (2023) constructed behavioral response curves of the blue mussel (*Mytilus edulis*), Pacific oyster (*Magallana gigas*), and the giant sea scallop (*Placopecten magallenicus*), respectively. These are key data demonstrating sound sensitivity, however, these unconditioned response curves do not necessarily provide the minimum thresholds of auditory detection. Behavioral response curves were developed by monitoring valve movements in response to sound at specific frequencies and intensities. If an animal closed its valves, it was assumed to be in response to the sound stimulus. However, it is possible that animals detect lower sound levels, but do not behaviorally respond by closing their valves. There are no current data reporting sound intensities which bivalves detect, but do not show a behavioral response. Determining if auditory thresholds are similar to sound levels inducing behavioral responses should be examined in the future. Consequently, the response map constructed here utilizes the best available data.

## Noise Impact Maps

Considering these factors, two-dimensional representations of noise impacts on bivalves were created, with the colors depicting relative noise amplitude and animal impact severity (Fig. 1). Stars represent noise impact studies with comparable units and sound types from Table 1. The letters within the stars represent studies cited

from Table 1. The location of the star describes the impact severity reported in the study and its associated number represents the measured noise intensity in decibels.

For Fig. 1a, only studies measuring either particle or ground acceleration in zero to peak and using impulsive noise sources were used (Roberts et al. [2015] was included in this analysis, which exposed animals to 8 s vibrations). For Fig. 1b, only studies measuring sound pressure in root mean square and using pulses, pulse trains, and sweeps were used. Again, as noted above, measures of pressure, especially in tanks, do not reflect the signals to which bivalves and other particle motion-sensitive animals respond. It is important to note that studies were combined across life stages, despite evidence that behavioral responses vary through ontogeny (Jézéquel et al. 2022b). The frequency of the noise stimulus was omitted from this analysis but is important to consider. The power spectra of the studies likely differed, and these relative frequency contributions may influence animal responses. However, all exposure frequencies were completely or partially in bivalve sound detection range (<1 kHz).

For both $PAL_{0\text{-peak}}$ (dB re 1 $\mu ms^{-2}$) and $SPL_{rms}$ (dB re 1 μPa), the measured noise impact tended to be more severe with increasing received sound level, although no statistical test was run due to the limited sample size. This finding intuitively suggests that, for $PAL_{0\text{-peak}}$ and $SPL_{rms}$, noise impact on bivalves is a function of distance from sound source (but see [Dahl et al. 2020]). In this context, marine bivalves closer to a noise source will be most impacted. Although there were some assumptions in this analysis, these methods can be used for other taxonomic groups to assimilate all data and identify thresholds between impact severities. Here it is demonstrated that noise sources greater than 115 $PAL_{0\text{-peak}}$ (dB re 1 $\mu ms^{-2}$) and 143 $SPL_{rms}$ (dB re 1 μPa) may lead to physiological and behavioral impairments. This information can be used to set exposure criteria guidelines for taxa (Popper et al. 2014).

## Conclusion

While there are some data in the bioacoustics literature on impacts of noise on marine bivalves, there are still several key knowledge gaps: auditory thresholds, noise exposures in varying contexts, dose-dependence impacts, and the need for studies measuring the appropriate sound metrics. The need for auditory thresholds was described in section "Lack of Audiograms."

Secondly, context such as time of day, behavior, or reproductive state may influence impact severity. For example, scallops show a clear diurnal pattern to their valve gape angle (Jézéquel et al. 2022b), and thus time of exposure would influence the extent of the response and also the vital activity occurring at that time. Context has a clear role in vertebrate noise studies and potentially for invertebrates as well (Deruiter et al. 2013).

Additionally, more noise impact studies should employ a before-and-after gradient design (Methratta 2020) when possible to address multiple noise amplitudes and concurrently monitor for a gradation of impacts. This experimental style is not only

better controlled but a more-natural reflection of likely exposure conditions (i.e., animals at multiple distances and received sound levels; Methratta 2020). The stepwise design will aid in identifying thresholds between behavioral, physiological, and physical impacts of sound, which are needed to understand how anthropogenic noise may impact the ecology of this vital taxon. Finally, considering that all bivalves live within or on top of the substrate and are thought to detect particle acceleration, future work should be directed at quantifying both water- and substrate-borne particle acceleration levels.

**Abstract**

With the UK aiming to achieve 50 GW of offshore renewable energy by 2030, offshore construction will increase in tandem. The construction noise associated with wind turbine installation has gained much attention over the years, with sound emissions threatening to have an impact on the ecology of marine mammals and fish. During operation, continuous vibration is produced by blade rotation and the operating machinery near the blades (the nacelle) that travel down the external surface of the turbine tower and into the foundation and neighboring seafloor. While vibration is known to affect the behavior and physiology of marine invertebrates, the potential for these seismic interface waves, to impact the animals living on the turbine or the seafloor adjacent to the turbine, has yet to be studied. Due to the difficulty of measuring offshore, in this study, substrate-borne vibrations (seismic waves) from a turbine in operation were measured at a terrestrial wind farm at three different locations (turbine tower, concrete foundation of the tower, and adjacent soil in a 10 m distance) at different wind speeds to assess their potential effect on associated animals, particularly invertebrates. The vibration was highest on the turbine tower, with a maximum vibration recorded at 91.3 $mms^{-2}$ (114 Hz). However, most of the values fell below 53 $mms^{-2}$. The lowest recorded vibration was found within the soil, with maximum vibration not exceeding 2.1 $mms^{-2}$ (50 Hz). The recorded substrate vibration showed little overlap with the known vibration sensitivities of invertebrates at their expected locations. Mussels (*Mytilus edulis*), regularly found to be attached to the towers of offshore wind turbines, dwell in the intertidal area and are often exposed to air. This study finds that their threshold sensitivity (60 $mms^{-2}$) is generally too low to perceive the measured vibrations of the tower. Similarly, hermit crabs (*Pagurus bernhardus*) and other decapod crustaceans, which dwell close to the foundation of the wind turbines, based on their sensitivity, are unlikely to perceive the minute seismic waves that are conducted into the sediment. However, under some specific but rare conditions, vibration amplitudes were high enough to be detectable by the marine invertebrates. These measurements, while conducted in terrestrial conditions, indicate potential temporary impacts of wind farm operational noise on associated epifauna. Additional information is needed to confirm the severity of the effects on the marine environment.

## Introduction

Wind farm developments in Europe and the UK, particularly offshore, are rapidly growing to reach the 2050 net zero targets for the global energy sectors (British Energy Security Strategy 2022). The energy strategy in the UK has increased current targets from 40 GW to 50 GW by 2030, with approved projects set to increase the current capacity by threefold (British Energy Security Strategy 2022). This increase in demand has led to turbines becoming larger and more powerful (IRENA 2019), as well as to an increase in the total marine space planned for offshore developments. Concerns surrounding underwater noise have typically been related to pile driving activities, generating high amplitude-low frequency noise and vibration that propagates through the water column (water-borne particle motion) and the seabed (substrate-borne particle motion). Documented effects range from behavioral changes to increased mortality. Study taxa include marine mammals (Brandt et al. 2011; Kastelein et al. 2019), and the less studied fishes and marine invertebrates (Casper et al. 2013; Spiga et al. 2016; Jézéquel et al. 2021; Siddagangaiah et al. 2021). Operational turbine noise and substratum vibration have gained less attention in comparison, likely due to their lower intensity (Madsen et al. 2006; Tougaard et al. 2020; Stöber and Thomsen 2021).

Installing offshore turbines creates a new habitat through the introduction of hard substrata to a previously predominantly sedimentary environment (Mavraki et al. 2020). This new habitat is colonized by epifaunal marine animals, predominately filter-feeding invertebrates such as mussels and fish (Andersson and Öhman 2010; Coolen et al. 2022). After installation, the turbines are in their operational phase for approximately 25 years before decommissioning, where turbines are either fully removed or the foundations are left in place to preserve the assemblages. During these operational years, vibrations are produced from two main parts of the turbine: the blade rotation and the machinery within the nacelle, such as the gearbox and the generator (Tougaard et al. 2009; Mollasalehi et al. 2013; Escaler and Mebarki 2018). Both the blades and the machinery are supported by the tower and the foundation, which anchors the turbine into the substrate (Tougaard et al. 2009). The vibrating tower produces acoustic noise which radiates into the environment, in the form of sound pressure waves and particle motion of the medium, traveling at the speed of sound (Hawkins et al. 2021). It will also, due to the elasticity of the tower wall generate several types of substrate vibration (substrate-borne particle motion). These waves travel down the tower surface and into the sediment with different speeds depending on the type of wave, and into the substrate (Mortimer 2017). Within the sediment, waves will travel as solid shear waves and compressional (P-) waves (Hawkins et al. 2021), while on the interface between water and substratum surface, vibration travels as seismic interface waves (i.e., Rayleigh or love waves; Aicher and Tautz 1990; Hawkins et al. 2021). These anthropogenic seismic waves may influence the associated invertebrates as they are very sensitive to these vibrations (Roberts et al. 2015; Popper and Hawkins 2018; Velilla et al. 2021).

Previous studies surrounding wind turbine vibration mostly focused on the acoustic noise radiating from the tower into the surrounding fluid (Pangerc et al.

2016). Substrate vibration has also been studied regarding structural health monitoring for fault detection and general operations and maintenance (Zhao et al. 2020; Pacheco-chérrez and Probst 2022). Little attention has been given to the impact of these vibrations on colonizing epifauna (Sigray and Andersson 2011; Velilla et al. 2021). Based on sound recordings in the surrounding fluid, operational turbines are expected to produce vibrations at low intensities in a frequency range below 500 Hz (Wahlberg and Westerberg 2005; Madsen et al. 2006; Sigray and Andersson 2011; Pangerc et al. 2016).

Research surrounding the biological impacts of turbine operation-induced substrate vibration is still in its infancy. One study at a terrestrial wind farm suggested that operational vibration in the soil reduces earthworm abundance near the turbine (Velilla et al. 2021). However, only relative vibration amplitudes were recorded, not the absolute magnitude of vibration (Velilla et al. 2021). Earthworms have the ability to detect substrate-borne vibrations in the soil (Holbrook and Mortimer 2018). However, it remains unclear how sensitive earthworms need to be to detect the minute turbine vibrations transmitted into the soil. Offshore, research mostly focused on the effects of sound waves (sound pressure or associated particle motion) originating from the operating wind turbines. The operation-induced sound appears to increase chorusing among fish, although it was suggested that this could be due to an increase in fish assemblages around the turbine (Siddagangaiah 2021). Apart from a few exceptions, previous biological studies of vibration effects on invertebrates have only considered the pressure component of sound (Hawkins et al. 2021). Invertebrates do not detect sound pressure and appear only sensitive to substrate vibration and particle motion (Breithaupt 2002; Roberts et al. 2015, 2016; Day et al. 2016). Sigray and Andersson (2011) measured water-borne particle motion near an offshore wind turbine (1.5 MW) using a wireless, three-axis sensor, placed 1 m from the outer rim of the foundation. The amplitudes of water-borne particle motion were strong enough to be within the detection range of some species of fish (Sigray and Andersson 2011). Vibration amplitudes were higher during lower wind speeds (5 $ms^{-1}$ – 12.3 $mms^{-2}$ at 16 Hz) compared to high wind speeds (11 $ms^{-1}$ – 4 $mms^{-2}$ at 29 Hz) (Sigray and Andersson 2011), despite the opposite being measured in turbine health monitoring reports (Zhao et al. 2020). Both Pangerc et al. (2016) and Sigray and Andersson (2011) measured turbines far smaller (3.5 MW and 1.5 MW) than offshore turbines that are currently being installed (12–14 MW; GE 2018) and there is therefore potential for higher levels of operational vibration both on the turbine tower and in the surrounding seabed.

This study aims to understand the magnitude and frequency of operational turbine-induced substrate-vibration and whether these are detectable by invertebrates that are attached to or live near the turbines. Substrate vibrations were measured perpendicular to the surface (considering only seismic interface waves, not the compressional P-waves) on a 2.0 MW onshore turbine. Due to the difficulty in data collection at an offshore wind turbine, vibration measurements were made at a terrestrial wind farm in the UK. The origin and spread of vibration measured on the turbine tower are expected to be similar between offshore and onshore turbines. While currently built offshore wind turbines are generally larger and more powerful,

tower vibration may be dampened due to their submergence in water. Three example invertebrates were used – the blue mussel (*Mytilus edulis*), the hermit crab (*Pagurusbernhardus*), and a terrestrial crustacean, the pill woodlice (*Armadillo officinalis*) – to give an approximate, initial indication into whether substrate vibrations may affect these invertebrates.

## Methodology

### Study Site and Turbines

The studied wind farm was located onshore in the North of England, UK (E492598, N438499), consisting of six turbines of 2.0 MW capacity. The turbines had a hub height of 58.5 m, a blade diameter of 83 m, and pitch-controlled blades. All measurements were taken on a single turbine. The power generation of the turbine is displayed using power output, measured in kilowatts (KW) and wind speed ($ms^{-1}$) (Fig. 1). The power curve can be split into different zones which relate to various dynamic conditions of the turbine which will likely influence vibration. The turbine will cut in (begins rotating) at a wind speed of 3 $ms^{-1}$ (zone 2) and cut out (stops rotating) at 25 $ms^{-1}$ (zone 6). The regions between these wind speeds are considered operational, and outside the turbine would be non-operational.

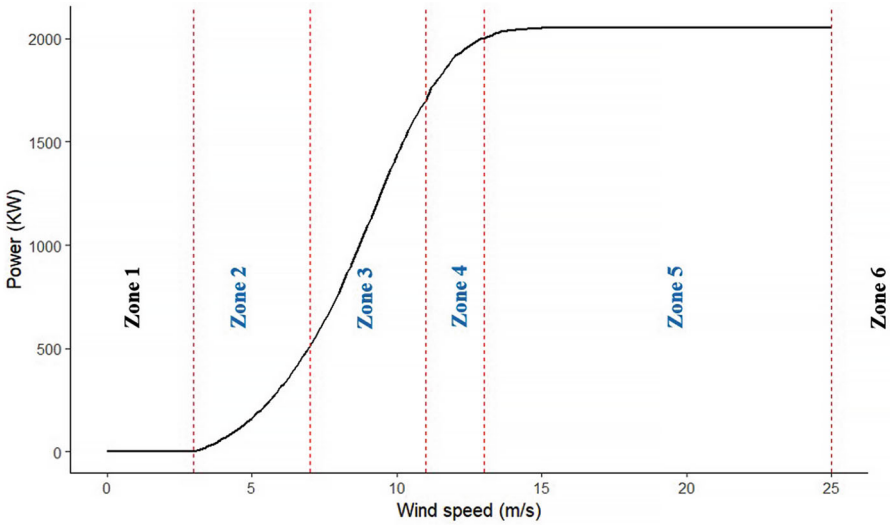

**Fig. 1** Power generation curve for 2 MW study turbine. Zones in black indicate a turbine in a non-operational state, while zones in blue relate to operational phases. Red dashed lines indicate operational zones. (Adapted from Pacheco et al. (2021))

## Study Design

Experimental data were measured and displayed as acceleration units ($mms^{-2}$). Measurements were collected across four days between August 2021 and February 2022. Measurements were taken at three different locations on and near the turbine (Fig. 2); at the turbine tower at 1 m height, on the surrounding concrete foundation, and on the soil at 10 m distance from the turbine. The accelerometer was buried in 10–15 cm depth to measure substrate vibration transmitted through the soil. Control measurements were taken on a separate day at the turbine tower during downtime periods when the turbine was switched off. During all measurements, wind speeds ranged from 3 $ms^{-1}$ up to 8.8 $ms^{-1}$, which correspond to zones 2–3 (Fig. 1). Conditions varied throughout the days, as detailed further in Table 1.

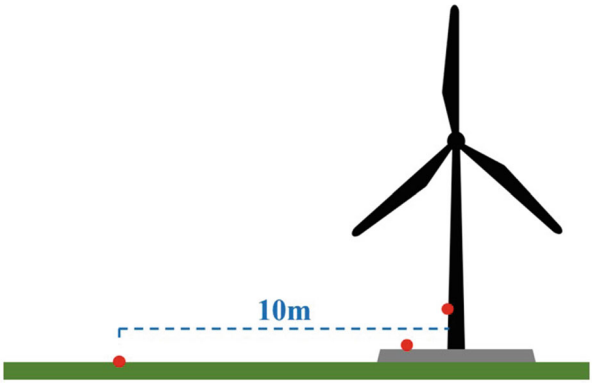

**Fig. 2** Measurement locations at the turbine sample site. Red dots indicate the placement of the accelerometer

## Measuring Equipment

Measurements were made using a calibrated Brüel & Kjær accelerometer Type 4370 (sensitivity 1.01 V/ms$^{-2}$), connected to a battery-powered Brüel & Kjær Charge Amplifier type 2635. The amplifier was further connected to a PicoScope oscilloscope (4200 series; Pico Technologies) and an HP Laptop with PicoScope 6 software (PC Oscilloscope version 6.14.44.5870). Data were collected at each location using two different frequency settings (Table 2). These frequencies were chosen based on preliminary data collected which highlighted dominant frequencies between 0 Hz and 500 Hz as well as above 500 Hz. All frequency spectra were made using a Blackman window. Spectral amplitudes were displayed as root mean square (RMS). The cable connecting the accelerometer to the amplifier was covered using tubing. The accelerometer and the cable were taped to the turbine tower or concrete to shield these cables from unwanted noise caused by wind and other disturbances. During soil measurements, the wires were also covered in tubing, and the accelerometer was covered in excess soil. Peaks recorded below 1 Hz are considered to be the result of vortex shedding behind the turbine tower rather than a result of turbine operation.

## Data Analysis

The frequency spectra of each recording were imported into MatLab, using a frequency resolution of 305.2 mHz for high frequencies (1–2 kHz) and 30.5 mHz for low frequencies (see all parameters in Table 2). At each location, recordings were replicated 32 times and averaged across each bin width using MatLab (Ver. 2021; MathWorks) to produce an average spectrum for each location. The acceleration (mms$^{-2}$) spectra were obtained using the Fast Fourier transform (FFT) built-in function in MatLab. These data were then used to calculate the overall average and standard error as a percentage (%). For invertebrate sensitivity comparison, each spectrum was scanned for peak amplitude and frequency. If frequencies (±3 Hz) appeared more than three times, these were chosen as dominant frequencies and selected for further analysis.

Supervisory control and acquisition data (SCADA) were provided by the turbine operator, including 10-minute averages of operational and environmental variables such as wind speed (ms$^{-1}$), rotor speed (rpm), gearbox and generator speed (rpm), turbine oscillation in the x- and y-axis (mG), and active power (kW). Variables are defined in Table 3. Selected data were used to understand changes in vibration associated with turbine variables (i.e., rotor speed, wind speed, and turbine oscillation).

**Table 3** Definition of variables used in SCADA data

| Variable | Definition |
|---|---|
| **Rotation speed (RPM)** | The number of rotations or spins something does in one minute, measured in revolutions per minute |
| **Turbine oscillation (x and y)** | Movement of the turbine structure in x- and y-axis measured in mG (mass and acceleration of gravity) |
| **Active power** | The power output of the wind turbine, measured in kilowatt (KW) |

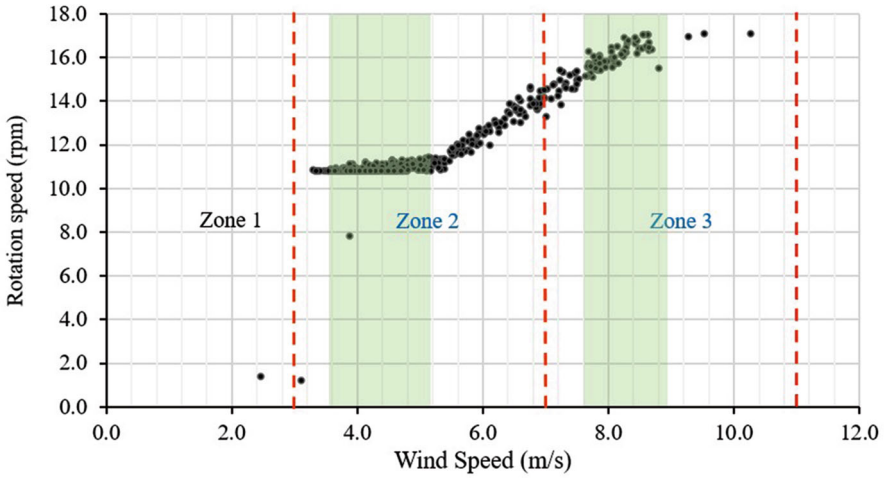

**Fig. 3** Relationship between wind speed and rotation speed of the sampled turbine. Dotted red lines indicate operational zones (see Fig. 1). Green zones indicate the wind speeds where measurements were made

The peak vibration amplitudes at selected frequencies were compared to threshold sensitivities of three invertebrates; the European hermit crab (*Pagurus bernhardus*; Roberts et al. 2016), pill woodlouse (*Armadillo officinalis*; Cividini et al. 2020), and the blue mussel (*Mytilus edulis*; Roberts et al. 2015), to understand if they would perceive the vibrations. These sensitivities indicate the amplitude at which the invertebrate started to show a response to a vibration source. For the mussel and hermit crab, responses consisted of valve closures at 60 $mms^{-2}$ (Roberts et al. 2015) and antennae flicking at 20 $mms^{-2}$, respectively (Roberts et al. 2016). The pill woodlouse displayed avoidance responses at 3.1 $mms^{-2}$, moving away from the vibration source (Cividini and Montesanto 2018).

## Results

### Turbine Vibration Characteristics

The rotation speed (rpm) of the turbine was positively correlated to wind speed (Fig. 3). Rotation remained constant at 10.8 rpm up to a wind speed of 5.8 $ms^{-1}$ (Fig. 3).

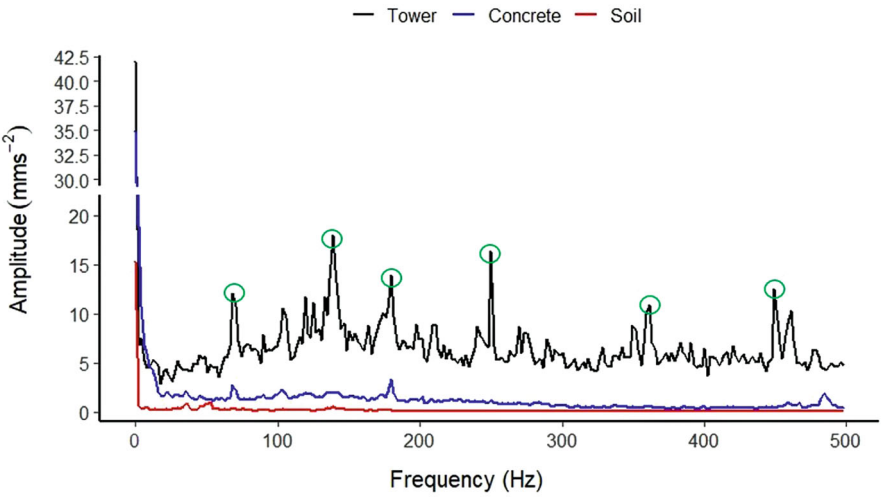

**Fig. 4** Averaged vibration amplitude at the tower (black), concrete (blue), and soil (red), as measured during visit 1. Wind speed was recorded between 7.7 and 8.2 ms$^{-1}$. Standard error ranged between 7% and 19%, 8% and 48%, and 3% and 12% on the tower, concrete, and soil, respectively

## Visit 1: Zone 3

Wind speeds on visit 1 were within zone 3 of the active power plot (Fig. 1), ranging from 7.0 to 8.2 ms$^{-1}$ (Table 1). Rotation speed (rpm) suggests that the turbine was operating at rated, or maximum power (Figs. 1 and 3) at 16.3–16.5 rpm on the tower and ranging between 13.3 and 16.3 rpm during concrete and soil measurements. Tower oscillation provided by SCADA data from the operator is shown in Table 1. Variables are different at each sample location due to wind speed changes when measurements were made at different times on that day. The average vibration measured at the tower had a peak amplitude of 18.1 mms$^{-2}$ at a frequency of 138.6 Hz (Fig. 4). Further prominent peaks are located at 68 Hz, 179 Hz, 250 Hz, 361 Hz, and 449 Hz at 12.1 mms$^{-2}$, 13.9 mms$^{-2}$, 16.4 mms$^{-2}$, 10.9 mms$^{-2}$, and 12.5 mms$^{-2}$, respectively (Fig. 4). Vibration decreased with distance from the turbine, with the dominant peak in the concrete measuring 3.3 mms$^{-2}$ at 179 Hz, while the soil measured at 1.1 mms$^{-2}$ RMS at 52 Hz, comparatively (Fig. 4). The initial peak measured between 0 and 1 Hz was 42 mms$^{-2}$, 34.8 mms$^{-2}$, and 15.3 mms$^{-2}$ at the tower, concrete, and soil, respectively.

## Visit 2: Zone 2

Throughout visit 2, wind speeds ranged from 3.8 to 5.3 ms$^{-1}$ and were within zone 2 of the active power plot (Fig. 1) and rotational speed zones (Fig. 3). Rotation speed remained constant throughout the measurements at 10.8–10.9 rpm. Tower oscillation was highest on the x-axis (back and forth motions) during all three measurements

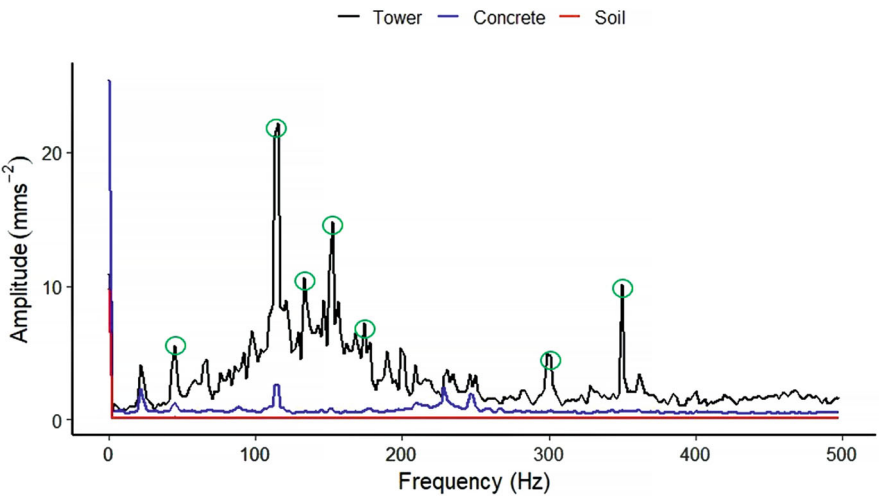

**Fig. 5** Averaged vibration amplitude at the tower (black), concrete (blue), and soil (red) as measured during visit 2. Wind speed varied between 3.4 and 5.4 ms$^{-1}$. Standard error ranged between 0.38% and 2%, 0.1% and 2%, and 3% and 16% on the tower, concrete, and soil, respectively. Peaks circled in green at 45, 114, 132, 152, 173, 298, and 349 Hz

(Table 1), exceeding the oscillations on the other visits. Variables are different at each location due to differences in wind speed as measurements were taken at different times on that day.

During tower measurements, the averaged data showed a peak frequency at 115.2 Hz with vibration of 22.2 mms$^{-2}$. Other prominent peaks were seen at 44, 132, 152, 173, 298, and 349 Hz at 5.5 mms$^{-2}$, 10.6 mms$^{-2}$, 14.7 mms$^{-2}$, 7.2 mms$^{-2}$, 4.9 mms$^{-2}$, and 10.1 mms$^{-2}$, respectively (Fig. 5). Measurements in the concrete during visit 2 showed a peak at 114 Hz at 2.6 mms$^{-2}$. For the soil, vibrations were lower with a peak of 0.08 mms$^{-2}$ at 50 Hz (Fig. 5). The initial peak recorded between 0 and 1 Hz for the tower, concrete, and soil were 10.9 mms$^{-2}$, 25.4 mms$^{-2}$, and 9.7 mms$^{-2}$ (Fig. 5).

## Visit 3: Zone 2

Wind speeds during visit 3 ranged from 3.6 to 5 ms$^{-1}$ and were within zone 2 of the active power plot (Fig. 1) and rotational speed zones (Fig. 3). SCADA data is summarized in Table 1.

Measurements on the turbine tower during visit 3 showed an average peak frequency of 115.2 Hz at 67.1 mms$^{-2}$. This was the highest peak vibration throughout all three visits. Prominent peaks on the turbine tower can be seen at 21, 42, 66, 132, 150, 193, 214, 228, and 449 Hz at 4.3 mms$^{-2}$, 6 mms$^{-2}$, 6.8 mms$^{-2}$, 21.7 mms$^{-2}$, 14.3 mms$^{-2}$, 12.4 mms$^{-2}$, 12.1 mms$^{-2}$, 15.3 mms$^{-2}$, and 9.5 mms$^{-2}$, respectively (Fig. 6). The vibration was smaller on the concrete and soil, with peaks

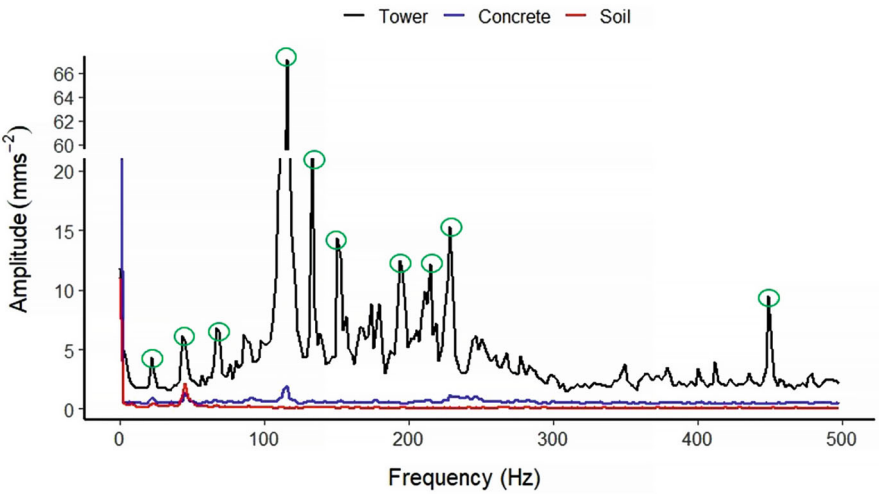

**Fig. 6** Averaged vibration amplitude at the tower (black), concrete (blue), and soil (red) as measured during visit 3. Wind speed varies from 3.6 to 5.0 ms$^{-1}$. Standard error ranged between 3% and 19%, 1% and 22%, and 1% and 23% for the tower, concrete, and soil measurements, respectively, displayed in acceleration units (mms$^{-2}$)

found on the concrete at 42, 114, and 232 Hz, measuring 0.68 mms$^{-2}$, 1.7 mms$^{-2}$, and 1.07 mms$^{-2}$, respectively (Fig. 6). The initial peak seen between 0 and 1 Hz measured at 11.7 mms$^{-2}$, 33.5 mms$^{-2}$, and 11.04 mms$^{-2}$ for the tower, concrete, and soil.

## Visit 4: Control Measurements

During the control measurement, SCADA data were still provided, and wind speeds ranged between 7.5 and 8.0 ms$^{-1}$, therefore within Zone 3 (Fig. 1). The rotation speed was at zero due to the turbine being switched off. This is summarized in Table 1.

Recordings during the downtime period show peak frequencies of 100, 200, 300, 400, and 450 Hz at 1.7 mms$^{-2}$, 1.5 mms$^{-2}$, 1.1 mms$^{-2}$, 1.2 mms$^{-2}$, and 0.5 mms$^{-2}$, respectively (Fig. 7). The initial peak between 0 and 1 Hz measured at 4.4 mms$^{-2}$.

## Comparison with Invertebrate Sensitivities

There is some overlap between the sensitivity for *A. officinalis* and the vibration amplitudes measured on the turbine tower and on the concrete base of the tower, while overlaps for *P. bernhardus* sensitivity appear only for measurements made on the turbine tower (Fig. 8). For *M. edulis* sensitivity, there appears to be no overlap

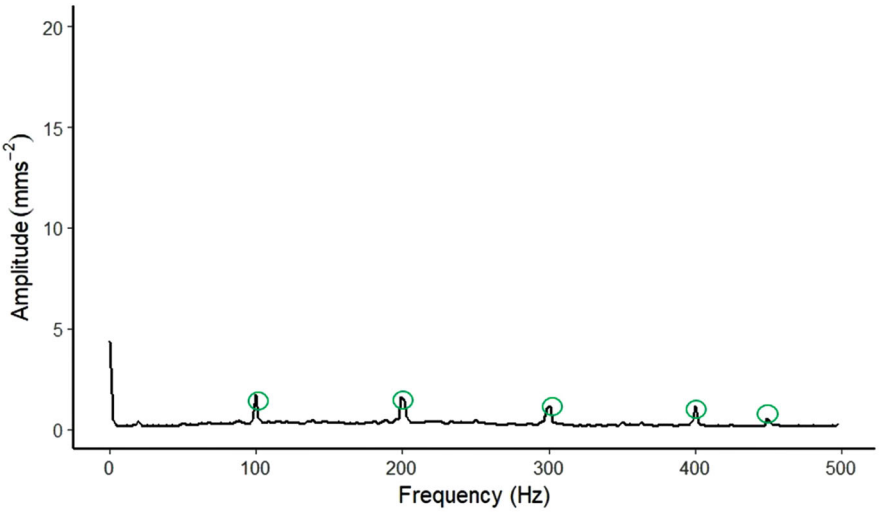

**Fig. 7** Averaged vibration amplitudes measured on the turbine tower during downtime (control measurement). Wind speed was measured at 7.8 ms$^{-1}$ and the standard error was between 3% and 41% of the mean. Green circles indicate peaks at 100, 200, 300, 400, and 450 Hz, displayed in acceleration units (mms$^{-2}$)

with the majority of the measured vibration amplitudes. Three outliers in surface vibration were recorded exceeding the threshold sensitivity of *M. edulis*. These were measured on the turbine tower at 114 Hz (78 mms$^{-2}$), 179 Hz (60 mms$^{-2}$), and 228 Hz (62 mms$^{-2}$), respectively (Fig. 8).

## Discussion

### Turbine Vibration Characteristics

Turbine vibration decreased with distance, with the highest vibration recorded at the turbine tower (maximum value 91.3 mms$^{-2}$ at 114 Hz) and the smallest measured in the soil (maximum value 2.1 mms$^{-2}$ at 50 Hz). Measurements in the soil peaked at around 50 Hz, potentially owing to ambient electrical noise picked up by the cables connecting the accelerometer to the amplifier. Overall, the highest tower vibration was recorded when wind speed was relatively low (3.6–5.0 ms$^{-1}$). This may be related to the turbine variables, such as tower oscillation, which were higher at the lower wind speeds. For example, the highest tower vibration of 67.1 mms$^{-2}$ was measured on visit 3, at a wind speed of 3.6–5 ms$^{-1}$ and a tower oscillation of 4.5–5.6 mG in the x-axis, 1.9–2.2 mG in the y-axis (Table 1). The higher x oscillation (back and forth motions) measured on the tower may be the cause of the increase in turbine vibration, due to the flexibility of the tower and the motion of the blades causing blade or tower vibrations (Staino and Basu 2015). At lower wind

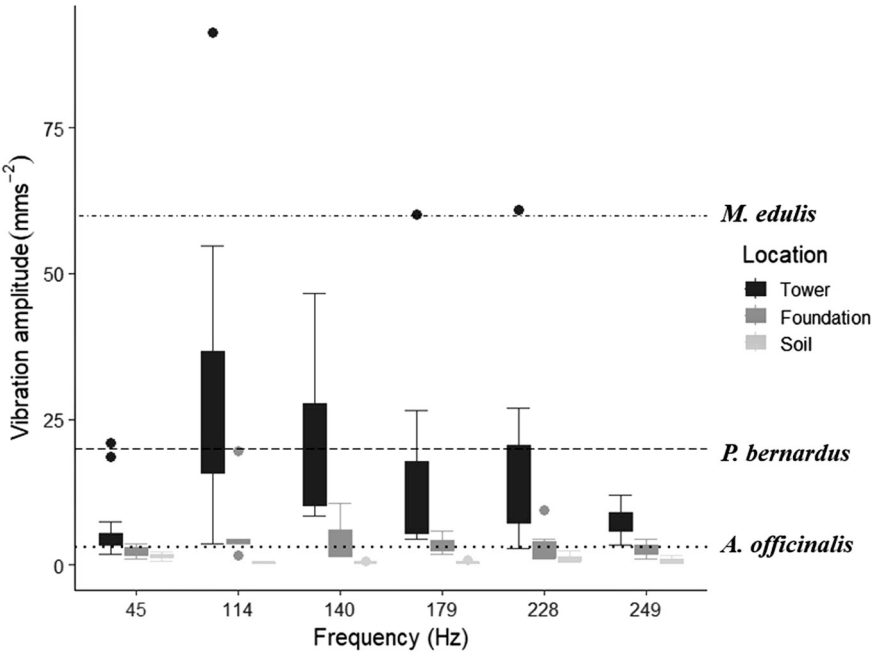

**Fig. 8** Dominant frequencies and associated vibration at the turbine tower (black), on the concrete (dark gray), and in the soil (light gray). Lines indicate sensitivities of invertebrates at 3.1 mms$^{-2}$ for the pill woodlouse *Armadillo officinalis,* 20 mms$^{-2}$ for the hermit crab *Pagurus bernhardus*, and 60 mms$^{-2}$ for the mussel *Mytilus edulis.*

speeds, the blades are fully pitched into the wind (Petrović et al. 2012). Therefore, vibrations may be higher as the turbine attempts to enhance energy capture. Tower oscillation was similarly strong during the second visit, where wind speeds ranged from 3.4 to 5 ms$^{-1}$ (Table 1) and oscillations were recorded in the ranges between 1.4 and 5.9 mG in the x- and y-axis. Peak vibration amplitudes differed with their frequency ranges on visit 1 (138 Hz) when wind speed was highest (8–8.2 ms$^{-1}$) compared to visits 2 and 3 (114 Hz), when wind speed was lower (3.4–5.4 ms$^{-1}$) (Figs. 5 and 6). Guo et al. (2017) studied the effects of gearbox fault signals, as they are particularly difficult to detect. Using their proposed methodology, it was suggested that a frequency change from 130 to 114 Hz corresponded to a faulty gearbox (Guo et al. 2017). However, there were no faults detected or noted on the days of measurements. The higher vibration found at lower wind speeds was similar to that found by Sigray and Andersson (2011) but differed from the findings of Escaler and Mebarki (2018), where a turbine of similar size showed an increase of vibration at higher wind speeds. However, Escaler and Mebarki (2018) measured the mechanical equipment within the nacelle, such as on the gearbox and generator, rather than on the tower itself. Sigray and Andersson (2011) noted that a new gearbox had been installed prior to their measurements, which may be the reason for lower vibration recordings at higher wind speeds than in other studies.

Between 0 and 1 Hz, amplitude peaks measured in this study appear to be higher when wind speed was faster because the turbine structure can create vortices on both sides of the tower when a flow passes around the structure (Viré et al. 2020). This vortex shedding creates pressure differences between wind facing and the opposite side and leads to movements of the tower (oscillations) (Viré et al. 2020). Oscillations at this frequency were higher when wind speeds were lower. The vortices may produce the same frequency as the natural frequency of the tower, leading to resonance and a larger vibration (Miceli 2020). This can be calculated using $f = St\ x\ U/D$, where St is the Strouhal number (0.2), U is the wind speed, and D is the diameter of the turbine. For example, at lower wind speeds (3.4–5.4 $ms^{-1}$) during visit 2, the vortex shedding frequency can be calculated as 0.22 Hz, within the region of the frequency peak found at the lower frequencies (Fig. 5). At the higher wind speeds of 8–8.2 $ms^{-1}$, the vortex shedding frequency can be calculated as 0.4 Hz, which can also be seen as a peak within Fig. 4. Similarly, Sigray and Andersson (2011) found that environmental variables such as waves appeared to dominate the spectrum below 4 Hz, with noisier signals occurring when waves were stronger. While there appears to be a positive correlation between wind speed and rotor speed (Fig. 3), wind speed and vibration show a negative correlation. The vibration of the turbine may be more closely related to the turbine attempting to maximize energy capture, with vibration dampening methods (such as blade pitch) coming in after energy capture is more stable at higher wind speeds. Offshore, the turbines are considerably larger, with rotor diameters reaching 222 meters (Siemens Gamesa Renewable Energy 2023), compared to 83 meters in this study.

## Sensitivity of Invertebrates to Turbine Vibration

The highest amplitude peaks were recorded at the tower, with absolute minimum and maximum values falling between 1.91 $mms^{-2}$ (50 Hz) and 91.3 $mms^{-2}$ (114 Hz). While 90% of the data fell under 54 $mms^{-2}$, below the perception threshold of the blue mussel, *M. edulis* (60 $mms^{-2}$) (Roberts et al. 2015), a few data points were within this sensitivity range. The data measured at the tower did overlap with the threshold of hermit crabs, *P. bernhardus* (20 $mms^{-2}$) (Roberts et al. 2016), and the woodlouse, *A. officinalis* (3.1 $mms^{-2}$) (Cividini and Montesanto 2018) (Fig. 8). However, tower vibration is not relevant for these species that would be found on or within the sediment surrounding the turbine rather than at the turbine tower. At the foundation, measurements were in the sensitivity threshold of *A. officinalis* (Cividini et al. 2020). It is expected that these values on the concrete would be undetectable by *M. edulis* and *P. bernhardus* due to being below threshold sensitivity values (Roberts et al. 2015, 2016). Measurements in the soil were lower than the sensitivity thresholds for all three species, and therefore it can be assumed that these would be undetectable by all three species. It is important to consider that these measurements were made on a smaller turbine than what is currently offshore, where a hub height of 83 m as in this study may have less structural loads and vibration than that of a 220 m offshore turbine. Therefore, vibrations on modern turbines may be larger and

overlap with the sensitivities of all three example invertebrates. This is supported in literature; larger turbines are often more flexible, leading to increased challenges such as greater vibrations from the blades and the tower (Staino and Basu 2015). However, submergence of the turbines in the water, due to the fluid's higher inertia, may dampen the vibration. This may explain why Sigray and Andersson (2011) recorded lower particle motion recordings (maximum value at 20 $mms^{-2}$), when measuring at a 1 m distance in the water column Their results have highlighted that turbine-induced water particle motion overlapped with the sensitivity of fish species, whose sensitivities are comparable to that of the invertebrates in this study. For example, a juvenile roach displayed startle responses at 23 $mms^{-2}$ (Karlsen et al. 2004), and a Cyprinid species showed avoidance responses to particle motions as low as 1 $mms^{-2}$ (Sonny et al. 2006).

Any overlapping of turbine vibration with invertebrate threshold sensitivities may lead to behavioral changes. The studies of both *P. bernhardus* and *M. edulis* showed changes in behavior when exposed to substrate vibrations at 20 $mms^{-2}$ and 60 $mms^{-2}$, respectively. For *P. bernhardus*, these behaviors included lifting of the shell from the substrate and antennae flicking (Roberts et al. 2015), while *M. edulis* displayed behaviors such as valve closure. Valve closures in the mussel, even if only partial, require more energy expenditure due to the use of the adductor muscles and a reduction in filter-feeding (Tang and Riisgård 2016). These partial closures are present even at levels below the threshold amplitudes measured by Roberts et al. (2015) as they are undetected in visual observations. Together, the potential underestimation of *M. edulis* sensitivity and the occasionally elevated levels of tower vibrations, indicate that blue mussels attached to offshore turbine towers may at least temporarily be exposed to conditions of high stress. Their permanence at these extreme locations indicates that they appear to be able to cope with these conditions. Spiga et al. (2016) suggested that mussels increased their filtration rate when exposed to simulated impulsive pile driving sound, while Wale et al. (2019) found that mussels decreased their filtration rate when exposed to continuous ship noise. This change in filtration rate may be due to an increase in metabolic rate (Spiga et al. 2016), which is also seen during other types of stressors such as in lead-polluted waters (Pessatti et al. 2002). Other studies suggest that mussels respond to the onset of pulse trains, but little response was seen in sequential pulse trains (Hubert et al. 2022), suggesting sensory adaptation or habituation. This variability in responses to anthropogenic sounds highlights the importance of further work on both species and sound types. While an antennae flicking response for *P. bernhardus* may not have a direct response on the individual and the local population, it may lead to the animal becoming distracted and therefore reducing fitness (distracted prey hypothesis) (Chan et al. 2010). This has been documented in terrestrial hermit crabs, whereby *Coenobita clypeatus* were exposed to boat noise (sound pressure) and simulated predators could get closer to the crab than those that were not exposed to noise (Chan et al. 2010). The terrestrial pill woodlouse (*A. officinalis*) is more sensitive, displaying a change in behavior, such as alternating turns (Cividini and Montesanto 2018), and an avoidance response to the stimuli when exposed to substrate vibrations at 3.1 $mms^{-2}$ (as recorded in the concrete measurements) (Cividini et al. 2020).

While predation change may not relate to the mussels who are sessile and attached to the turbine towers, more mobile invertebrates such as other crustaceans may also show sensitivity to turbine vibration, and therefore a potential reduction in their anti-predator response, such as that seen in the distracted prey hypothesis (Chan et al. 2010), potentially leading to population-level changes in the longer-term.

While the threshold sensitivities overlap with measurements made at the turbine; tower vibration is only relevant to *M. edulis*, given their attachments to offshore turbine towers. For *P. bernardus* and *A. officnalis*, measurements made on the concrete and the soil would be most relevant. While *A. officinalis* is not found offshore, this species highlights the variability in invertebrate sensitivities (20 times more sensitive than *M. edulis*). Even within marine species, *M. edulis* has a sensitivity three times lower than *P. bernhardus*, meaning other invertebrates offshore may be more or less sensitive to offshore vibrations. Velilla et al. (2021) suggested there was a positive correlation with turbine vibration levels and proximity to the turbine, similar to the findings in this study. They also suggested that onshore turbine vibration reduced earthworm abundance, decreasing with proximity to the turbine and increasing vibration levels. Threshold values do not currently exist for the earthworm; however, there is existing research surrounding other polychaete responses to vibration, such as that of artificial grunting using seismic vibrations below 500 Hz (Catania 2008; Mitra et al. 2009), and bird foot vibrations to hunt for polychaete prey through observations (Pienkowski 1983). Based on the low vibration measured in the soil during this study, it is unlikely that turbine vibrations are strong enough to result in population-level changes as suggested by Velilla et al. (2021). Vibrations in the soil were too low to be detected by even the most sensitive invertebrate, *A. officinalis*, studied so far (Cividini et al. 2020).

The variation in invertebrate sensitivities seen here from 3.1 to 60 $mms^{-2}$ demonstrates the complexity when considering the effects of vibration on invertebrate species. While this study suggests that there may be behavioral changes in two of the three invertebrate species, greater level changes may be seen in other species. The wide range of threshold sensitivities, between the species used in this study, highlights the difficulty in concluding how turbine vibration may impact other marine invertebrates. Offshore, other stressors will excite a turbine more than onshore, for example, waves and stronger winds. Wind speed increases with height, therefore, the larger offshore turbines will experience greater loads and vibration, likely in the lower frequencies (vortex shedding frequency) (Rueda-bayona et al. 2023). These environmental variables further add to the difficulty of measuring vibration impacts on marine species offshore. The offshore wind industry is now looking to utilize deeper waters, moving from fixed bottom structures, such as the one used in this study, to floating structures. These novel turbines will introduce new vibratory characteristics into the marine environment, mostly owing to the mooring systems (Feng et al. 2023), which also require research and understanding (Zhang and Høeg 2018). The current study highlights what kind of measurements are needed on offshore wind farms to draw any conclusions about the ecological impact on the communities associated with windfarms.

## Conclusion

The results from this study show that substrate vibration levels on the turbine, concrete, and soil from a 2 MW turbine are unlikely to influence the three invertebrates based on their sensitivity threshold values, apart from a few outliers. The outliers on the turbine tower did overlap with the sensitivity of *M. edulis,* which is particularly relevant given their attachment to the towers. Vibration in the soil at a 10 m distance was below all threshold values and it is expected that the seismic vibrations traveling through the soil are unlikely to affect species living on or within the sediment. Substrate properties at offshore turbines need further consideration, as well as more information on threshold values of other marine invertebrate species, given the high variability in sensitivity values used in this study. This study is a start to understanding how marine invertebrates may be impacted by wind turbine developments and their associated substrate vibrations. Further cumulative and longer-term understandings are required to fully assess the impacts.

**Acknowledgments** We would like to thank Frank Thomsen for their comments and suggestions on the manuscript. Further thanks extend to Ethan Clark for their assistance during fieldwork.

**Abstract**

Sound-generating human activities have considerably increased ambient noise levels in marine and freshwater ecosystems across the globe. Anthropogenic, human-made noise is an issue of international concern and rising in ambient sound levels may have negative consequences on aquatic animals at the individual and community level. Anthropogenic noise can negatively affect the behavior of aquatic animals in several ways. While some studies have addressed the effects of noise on fish species, there are considerable gaps in our understanding of the effects of noise more widely, especially on invertebrates. Our interest lies in the effect of noise on the "lower levels of food web members," i.e., small crustaceans such as the red cherry shrimp (*Neocaridina davidi*), as model for the link between

trophic levels. The red cherry shrimp is a gregarious species, abundant in freshwater habitats, and native to Asia. The red cherry shrimp has economic importance in the ornamental trade and ecological threat as a potential invasive species; however, its behavioral performance in response to anthropogenic noise is unknown. This chapter details the effect of sound exposure on shrimp under laboratory conditions. The findings revealed that noise impact assessments on invertebrates are critically important for understanding how anthropogenic noise alters food webs and reverberates through communities.

## Introduction

Sound is an important cue for many terrestrial and aquatic animals that can provide crucial information about their habitats. Underwater sound with low attenuation over large distances has quite high propagation rates and allows long-range transmission of information in the aquatic environment (Rogers and Cox 1988; Bass and Clark 2003). Sound travels almost five times faster in water than in air; therefore, it can be a useful and effective tool to transfer information in the aquatic environment (Slabbekoorn et al. 2010). Therefore, soundscapes play vital roles in the environment for transferring intricate biological signals and conveying specific information to aquatic animals for communications within and across taxa (i.e., fish, invertebrates, and marine mammals) (Ladich 2013; Putland et al. 2019; Tyack 1998). Anthropogenic activity in aquatic habitats has increased, causing environmental pollution across different modalities such as anthropogenic noise, ocean acidification, and chemical pollution, which in turn elevate ambient noise levels and enhance low-frequency sound propagation as the ocean becomes more acidic (Hildebrand 2009; Brewer and Hester 2009).

## Anthropogenic Noise Is Ubiquitous in Aquatic Habitats Worldwide

Anthropogenic activities are frequently linked to acute and chronic detrimental changes of the sensory environment in terrestrial and aquatic habitats (Swaddle et al. 2015; Wilson et al. 2020). Aquatic environments have been increasingly exploited and are exposed to anthropogenic noise-generating human activities (Slabbekoorn et al. 2010; Radford et al. 2014). Industrial developments and commercial human activities have become more frequent and have increased ambient sound levels in aquatic ecosystems, which in turn may expose aquatic organisms to a wide range of physiological and behavioral impacts (Hawkins et al. 2015; Duarte et al. 2021). Globally, anthropogenic noise sources are diverse, each with specific temporal noise features and acoustic components. Low-frequency sound pressure propagates over long distances with little

energy loss (Caruthers 1977). Although, anthropogenic noise sources have been previously examined in the scientific literature (Hawkins et al. 2008; Hawkins and Popper 2014; Popper and Hawkins 2016), there are massive information gaps in our bioacoustics knowledge, particularly on the mechanisms and impacts of anthropogenic noise on aquatic organisms across taxa (Popper and Hastings 2009; Hawkins et al. 2015). Anthropogenic noise outputs can potentially interfere with environmental information processing and resource exploitation of many aquatic organisms, therefore disrupting sensory processes and the utility of acoustic information for aquatic vertebrates and invertebrates (Popper and Hastings 2009; Slabbekoorn et al. 2010). Aquatic animals exploit sounds in the environment for many purposes. They can use sound to display courtship behavior and attract mates, detect prey, and avoid predators, all necessary adaptations that are strongly correlated with growth, reproductive success, and survival (Slabbekoorn et al. 2010). Behavioral observations can provide information on the impact of anthropogenic noise on aquatic animals. Behavioral activities such as swimming performance, movement, and spatial displacement, alongside other behavioral changes in response to noise, are research priorities for anthropogenic noise effects on fish and invertebrates (Popper et al. 2022a).

## The Importance of Aquatic Invertebrates in Food Webs

"Invertebrates" represent almost more than 95% of extant animals with enormous morpho-functional and ecological diversity within each phylum and more than 30 phyla in total (Brusca et al. 2022). They occupy all known niches in marine, freshwater, and terrestrial habitats, with a mass of ecological adaptations. However, little is known or understood about their adaptive responses to changes in ambient, anthropogenic noise (Schierwater and De Salle 2021; Brusca et al. 2022). In addition to their vast biodiversity (e.g., number of species, number of taxa), invertebrates have complex life cycles that, for many species, include agonistic interactions, courtship and mating, brooding (maternal care), larval, postlarval stages, and complex patterns of metamorphosis that could be vulnerable to anthropogenic activities such as man-made noises (Wale et al. 2021 and references therein). The large diversity of invertebrates also implies differences in the role of each species within aquatic marine, brackish, or freshwater food webs, and thus, noise impacts on some species may affect the integrity of ecological interactions within these systems (Elliott et al. 2007; Compson et al. 2019). In addition to this, many species live within a benthic habitat, either as adults and/or as larvae, and benthic invertebrates are particularly recognized to play a key role in sediment dynamics as "ecosystem engineers," but they may be particularly vulnerable to low-frequency noise (Popper et al. 2022b; Wang et al. 2022). In fact, invertebrates still only represent a small proportion of animals studied within the marine noise literature (Popper et al. 2022a; Wale et al., 2021) despite pioneer studies recognizing invertebrates as vulnerable species for anthropogenic noise (Morley et al. 2014). This highlights the necessity of further laboratory and field studies specifically involving the study of invertebrate responses to noise environments.

## Noise Impacts on Invertebrates

Empirical data, based on behavioral studies, demonstrate an expanding functional role of anthropogenic noise in the lives of aquatic animals among many taxa including fish and marine mammals (Slabbekoorn et al. 2010; Hawkins and Popper 2014). However, most recent behavioral studies explored such impacts and still speculation and anecdotal observations continue to play a dominant role (Myrberg 1997; Popper et al. 2022b). Invertebrates detect kinetic sound energy in the form of particle motion (Popper et al. 2001; Popper and Hawkins 2018; Dinh and Radford 2021), and recent evidence suggests they also respond to vibration stimuli (Roberts et al. 2016; Roberts and Howard, 2022; Roberts and Wickings 2022). Crustaceans, and invertebrates in general, are thought to benefit from mechanoreceptor organs such as the setae cells, hair-like structures that detect particle motion components of sound (Weatherby and Lenz 2000; Popper et al. 2001). Most aquatic invertebrates "hear" using three types of sensory organs including chordotonal organs, internal statocysts systems, and superficial body receptor systems (Breithaupt and Tautz 1988, 1990; Breithaupt 2002). There is also evidence that some crustacean zooplanktons in large swarms can produce sounds (Kühn et al. 2022) and these acoustic signals can be used for intra- and interspecific communication (Slabbekoorn et al. 2010; Simpson et al. 2016). However, relatively little information is known about the effects of anthropogenic noise on the behavior of aquatic invertebrates in marine habitats (Fewtrell and McCauley 2012; Olivier et al. 2022). Recent research has revealed a range of behavioral impacts of noise on marine invertebrates including molluscs (Mooney et al. 2016; Wale et al. 2019; Jones et al. 2021), crabs (Wale et al. 2013; Roberts et al. 2016), and shrimps (Spiga 2016; Ruiz-Ruiz et al. 2019). Despite the huge diversity of freshwater invertebrates, even less empirical information on this issue exists for these taxa. Azarm-Karnagh et al. (2022) demonstrated the capacity of freshwater red cherry shrimp for low-frequency sound detection (400–2000 Hz). In a laboratory-based experiment, the authors observed immediate behavioral changes both in terms of movement activities, spatial distribution, and feeding performance when exposed to acoustic stimuli using an underwater speaker (Fig. 1).

Clear, detailed accounts of experimental setups, including properties of the acoustic environment applied, are important for reproducibility in science and to facilitate enhanced interpretation of behavioral observations and research findings, particularly when contradictory sound-related behavioral responses occur. A previous study on a freshwater zooplankton, the water flea (*Daphnia magna*), used an in-air speaker to broadcast continuous broadband noise (300–1500 Hz) (Shafiei Sabet et al. 2015). Although behavioral changes in response to acoustic stimuli were observed for vertebrate animals (in this case, the zebrafish, *Danio rerio*), no sound-related behavioral changes were observed for water fleas. In another study, in-air speakers were used to ensonify a water flea tank (Shafiei Sabet et al. 2019) with continuous broadband noise (400–2000 Hz); however, no statistically significant behavioral changes were observed for the fleas. Despite this, authors found some evidence (a trend) of sound-related behavioral changes (number of hops), suggesting that water flea can detect acoustic stimuli and respond behaviorally to

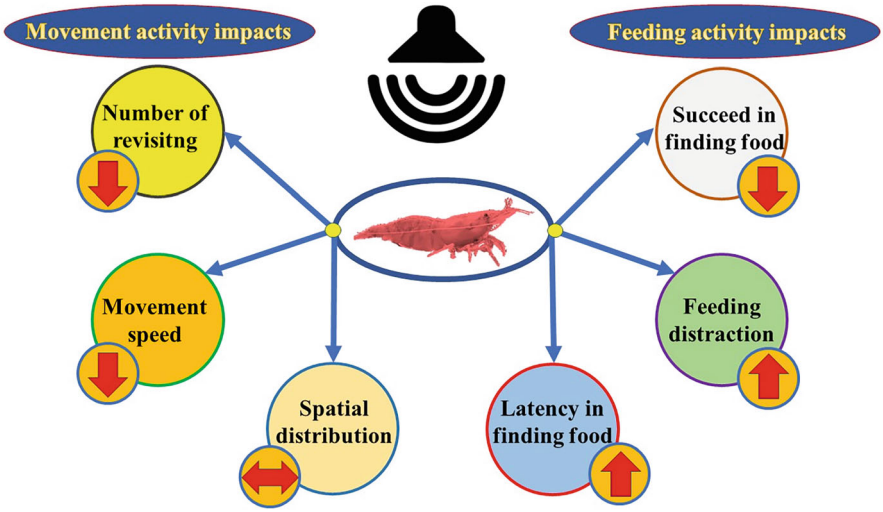

**Fig. 1** Behavioral changes of the freshwater red cherry shrimp in response to an underwater speaker. Behavioral responsiveness of shrimps when exposed to acoustic stimuli was categorized as movement activity impacts (**a**) and feeding activity impacts (**b**). For the movement activity impacts, a clear reduction occurred in the number of food source revisits, a reduction in movement speed, and avoidance of the noisiest area close to the active underwater speaker. For the feeding activity impacts, there was an increased latency to find food and feeding distraction also reduced success in locating food

it. The frequency range of auditory sensitivity for invertebrates varies (Morley et al. 2014), and no data is currently available for water flea. The main conclusion was that sound exposure levels in the experiment were not enough loud to trigger sensory mechano-receptors in the water fleas, or the frequency of sound exposure was beyond their detection range (Shafiei Sabet et al. 2015).

Recent complementary studies have further advanced knowledge on the same genus *Daphnia,* revealing that water fleas are prone to be affected by anthropogenic noise. Prosnier et al. (2022a), using an underwater speaker, found impacts of continuous broadband noise (100–20,000 Hz) on water fleas; reducing mobility and swimming activity under noisy conditions. The observed impacts on swimming speed and hopping behavior found in Shafiei Sabet et al. (2019) and Prosnier et al. (2022a) may indicate that slower individuals save energy in order to prioritize survival-relevant activities. Similarly, a reduction in swimming activity and mobility is also pronounced when water fleas are infected by parasites and potentially may be more visually profitable by predators to detect them easier (Prosnier et al. 2022b). On the other hand, increased swimming activity provides more opportunities for finding food, avoiding predators, and prioritization of their diel migration activities (Larsson and Kleiven 1996; Dodson et al. 1997; O'Keefe et al. 1998; Roozen and Lürling 2001; Chang and Hanazato 2003). A trade-off between mobility and fitness has already been reported for water fleas (Prosnier et al. 2022a). Therefore, these large variations in invertebrate behavioral responses (Wale et al. 2013; Morley et al. 2014)

support the need for further investigations and complementary studies on water fleas and other aquatic invertebrates.

In small tank environments, underwater sound fields can be complex (Campbell et al. 2019). It is important to consider that sound-related behavioral changes may be difficult to extrapolate to determine real-world impacts, both in terms of behavioral validations and acoustical complexity (see Fig. 2) from laboratory-based experiments. This may be further compounded by factors such as differences in air or underwater speakers, sound sources, sound-level variation in sampling techniques, and other method-related limitations (Fewtrell and McCauley 2012).

All fish species can detect particle motion, and some have special structures to also perceive sound pressure in their habitats. It is most likely that all sound-detecting invertebrates acquire acoustic information through the detection of particle motion and/or substrate vibration (Nedelec et al. 2016; Popper and Hawkins 2018). There is evidence that marine invertebrates, in taxa other than crustaceans, also exploit environmental soundscapes to disperse in search of suitable habitats, e.g., the Australian flat oyster (*Ostrea angasi*) (Williams et al. 2022) and coral larvae (Lecchini et al. 2018). We suggest that findings of behavioral changes in response to sound in freshwater red cherry shrimp of the present study are due to particle motion components of the acoustic stimuli used. The implication is that aquatic animals who fail to perceive and detect important acoustic information about their environment, because of distraction or the masking of relevant biological acoustic cues, may experience significant impacts to their overall performance, biological activities, and their ultimate survival (Slabbekoorn et al. 2018; Carroll et al. 2017).

## Gaps in Noise Impacts on Invertebrates: The Need to Consider Particle Motion and Vibration

All fish can detect particle motion using their inner ear and some species that have air filled cavities (e.g., swim bladders) (Slabbekoorn et al. 2010; Popper and Fay 2011). They are also able to perceive sound pressure levels. There is growing evidence in the literature that invertebrates detect sound and response to sound (Wale et al. 2013; Spiga 2016; Hill et al. 2019). In comparison to fish, invertebrates are more likely to be able to perceive low frequencies and particle motion components, and recent

**Fig. 2** Soundscapes of the experimental setup. Rectangular tank visualization (frontal view) for frequencies between 400 Hz and 2000 Hz ensonified by an underwater speaker placed on the right side in the tank. Numbers in colored squares show sound pressure levels (SPL, dB re 1 μPa). The higher SPLs, indicated by stronger color densities, occur close to the active speaker. Measurements were conducted in the center of each square

studies have revealed that they can also detect sediment vibrations and respond accordingly to these stimuli. However, details regarding their sensitivity to particle motion or vibration, as well as the importance and consequences of their responses, are not well known (Roberts and Elliott 2017; Roberts and Wickings 2022). With progress in technology and the development of new sensory detection devices, the measurement of particle motion sound components and substrate surface vibrations is becoming more achievable. Such advances in technology and computer processing can shed further light on mechanisms that influence invertebrate behavioral change in response to acoustic stimuli (Hill et al. 2019).

Vibration sensitivity has been tested in a wide range of invertebrate species across many taxa (Budelmann 1992), as well as some vertebrates, such as bottom-dwelling fish species (e.g., flatfishes) (Berghahan et al. 1995). Despite this, research relating to the potential effects of vibrational noise is sparse and only a few recent studies have explored the effect of sediment vibration stimuli on behavioral responses of aquatic organisms, especially invertebrates. In a recent review, it was highlighted that less than 25 species, representing different taxa, have been tested across environments and these are primarily bivalves and crustacean species (Roberts and Howard 2022). The behavioral observations of red cherry shrimp suggest they avoid or escape from noisy areas in response to acoustic stimuli, and spend less time close to the active speaker with the noisiest sound environment (Azarm-Karnagh et al. 2022). They also exhibited feeding problems in the noisy area; experiencing more failures to find food sources, making fewer revisits to the food source, and displaying greater distraction in noisy conditions.

We suggest that by providing controlled settings that limit confounding factors within experimental design, laboratory-based research is still essential for exploring and answering fundamental research questions around behavioral changes and activity patterns in response to anthropogenic noise (Slabbekoorn 2016). One challenge in laboratory-based research on this topic is the ongoing debate over the validity of measuring acoustic fields within artificial environments. Fish tanks are acoustically complex as tank walls act as a secondary noise source and distort natural sound propagation patterns (Parvulescu 1967; Van den Berg and Schuijf 1985; Akamatsu et al. 2002; Gray et al. 2016; Rogers et al. 2016; Shafiei Sabet and Alizadeh Lademakhi 2022). Therefore, to ensure behavioral relevance, validity, and acoustically relevant results, it is necessary to also conduct field experiments that assess the most relevant and perceivable sound components when conducting behavioral experiments on invertebrates.

Currently, well-replicated experiments have shown two invertebrate species from different taxa, blue mussels (*Mytilus edulis*), and hermit crabs (*Pagurus bernhardus*) that are sensitive to sediment vibrations and will change their behavior in response, by, respectively, closing their shells and changing their movements after exposure to substrate-borne vibrations (Roberts et al. 2015, 2016). Vibration sources (i.e., wind turbine structures) are not only limited to the ground and substrate-borne vibrations at the sediment level of habitats (Popper et al. 2022b), but even sounds produced during seismic surveys may indirectly translate into the substrate in the aquatic environment (Hawkins et al. 2021). Auditory stimuli and acoustic perceptions play

vital roles for many aquatic species, depending on their adaptive abilities to perceive and process those acoustic signals in their daily life. Unlike sound pressure, particle motion conveys substantial information about the sound and its traveling direction (Popper et al. 2022a, b). Therefore, it has been suggested that hearing sensitivity studies for a range of animal taxa should incorporate, not only sound pressure, but also particle motion and substrate acoustical vibration (Popper et al. 2022b). Such studies do exist for marine invertebrates, but comparatively little is known about freshwater invertebrates.

We also call for the need to study more complex responses and behaviors that are directly involved for reproductive successful and survival (e.g., courtship and mating interactions, brooding and maternal care, burrowing, and other activities as ecological bioengineers). It is also necessary to prioritize the exploration of noise impacts on behavior at early life stages and during periods of large morphological and physiological changes in invertebrates (i.e., larval and postlarval swimming and feeding behavior, metamorphosis, and settlement-stage). Finally, it is important to emphasize the need for more study of invertebrate taxa and food webs as integrative units, both under environmentally controlled laboratory conditions and under real field conditions, in order to fully understand the impacts of underwater anthropogenic noise on invertebrates, at both the individual and community level (Shafiei Sabet et al. 2016).

## Conclusion

In a recent study, the anthropogenic noise effects on a freshwater red cherry shrimp in captivity. Although some behavioral changes (avoidance of noise sources and increased feeding disturbance) in response to acoustic stimulus were identified, we speculate that those changes are related to particle motion components of acoustic stimuli and potentially also vibrational noise at the substratum of the fish tank. Assessment of sound pressure, particle motion, and substrate-borne vibration on this species, simultaneously, are suggested in terms of research priority to quantifying acoustic components at the precise location of the animal. In this way, more empirical assessments of both underwater acoustic properties and behavioral response interpretations will be addressed. Careful behavioral observation with validated experimental design, controlled methodological approaches, by taking into account the complex nature of underwater acoustics, and explicit interpretation of invertebrate behavioral changes in response to anthropogenic noise need further research.

**Abstract**

Maternal care in marine decapods encompasses eggs caring until larvae hatching, ensuring healthy embryonic development. The effect of different sound sources (anthropogenic and biologic) and temporal patterns (low and high rate) was studied on the maternal care of the key crab species, *Neohelice granulata*, through laboratory experiments. Three acoustic stimuli were emitted: two anthropogenic, an artificial white noise and motorboat passes obtained from the crabs' natural habitat, and one biologic, signals from a crabs' predator (fish). Behavioral variables quantified included duration of still position and maternal care behaviors. Preliminary findings showed that the high-rate anthropogenic stimuli

increased the still position and diminished maternal care behaviors. The predatory stimulus did not affect the still position, although the high-rate temporal emission pattern reduced the maternal care behaviors. The fact that all stimuli affected the maternal care behaviors indicates a negative effect that potentially could affect offspring survival. This is important to consider given the ecosystem engineering function (e.g., burrowing) of the studied key crab species.

Biologic sound · Anthropogenic sound · Maternal care behavior · Impact · Crustaceans

## Introduction

Maternal care is widespread among many animal taxa. In crustacean marine decapods, maternal behaviors involve the care of the eggs that females carry in their brood compartment until larvae is released (Diesel 1992). This behavior is related to the supply of oxygen to the embryo mass, exhibiting active brooding comportment directed toward their ventilation (Fernández and Brante 2003). Maternal care is a critical factor during embryonic development, given that oxygen limitation was demonstrated to influence survival (Baeza and Fernández 2002).

The sound production in crustaceans has been widely measured. In marine decapods, sound production was demonstrated to be involved in diverse behaviors such as defensive, mating, and agonistic interactions (e.g., Boon et al. 2009; Buscaino et al. 2011; Filiciotto et al. 2019; Flood et al. 2019). It was demonstrated that decapods appear more sensitive to low-frequency acoustic stimuli resulting from the particle motion sound component (Roberts and Elliott 2017). However, a recent study comparing the sound detection abilities among four crab species proposed that crustaceans may have alternative and complex sensory systems involved in sound perception (Radford et al. 2022).

The effect of anthropogenic sound on marine animals typically depends on noise intensity and temporal patterns of exposure (Popper et al. 2014). Particularly in crustaceans, relative few studies have been performed to assess the effect of human noise on their biology, and no previous studies have tested its effect on the maternal care behavior. In contrast, the effect of noise on parental care behavior has been demonstrated in fishes (Picciulin et al. 2010; Nedelec et al. 2017).

*Neohelice granulata* is a varunid semi-terrestrial key crab species inhabiting the intertidal zone of estuaries, salt marshes, and mangroves of the Southwestern Atlantic Ocean (Spivak et al. 2019). In the Mar Chiquita coastal lagoon (Buenos Aires Province, Argentina), a Man and the Biosphere (MAB) Reserve declared by UNESCO, *N. granulata* is a dominant species. The soundscape of the lagoon was previously characterized, describing anthropogenic (motorboat passages) and biologic (fish and crustaceans) sounds (Ceraulo et al. 2020). The sound production in *N. granulata* was reported and linked to the reproductive behavior (Filiciotto et al.

2019; Sal Moyano et al. 2019). The maternal care behaviors in *N. granulata* were previously characterized (Silva et al. 2007). In this context, this chapter aimed to analyze the effect of different sound sources, anthropogenic and biologic, considering two temporal patterns of emission, low and high rate, on the maternal care behaviors of *N. granulata*.

## Methods

Similar-sized ovigerous females ranging from 22.5 to 26.5 millimeters (mm) of carapace width in a late stage of embryonic development were collected manually from the Mar Chiquita coastal lagoon. Individuals were acclimated for 24 h in laboratory in natural seawater under a controlled photoperiod and continuous aeration.

### Acoustic Stimuli

Three acoustic stimuli were used: white noise (bandwidth range of 10 Hz–20 kHz) and two sound stimuli acquired from a previous soundscape study conducted in the natural crab's habitat – biologic sounds produced by a crab's predator fish (fish choruses), the black drum *Pogonias courbina*, and anthropogenic sounds emitted by motorboat passages (Ceraulo et al. 2020). Fish choruses have been tied to increase predation risk (e.g., Hughes et al. 2014). Spectrograms of original stimuli are shown in Fig. 1. Two patterns of emission were considered: low and high rates. In the high-rate pattern, playlists contained 1 min of the sound stimulus +1 min of silence, while in the low-rate one, playlists contained 1 min of the sound stimulus +5 min of silence. Both temporal patterns of sound emission are commonly found in the Mar Chiquita coastal lagoon during the warm season: high-rate motorboat passes on weekend days while low-rate motorboat passes during weekdays and high-rate fish choruses during peak hours (sunset: 19:00–21:00 h) while low-rate fish choruses in the rest of the day (see Ceraulo et al. 2020). Playlists for each stimulus and pattern of emission were constructed by randomly choosing different files. Ten different playlists were created for each stimuli and pattern of emission.

### Experimental System

A circular experimental PVC tank (1.2 m diameter and 1.5 m depth) filled with natural seawater was used. A subaquatic video camera connected to an NVR (network video recorder) was placed on the top and center of the tank. An underwater loudspeaker connected to a power amplifier plugged into the stereo output of a laptop was located suspended 10 cm from the tank lateral wall.

To test the experimental system, a calibrated RESON hydrophone coupled with a preamplifier connected to a digital acquisition card (Avisoft UltraSoundGate 116 h)

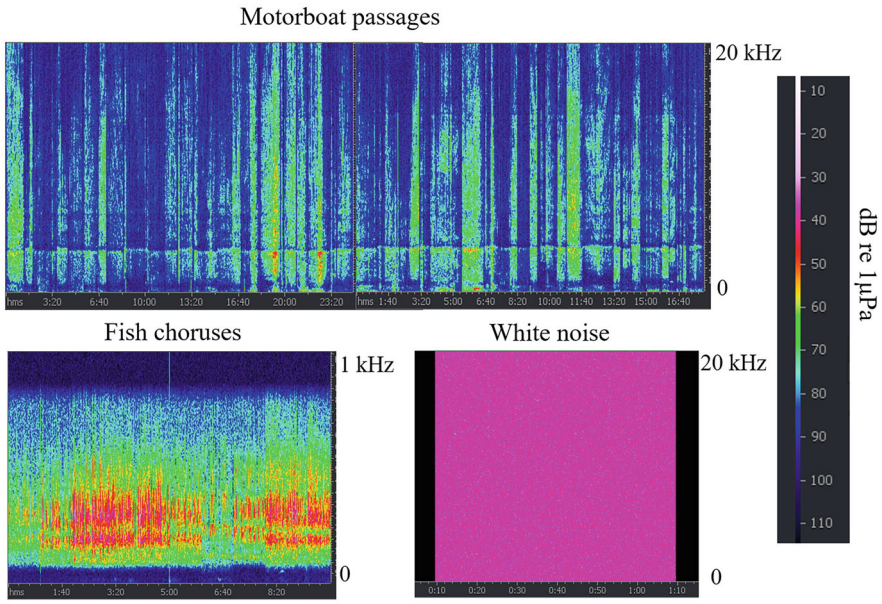

**Fig. 1** Spectrograms of the original stimuli: motorboat passages ($n = 45$ passes), fish choruses ($n = 10$ 1-min files), and the white noise. Ten different playlists were constructed for each stimulus (motorboat and fish) and pattern of emission (low and high rate)

managed by the Avisoft-RECORDER USGH software (Avisoft Bioacoustics) was used. The acoustic stimuli and tank background noise were acquired at the sampling frequency of 100 kHz with 16-bit resolution and analyzed by the Avisoft-SASLab Pro software (Avisoft Bioacoustics). The peak frequencies for emitted motorboat, white noise, and fish stimuli were 3442 Hz (amplitude 130 dB re 1 µPa), 6177 Hz (126 dB re 1 µPa), and 195 Hz (121 dB re 1 µPa), respectively. During the 30 min of sound emission, the sound pressure levels (Lp,rms dB re 1 µPa) changed differently for each stimulus (see Fig. 2). However, over the entire time interval exposition, the Lp,rms were comparable between the playlists with an average of 140 dB re 1 µPa for motorboat playlist, 138 dB re 1 µPa for white noise playlist, and 136 dB re 1 µPa for fish playlist (Fig. 2).

## Experimental Design

A female was located in the center of the PVC tank by using a net, and after a 10 min habituation period, the experiment began. The total experiment duration was 60 min, divided into two phases of 30 min each: the "before phase" without sound exposure and the "test phase" with sound exposure when the different stimuli were emitted. Ten replicates for the control and per treatment (low-rate motorboat, high-rate

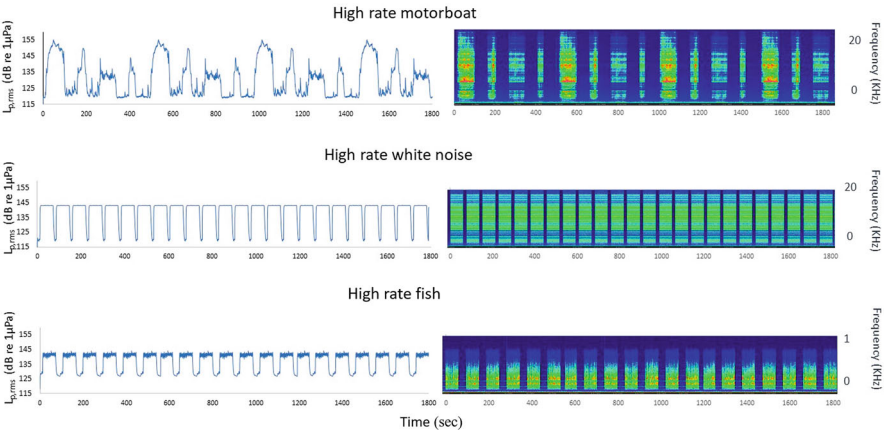

**Fig. 2** (Left) Temporal variation of the sound pressure levels (Lp,rms dB re 1 μPa) during 30 min of exposition. (Right) Spectrograms of an example of a motorboat, white noise, and fish playlist emitted during the sound exposition

motorboat, low-rate white noise, high-rate white noise, low-rate fish, high-rate fish) were performed.

Two maternal care behaviors were recognized: "abdominal flapping," characterized by the abdomen forward and backward movements, beating rhythmically the egg mass, and "chela probing," when females used the chela to pierce the egg mass (Silva et al. 2007). The time in which females were observed still (without walking or moving the pereiopods nor the chelae) for 5 s or longer was also quantified and considered as a "still position." The time duration (in s) of both behavioral variables, still position and maternal care behaviors, was quantified.

## Preliminary Findings

Statistical data analysis is currently in progress. However, preliminary findings indicate that all stimuli, anthropogenic and biologic, affected the maternal care behaviors by diminishing the duration of both flapping and probing, although only the anthropogenic stimuli increased the duration spent in the still position. The high-rate temporal emission pattern of all stimuli had a greater effect on the three behavioral variables quantified compared to the low-rate ones. Figure 3 shows the preliminary findings.

## Remarks

The fact that all stimuli, both anthropogenic and biologic, seemed to diminish the duration of the maternal care behaviors would imply a negative effect on this species that potentially could impair embryonic development. The greater effect of the

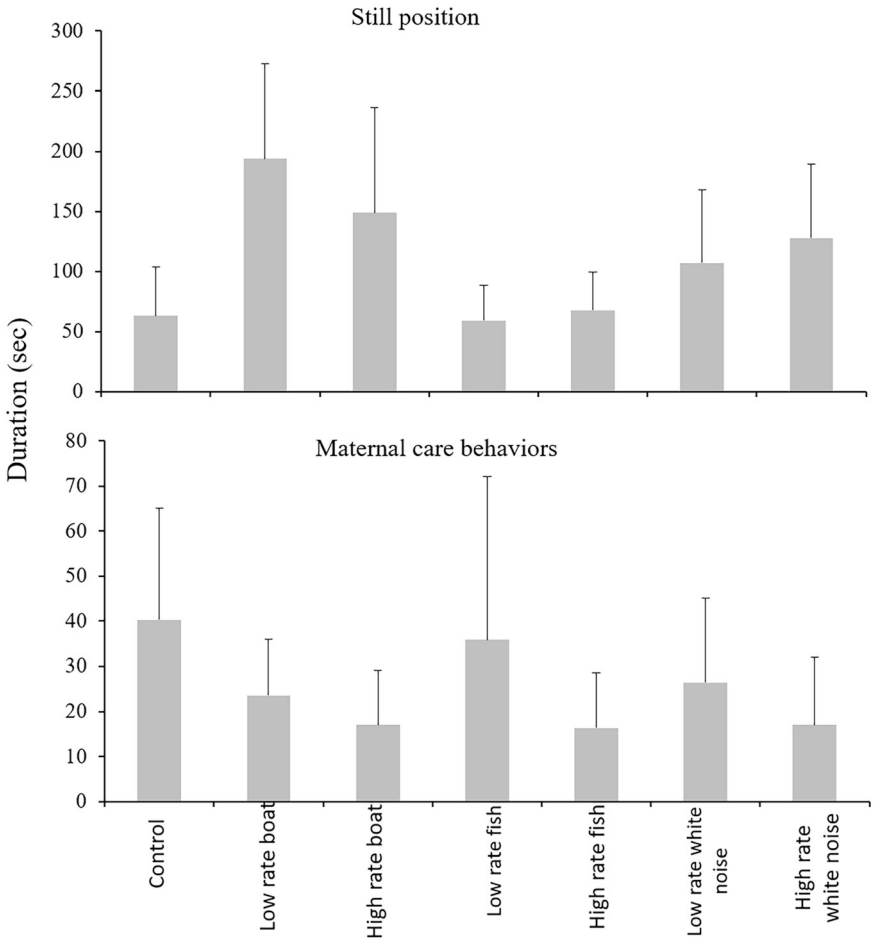

**Fig. 3** Preliminary findings showing the effect of the different stimuli emitted (low- and high-rate motorboat, low- and high-rate fish, low- and high-rate white noise) compared to the control without sound stimulus for the behavioral variables quantified: duration of still position and maternal care behaviors

high-rate temporal emission pattern compared to the low-rate stimuli may suggest that reducing the sound emission in the natural habitat could conform a mitigation strategy to diminish negative sound effects on this species.

The preliminary finding showing that only anthropogenic noise increased the duration of the still position may indicate that crabs distinguish among sound sources and, thus, their response behavior is different. In this sense, the increased duration of the still position could be related to a distraction or confusion effect given that the noise stopped the crab's locomotion. In this sense, a previous study demonstrated

that boat noise distract hermit crabs making them more vulnerable to predation (Yim-Hol Chan et al. 2010).

## Future Studies

The preliminary findings suggest a potential effect of the sound stimuli on the reduced maternal care, likely affecting eggs' oxygen supply and, thus, offspring survival. Negative effects could not cause direct egg mortality but involve a reduced larvae quality, such as a smaller size or less energy reserves, which could impair survival after hatching. In addition, the changeable and vulnerable estuary habitat of the species is characterized by high fluctuations in chemical parameters, such as dissolved oxygen. In this context, the effect of sound may imply a greater threat given that it could add negative effects, impairing embryonic development. Future long-term experiments testing the effect of sound stimuli throughout the embryonic development and assessing direct traits associated with brood survival (e.g., number of hatched larvae) would help to better quantify the effect on offspring fitness.

## Experimental Considerations of the Study

The experiment was conducted in a tank; consequently, conditions such as environmental variables were completely controlled. This is important to highlight given the high variability of the natural habitat of the crab (e.g., dissolved oxygen, salinity; see Luppi et al. 2013), the Mar Chiquita coastal lagoon estuary. However, experiments conducted in tanks can modify the transduction sound properties of the acoustic stimuli, implying differences compared to habitat sound propagation (Akamatsu et al. 2002).

Moreover, a limitation of the study includes the absence of measurements of the particle motion sound component. It was previously described that crustaceans might mainly detect the particle motion component of the sound because of the lacking of gas-filled organs inside the exoskeleton (Popper et al. 2001). In this sense, to obtain results that are more representative of what occurs in nature, future studies should be conducted in nature, or in bigger tanks, and with systems able to characterize also the particle's motion.

## Importance of the Study

This preliminary study is the first study in assessing the effect of different artificial and habitat sound sources, both anthropogenic and biologic, on the maternal care behavior of a crustacean species. In addition, *N. granulata* is a crab key species and an ecosystem engineer because of its burrowing activity that regulates the estuarine ecosystem functioning. In this sense, very few previous studies have focused on the impacts of noise on marine ecosystem services considering how it affects species that mediate ecosystem functioning (Solan et al. 2016). The present study provides important data that can be used in the development of management plans and

sustainable use in the Mar Chiquita coastal lagoon, a MAB UNESCO-declared area that provides important ecosystem services.

**Abstract**

Plants have been considered passive, static, and immutable organisms for a long time, but research shows that plants can perceive their environment and respond to stimuli by modifying their growth and development. Plants communicate with each other and with the world around them. This communication has been explained through the contact between mycorrhizae and volatile organic compounds, but recently, plant acoustic perception and communication have become a new line of research. The sounds produced by plants would contain information with ecological implications, which could be used in the management of crop fields or in the prevention of biodiversity loss. In addition, anthropogenic noise inflicts ultrastructural damage on various tissues of marine plants that could have implications at ecosystems level and in the planet's biodiversity in general. This chapter provides an overview of the plants bioacoustics and aims to underline the need to develop criteria to assess the impact of sound on marine plants. Understanding how the intricate communication networks between the roots supplies vital information for individuals in marine ecosystems, the possible capacity to

## Introduction

Undersea natural soundscapes include sounds from wind, water currents, earthquakes, lightning, rainfall, and marine organisms (Lindseth and Lobel 2018). The relative recent introduction of anthropogenic noise (fishing, oil and gas exploration, shipping, dredging, pile driving, and drilling, sonar, scientific, and recreational activities) is having an enormous impact upon the marine environment (Popper et al. 2020). These sound sources introduce waterborne acoustic stimuli, including vibration within the seabed (e.g., direct contact with the sediment or propagation via the water column) (Roberts and Elliott 2017).

The distinction between sound and vibration in the marine environment is less clear than in terrestrial environment. Commonly, "sound" is used to describe pressure changes that may be detected by a specialized organ (Hill 2008). The particle motion component of an underwater sound may propagate not only via the water column but also through the seabed (Miller et al. 2016). Recent publications in the marine literature have used the term "substrate borne vibration" (Roberts et al. 2016) or "ground vibration" (Hawkins et al. 2021).

Biotremology, the study of the biological use of vibrational waves, is a relatively new discipline (Hill and Wessel 2016). Animals use vibrations for communication (parental care, foraging, detection of environmental cues, recognition, and predator-prey interactions) (Hill 2008; Roberts and Wickings 2022) and detect incidental vibrations for locating prey and avoiding predators, or abiotic vibratory cues such as thunder and tsunamis (1–100 Hz) as demonstrated in elephants (Roberts and Wickings 2022).

Hanlon and Budelmann (1987) define hearing as "*the ability of an animal to sense vibrations (either pressure oscillations or particle displacement) covering a wide frequency range and to integrate this information to produce an appropriate behavioural response*." In the light of this definition, they argue that cephalopods are not deaf because they can detect particle motion. The same idea can be applied to other marine invertebrates and plants. In addition, sound does not need to be "heard" to cause an effect or damage to an organism (Roberts and Elliott 2017). If acoustic or vibratory stimuli cause a behavioral change, perhaps it is more appropriate to say that these invertebrates have an "acoustic [or vibratory] sense" (Roberts and Elliott 2017).

Noise has been shown to negatively affect fishes and invertebrates, in terms of physical damage, physiology, and behavioral changes (André et al. 2011; Casper et al. 2013; Wale et al. 2013, 2019; Hawkins et al. 2014; Solé et al. 2016, 2022; Day et al. 2019). Given the prevalence of seabed vibration-producing activities, such as pile driving, many benthic species are exposed to a variety of stimuli that have the

potential to impact benthic invertebrates in their vicinity. Noise/vibration could also affect aquatic plants, particularly from sources directly contacting the sediment, because their immobility makes them highly susceptible to chronic effects. The information regarding the range of sensory capacities of aquatic plants, sound source types, and propagation conditions in the marine environment is practically inexistent. A review summarizing the current knowledge on sound perception and communication in plants and the possible implications of the introduction of anthropogenic noise in the marine environment is actually lacking. The purpose of this chapter is to provide an outline of this knowledge and to highlight the urgent need for research to assess the impact of sound on marine plants.

## The Senses of Plants

Despite their obvious immobility, plants possess the same senses as higher evolved organisms such as animals, as well as other sensory capabilities unique to plants. Generally speaking, they are able to see, smell, taste, touch, and also perceive sound (Mancuso and Viola 2015). Plants use photoreceptors, molecules that act as light receptors, which are capable of receiving and transmitting information on the direction and quality of light. These photoreceptors distinguish the quality of the wavelength of each color and use this information to regulate the processes of germination, flowering, and growth (Mancuso and Viola 2015). In addition, plants use their entire organism to "smell." From roots to leaves, plants harbor millions of cells that have receptors on their surfaces capable of capturing biogenic volatile organic compounds (VOCs). They use these compounds to gather information about the environment and to communicate with each other as well as with insects. Each compound carries specific information (imminent danger, stress, pollinating insect attraction messages, harmful insect repulsion, etc.) (Bouwmeester and Schuurink 2019). Plants also have receptors for chemicals, to search for food in the soil through the scouting action of roots, in a function analogous to our sense of taste. The roots perceive the slightest variations in the chemical gradients of the mineral salts present in the soil and are capable of detecting nitrates, phosphates, and potassium that are essential for their nutrition, developing a greater number of roots where their concentration is higher. A special case would be that of carnivorous plants that adopted an evolutionary solution to compensate the lack of nitrogen in swampy areas by modifying the shape of their leaves to turn them into traps for reptile, insects, and even small mammals (D'Amato 1998). In plants, the senses of touch and hearing are closely related. They have "mechanical-sensory channels" scattered throughout their body, but especially in the epidermal cells on their surface, which are activated when they pick up a vibration or come into contact with an object. Carnivorous plants show this "tactile" ability by triggering their traps only when the weight comes into contact with them. Other examples would be plants that react to the contact of their pollinating insects, climbing plants or roots that grow around an obstacle on their way to nutrients (Del Stabile et al. 2022). In terms of the sense of "hearing," land plants have at their disposal two sound transmission vectors, air and earth. The soil is an extraordinary conductor where the vibrations are transmitted and captured by the

mechanoreceptor channels of the plants. Like the other senses, in plants, the "ear" is a diffuse organ. Plants perceive the sound vibrations by all the cells of their body. The roots perceive a very high range of sound vibrations that can influence their directional movement (phototropism). In addition, the roots are capable of producing sounds (clicking) (Gagliano et al. 2012) probably due to the rupture of their cell wall during growth. In fact, plants emit sounds through different organs and at different stages of growth or in response to different situations. Plants have been reported to emit low frequency sounds (50–120 Hz) from the xylem (Jung et al. 2018) or ultrasonic vibrations (20–100 kHz) in case of stress (Hassanien et al. 2014; Khait et al. 2018). This ability to emit, although not voluntarily, and perceive sounds led authors to think that there could be an underground communication channel between plants (Gagliano et al. 2012; Del Stabile et al. 2022). For example, root systems behave like a swarm (Ciszak et al. 2012), which would indicate that each individual plant has some communication capacity that allows it to explore the soil effectively.

At this point, it is worth noting the fundamental role played by the plant roots due to their analogous role to the brain in the animal world. Darwin launched this "root-brain hypothesis" in his book "The power of movement in plants": "It is not an exaggeration to say that the tip of the root, thus endowed [with sensitivity] and being able to direct the movement of the adjacent regions, acts like the brain of a lower animal; the brain, located in the front part of the body, receives the impressions of the sensitive organs and directs the different movements" (Darwin 1880). The apex of the root is the zone of the plants that presents more capacities comparable to an intelligent organ: (i) perception ability of environmental stimuli – gravity, temperature, humidity, electric field, light, pressure, chemical gradients, presence of toxic substances (poisons, heavy metals), sound vibrations, and presence or absence of oxygen and carbon dioxide; (ii) decision capacity on the needed movement; and (iii) final movement implementation (Mancuso and Viola 2015). The root apparatus is a physical network in which the roots maintain an anatomical relationship with each other (Baluska et al. 2010). These roots communicate with each other through chemical signals. But these roots could be sensitive to electromagnetic fields (Masi et al. 2009) and sounds that other roots produce when growing (Gagliano et al. 2012). This enormous sensitive capacity of the roots makes them strong candidates to be authentic recipients of the consequences of noise pollution. Research on the effects of noise pollution on plants, specifically on roots, is urgent and necessary. The knowledge, practically nonexistent at the moment, of the consequences of artificial noise in the plant world would help the responsible and respectful management of biodiversity in all Earth's ecosystems.

## Communication in Plants

Like gravity, wind, tidal currents, and rain, sounds include pressure waves that have a mechanical influence on organisms (Telewski 2006). Plants respond to vibrations in a selective way (Gagliano et al. 2012; Appel and Cocroft 2014). Through their senses, plants receive information on their habitat and position themselves in their

environment. To transport information from one part of the body to another, plants use electrical, hydraulic, and chemical signals that are transmitted through their main vascular system (xylem and phloem) that connects the roots to the leaves. But plants can also communicate with each other and with their environment through chemical signals or by "touching" their roots or tops (Mancuso and Viola 2015). Sound and touch have similar physical properties (via mechano-stimulation), but plants seem to distinguish between them in sophisticated ways (Mishra et al. 2016). Trees of the same species form a community and often establish alliances with trees of other species. Trees in forests have evolved to live in cooperative and interdependent relationships, maintained by communication and a collective intelligence. Although the most visible part of the trees are their tops, the real action takes place underground (Wohlleben and Flannery 2016).

Roots are able to communicate with microorganisms, bacteria, fungus, and insects inhabiting soil. For instance, mycorrhizae are symbiotic associations between the root plants and fungi. The fungus supplies the root with minerals that are difficult to obtain, such as phosphorus, and receives in exchange sugars produced by the plant in photosynthesis, which it uses as an energy source. Fungi consume about 30% of the sugar that trees photosynthesize from sunlight. Sugar is what feeds the fungi as they search the soil for nitrogen, phosphorous, and other mineral nutrients, which are then taken up and consumed by the trees (Wohlleben and Flannery 2016). In addition, fungi supply trees with essential amino acids, protective metabolites against cryptogamic predators, other fungi, bacteria, and viruses, as well as special sugars that are stored in the soil for protection against contaminants. These soil sugars are particularly important for marine plants, as they bind metals that could become toxic in ionic form. They also contribute to the marine plant being able to resist salinity.

But not all fungi are beneficial. Plants need to be able to identify pathogenic fungi through chemical signals to avoid harmful symbiosis with them. Harmful fungi colonize tree tissues, digest them, and weaken trees. Some of these fungi feed on heartwood (inner wood), other on sapwood (outer wood), and some on roots. Fungus can destroy strong wood and create spongy or brittle wood. Examples of fungus that could cause root rot are honey fungus (*Armillaria mellea*), oak bracket (*Inonotus dryadeus*), and annosum (*Heterobasidion annosum*), but this process could rather consist of a biotic balance of the immune system, since, for example, these same species can establish symbiotic relationships with ancient trees. Process for recognizing the nature of the fungus consists of a true chemical dialogue between the root and the fungus. If it is a harmful fungus, hostilities will begin. Mycorrhizal fungi release suppressive exudates (antibiotics that inhibit infection by fungal root pathogens). Mycorrhizae also defend root systems by forming a physical barrier made of chitin to deter invasion by soil pathogens. This barrier forms a protective layer protecting root cells (St-Arnaud 2007). If the plant recognizes the fungus as beneficial, it could allow the establishment of ectomycorrhizae (the fungus generates a sleeve around the root of the plant) and even manages to penetrate its cells (endomycorrhizae). The fungal filaments could penetrate the root's cell and can lead to the creation of true hybrid organs in arbuscular endomycorrhizae where DNA sharing and gene exchange occur (Johnson and Gehring 2007).

This symbiotic relationship is essential for both tree and fungus survival. For example, tree decline processes such as that observed for cork oak (*Q. suber*) in Mediterranean forests can modify the mycorrhizal landscape and as a consequence alter the oak seedling establishment, which is a process mediated by the fungus (Ibáñez et al. 2015).

All the trees in the forests are connected to each other through underground networks of fungi. For young trees in shady areas of the forest where they cannot normally photosynthesize, the mesh is a lifesaver. They survive because large trees pump sugar into their roots through the network (Wohlleben and Flannery 2016). Trees share water and nutrients through networks and also use them to communicate. They send out distress signals about drought and disease, for example, or insect attacks, and other trees alter their behavior when they receive these messages. It seems that alarm and distress are the main topic of tree conversations. As said before, some plants emit and detect sounds (e.g., behavioral response of young roots to a continuous 220 Hz sound crackling noise, Gagliano et al. 2012). It is easy to think on mycorrhiza as a channel for efficiently transmitting these sonorous messages between trees, given their close connection with their roots. Future research could try to decipher the sonic conversations between the roots of trees to understand how the cooperative and supportive lifestyle between plant communities is essential for the conservation of biodiversity of the entire ecosystem.

Plants can communicate with animals too. In addition to chemical adaptations, plants also have adapted to different sounds in their environment. Pollination is one of the periods in which the plant depends more on communication with animals. At this time, the plants need vectors that transport the pollen from one flower to the pistil of another flower. Insects use vibrations to extract pollen from flower anthers (buzz pollination). Solanum-type flower has evolved specifically in response to sonicating bees. The bees adjust their duration of their buzzing depending on the pollen content of the flower (De Luca and Vallejo-Marìn 2013). The peak frequency of the buzzing varies between 100 and 400 Hz depending on the species of bee.

Although animals most used as vectors are insects, also birds and bats can serve this function. A special case is the carnivorous plant *Nepenthes hemsleyana*, whose pitchers have evolved to reflect the echolocation of bats. This plant had established a symbiosis with bats; they have a safe, parasite-free roosting spot, and the bats in return fertilize the plant with nitrogen-rich droppings (Schöner et al. 2015). Bats are responsible for transporting the pollen of many of the cacti of the American desert, such as the Joshua tree. Another curious case is the Cuban liana *Marcgravia evenia*, which possesses leaves in the shape of a parabolic antenna with the function of signaling the presence of flowers to the bats' sonar. The echo emitted by the leaf acts as a beacon, providing a strong, multidirectional, and recognizable signal (Simon et al. 2011). The authors of this work hypothesized that it would be necessary to analyze whether flowers pollinated by bats have developed similar acoustic signals in order to attract echolocating pollinators. Bat-pollinated flowers need to attract their pollinators in the dark and some species have developed this specialized echoic flower parts, usually concaves, that act as acoustic retroreflectors, making the flowers acoustically visible to bats. Species-specific echo sequences inform the bats about

flower morphology and show them the best way to get the nectar. This acoustic information provides essential support for efficient foraging. Bat-pollinated flowers have higher echo target strength, independently of their size, and differ in their morphology from species pollinated by insects or birds (Simon et al. 2021).

## The Plant "Ear": Sound Perception

Although various scientific papers highlight the ability of plants to perceive and react to sounds, the mechanism by which these processes occur is largely unknown. Plants have been shown to react to specific sound frequencies (Hou and Li 1997), for example, by building up defenses against the chewing of caterpillars (Appel and Cocroft 2014), the mating sounds of insect larvae, or sweetening their nectar if they sense pollinating insects (De Luca and Vallejo-Marìn 2013; Schöner et al. 2016; Veits et al. 2019). The sound waves make the leaves of the plants vibrate, accelerating the plasmatic movement of their cells (Cai et al. 2015).

Cells respond to external stress by changing a number of factors, including cell division, growth, signal transduction, gene expression, and activation of membrane ion channels (Hamant and Haswell 2017; Sparke and Wünsche 2020). Mechanosensitive ion channels have the ability to open and close as a result of mechanical forces resulting from gravity, osmotic pressure, and sound. The process of sound signaling at cellular level is unknown, but the most accepted idea is that sound vibrations activate the plasma membrane channels, evoking a membrane potential-based signaling cascade, where $Ca^{2+}$ acts as second messenger. Several studies have shown an efflux/influx of $Ca^{2+}$ after sound vibrations exposure. Also at intracellular level, exposure to sound can cause activation of stress-related genes or regulate their transcription, increase the level of soluble sugars and proteins (or change their activity), and influence the reorganization of microtubular structures as well as the amylase activity in the cap root (Sun et al. 1999; Wang et al. 2002a; Qin et al. 2003; Xiujuan et al. 2003; Hongbo et al. 2008; Mishra et al. 2016). Mechanosensory proteins present in the plasma membrane may mediate the transmission and response to mechanical stimulation of sound in plant cells, through their influence on hydrostatic pressure, plasma membrane tension, and thus traffic through it. Changes in these characteristics would cause the alteration of the resonant frequency of the cell. Plasma membrane tension modulates the processes of exocytosis and endocytosis of the cell. An increase in membrane tension stimulates exocytosis and inhibits endocytosis. Decreased membrane tension slows down exocytosis (Del Stabile et al. 2022).

More precisely, the process of sound signaling could be described as below. Sound generates mechanical tension in the membrane and cell wall, activating mechanosensitive ion channels and mechanoreceptor proteins. When ion channels are open, in response to mechanical forces, they allow ions ($Ca^{2+}$ and $K^{+}$) to cross the membrane and cause an ionic current that is translated into an electrical or chemical signal (Alexandersson et al. 2004; Ingber 2006; Mishra et al. 2016). Increase in cytoplasmic $Ca^{2+}$ activate protein kinases that stimulate H+ ATPase pump to generate

electrochemical gradients across the membrane. This process activates the increase of cytoplasmic proteins and provoke changes in the cytoskeleton. In addition, alterations in phytohormones derive on transcription changes within the nucleus and alters chromatin structure (Kim et al. 2021), and consequently the specific proteins and metabolites expression that brings to physiological changes (Mishra et al. 2016).

Different experiences have been described where this ability to perceive sound was used to influence production processes in agriculture and biotechnology. Certain frequencies, especially between 100 and 500 Hz, favor seed germination and plant and root growth, while, when subjected to high frequencies (ultrasounds, 1–3 MHz), an inhibitory effect is observed (Qin et al. 2003; Creath and Schwartz 2004; Cai et al. 2014; Hassanien et al. 2014; Mishra et al. 2016; Vicient 2017). In addition, sound can improve the immune system and the efficiency of light absorption for photosynthesis (Cai et al. 2014; Choi et al. 2017; Kratochvil and Pollirer 2017). Although sound vibrations were suggested to increase yield, quality, and protein content, organogenesis (e.g., 400 Hz and 106 dB increased the germination index, shoot height, and root activity (Wang et al. 2003a; da Silva and Dobranszki 2014; Hassanien et al. 2014) and stimulate the in vitro growth and development in rice (*Oryza sativa*) (Liu et al. 2003b), higher frequencies (70 kHz ultrasound) produced harmful effects, reinforcing the idea that the use of sound vibrations on agriculture has to be very selective and avoid ultrasounds because it causes negative botanical effects (Hassanien et al. 2014). Similarly, increased organogenesis stimulated by sound vibrations has been described in aloe (*Aloe arborescens*, Liu et al. 2003a), gerbera daisy (*Gerbera jamesonii*, Wang et al. 2003b), pumpkin (*Cucurbita pepo*, Ananthakrishnan et al. 2007), and European hazelnut (*Corylus avellana,* Safari et al. 2013), among other species. Treatment with a sound of 1000 Hz at 100 dB promotes the seed germination of *blacksamson* (*Echinacea angustifolia*) (Chuanren et al. 2004). Sound vibrations were used to increase the tomato, lettuce, and spinach number of leaves, flowers, and chlorophyll content (Hassanien et al. 2014). Treatment with sound could reduce the use of fertilizers and increase the immune response against harmful insects and diseases (Hassanien et al. 2014). In addition, these treatments can promote the acceleration of seed germination and organogenesis process by modification of phytohormonal levels (Wang et al. 2003a, 2004; Zhao et al. 2003; Appel and Cocroft 2014).

## Algae and Aquatic Plant Sound Production and Perception

Algae, both macroscopic and microscopic, are photosynthetic organisms that live in the aquatic environment (Brodie and Lewis 2007). The production and perception of sound in algae are almost unexplored processes. However, algae and aquatic plants have been shown to produce sound during photosynthesis (Kratochvil and Pollirer 2017; Freeman et al. 2018). This sound is produced by the release of oxygen bubbles by plant structures. The oxygen bubble assumes a spherical shape creating a monopolar sound source that is distributed by resonance over the seabed. This phenomenon,

where plants produce sounds from 2 to 20 kHz (Freeman et al. 2018), can be used for quantification of algae/aquatic plants in their ecosystem (Kratochvil and Pollirer 2017) and could be the basis for exact acoustic measurements, opening entirely new possibilities for plant physiology. As with terrestrial ecosystems, the identification of sound sources that contribute to underwater biological soundscapes would constitute a noninvasive method, capable of remotely quantifying their ecological status. As previously highlighted, photosynthesis in macroalgae is an acoustically active process, driven by the oxygen bubbles they produce. Soundscapes are correlated with macroalgal cover during light periods. The production rate, the size of the bubbles, and the level of sound are directly related to the dissolved oxygen concentration, which in turn depends on the amount of photosynthetically active radiation. The stress produced by climate change, overfishing, or pollution causes an increase in the macroalgae cover, which serves as an indicator of the degradation of underwater ecosystems. These signal processing methods could quickly and passively assess the relative abundance of algae and consequently the underwater ecological status of the referred habitat (Freeman et al. 2018).

The possibility of using acoustic methods to monitor the in situ response of seagrasses to environmental factors has been proposed too. Photosynthesis effects on sound propagation were assessed in grasslands of *Posidonia oceanica*. Measurements of acoustic response were conducted in situ over an extensive bed of *P. oceanica* through the monitoring of their oxygen synthesis (Hermand et al. 1998). This research showed a strong correlation between photosynthesis and the impulse response of the acoustic waveguide with a marked change of attenuation and time dispersion at the start of the photosynthesis process. During the active photosynthesis phases, sound speeds were lower (due to solved gases adhering to the leaf or running inside the leaf blades, or to gas movement in the rhizome and root systems) than in bubble-free seawater (Hermand 2004).

The plant's ability to perceive and react to sound stimuli has also been used to increase the growth and productivity of aquatic plants. *Chlorella pyrenoidosa* and *Picochlorum oklahomensis* microalgae showed a significant improvement in their growth (biomass productivity and lipid yield) after exposure to sound waves of frequency of 0.4 and 2.2 kHz, respectively (Jiang and Chen 2012; Cai et al. 2016). Furthermore, it was shown that natural sounds increase algal biomass production and that the 2.2 kHz frequency is the predominant component of most sounds found in nature (e.g., the main frequency composition is from 1.5 to 2.0 kHz in most of the wild birds' chirp, from 2.0 to 4.0 kHz in most of the crickets and cicadas' chirp, and from 1.5 to 2.0 kHz in the sound of trickling water and the sound of rain (Cai 2013). Ecological data encoding could be used to induce ecosystems to reproduce and synthesize biotechnologically relevant cellular components (such as triacylglycerol synthesis in *Chlorella pyrenoidosa* microalgae, which suggests the use of acoustic signals to improve biodiesel production (Golub and Levtun 2016)) and to improve the yield rate in different algae species (*Chlorella pyrenoidosa*, Jiang and Chen 2012; *Picochlorum oklahomensis*, Cai et al. 2016; and *Haematococcus pluvialis*, Christwardana and Hadiyanto 2017).

## Noise Effects on Plants

The ability of plants to detect vibrations may represent a very efficient way of finding information from distant sound sources, for example, for orientation towards water. Roots may detect the sounds of water moving through the soil or flowing through channels (Gagliano et al. 2017). Roots of corn seedlings can detect sound waves or vibrations and selectively use them for orientation (Gagliano et al. 2012). Gagliano et al. (2017) showed that *Pisum sativum* roots were able to locate a water source by sensing the vibrations generated by water moving inside pipes and that the presence of noise (computer-generated white noise) affected the abilities of roots to respond correctly to the surrounding soundscape (masking effect).

If investigations addressing water-seeking abilities of roots (Cassab et al. 2013) and the possible noise impact affecting them (Gagliano et al. 2017) or other noise-based affected capacities in terrestrial plants have been extremely limited, research on acoustic impact on aquatic plants has been practically nonexistent. Although considerable scientific attention has been devoted in the last decade to determining the sensitivity of aquatic animals to noise, focusing especially on cetaceans, pinnipeds, and fish (Richardson et al. 1995; Slabbekoorn et al. 2010), and recently in invertebrates (Solé et al. 2016, 2017, 2022; Day et al. 2019; Wale et al. 2019), little attention has been dedicated to assessing how much waterborne artificial noise could affect sessile organisms as plants, whose immobility makes them highly susceptible to chronic effects. Only a recent work has reported morphological and ultrastructural damage on seagrass *Posidonia oceanica* after exposure to sound, which is new to aquatic plants (Solé et al. 2021).

Columella cells, located in the inner, central region of the root cap and characterized by numerous starch-filled plastids (amyloplasts) in the distal part, are involved in gravity sensing (Yoder et al. 2001; Hashiguchi et al. 2013). The amyloplasts are double-lipid membrane cytoplasmic organelles containing DNA and store starch grains inside the membrane compartments (Pozueta-romero 1991) (Fig. 1). The sedimentation of these amyloplasts triggers gravity signal transduction, which is transmitted to the elongation zone, where it promotes differential cell growth, allowing the root to direct itself downward (Hashiguchi et al. 2013). *P. oceanica* also exhibits starch-containing amyloplasts in the cortical cells of the rhizome (Kuo 1978). Amyloplasts are responsible for gravity sensing and signal processing (Hashiguchi et al. 2013), operating like statocysts and play a fundamental role in sound and vibration reception (Gagliano et al. 2012).

Solé et al. (2021) revealed that aquatic plants present acoustic trauma when exposed to noise. Low-frequency sounds (50–400 Hz sinusoidal wave sweeps with 100% duty cycle and a 1-s period, received sound pressure level RL = 157 ± 5 dB re 1 μPa with peak levels up to sound pressure level SPL = 175 dB re 1 μPa) produced alterations on seagrass *P. oceanica* root and rhizome statocysts. Exposed plants showed a decreasing number of starch grains with time when compared with control specimens (Figs. 1 and 2). Some starch grains presented a deformed structure lacking the typical spherical shape (Figs. 1c and 2f). Other amyloplasts had deformed inner organelles and superficial holes (Fig. 2h). Exposure

exposed to sound showed internal degradation (Fig. 3d–f) unlike controls (Fig. 3a–c). The exposed hyphae presented altered intracellular organelles, showing an empty cytoplasm 120 h after exposure to noise.

The damage was acute and immediate, significantly affecting the amyloplasts. The plant gravity perception and correct functioning mediated by these organelles could be altered. In addition, the storage capacity of the rhizome could be decreased due to the low number of amyloplasts.

Different explanation can be hypothesized to explain the loss of the starch grains after sound exposure. An acoustic trauma in the mammalian organ of Corti produce cytoarchitectural organization and actin arrangement alterations (Slepecky et al. 1982). Also in invertebrates, a downregulation of cytoskeletal proteins and microtubular proteins of the statocyst sensory epithelia has been shown after sound exposure (Solé et al. 2019). Actin microfilaments are responsible from organelles positioning in plant cells (Pozueta-romero 1991; Hashiguchi et al. 2013). The vacuolar membrane and actin cytoskeleton are involved in the amyloplast movement. The decrease in the number of starch grains after sound exposure could be explained by the distortion of the anchorage of the starch grains into the vegetal cell, resulting from changes in actin arrangements.

Sound-induced amyloplast loss could be explained by molecular mechanisms too. Double-bound organelles involved in energy storage production, e.g., mitochondria has been shown to be impacted by noise exposure in animals (Wang et al. 2002b). In *P. oceanica*, amyloplasts, which are surrounded by a double membrane, are in charge of energy storage. In mammal acoustic trauma, mitochondria trigger cell death pathways in auditory hair cells in a process mediated by calcium overload (Vicente-Torres and Schacht 2006) and by an overproduction of mitochondria ROS (reactive oxygen species) (Gonzalez-Gonzalez 2017). In a similar way, *P. oceanica* root and rhizome statocyst lesions could be originated in calcium overburden and increased oxidative stress after sound exposure. A functional interaction between cell-filling vacuoles and adjacent actin microfilaments is fundamental for controlling amyloplast status and movement in shoot statocysts of *Arabidopsis* (Hashiguchi et al. 2013). Vacuolar fragmentation, vacuolar dynamics deficiency, or endoplasmic reticulum disorganization in several types of plant cells, creating myelin-like formations (i.e., a massive accumulation of membranes that disrupt amyloplast dynamics), have been observed after drug treatments (Hashiguchi et al. 2013). The present

results show a similar cell organelle breakdown (Fig. 1i), which could provoke (i) a dysfunction of the normal gravitropism from amyloplast dynamics disruption and (ii) a modification of the rhizome storage function, which is fundamental for seagrass survival.

Sound exposure can be the origin of plastoglobuli detected in amyloplasts of the columella cells. Plastoglobules play a fundamental role in plastid metabolism (they are involved in their biogenesis, redox regulation, senescence, and environmental adaptation) (van Wijk and Kessler 2017). The overproduction of reactive oxygen species (ROS) would cause reactive stress, which in turn would be at the origin of processes associated with plastid biogenesis or repair mechanisms at the cellular level, resulting in the presence of plastoglobuli after sound exposure. Oxidative stress refers to elevated intracellular levels of ROS, which cause damage to lipids, proteins, and DNA.

In a similar way that dark septate endophytes colonize the roots of terrestrial plants, *P. oceanica* roots are known to be colonized by symbiotic melanized septate hyphae (Vohník et al. 2015). These symbiotic hyphae could be involved in the nutrient uptake by *P. oceanica* (Vohník et al. 2019). The degradation of symbiotic root fungi after exposure to sound could alter the nutritional capacity of seagrass

**Countries and areas with recorded seagrass:**

**NORTH AMERICA:** Canada, United States.

**SOUTH AMERICA:** Brazil, Chile, Colombia, Suriname, Venezuela.

**CENTRAL AMERICA AND THE CARIBBEAN:** Anguilla, Antigua and Barbuda, Aruba, Bahamas, Barbados, Belize, Bermuda, British Virgin Islands, Cayman Islands, Costa Rica, Cuba, Dominica, Dominican Republic, Grenada, Guadeloupe, Guatemala, Haiti, Honduras, Jamaica, Mexico, Montserrat, Nicaragua, Panama, Saint Barthelemy, Saint Kitts and Nevis, Saint Lucia, Saint Martin, Saint Vincent and the Grenadines, Trinidad and Tobago, Turks and Caicos Islands, United States Virgin Islands.

**EUROPE:** Albania, Croatia, Cyprus, Denmark, Estonia, Finland, France, Germany, Greece, Greenland, Guernsey, Iceland, Ireland, Isle of Man, Italy, Jersey, Lithuania, Malta, Monaco, Montenegro, Netherlands, Norway, Poland, Portugal, Romania, Slovenia, Spain, Sweden, Ukraine, United Kingdom.

**AFRICA:** Algeria, Angola, Benin, Comoros, Egypt, Eritrea, French Southern and Antarctic Lands, Ghana, Guinea, Guinea-Bissau, Kenya, Libya, Madagascar, Mauritania, Mauritius, Mayotte, Morocco, Mozambique, Nigeria, Reunion, Sao Tome and Principe, Senegal, Seychelles, Sierra Leone, Somalia, South Africa, Sudan, Togo, Tunisia, Tanzania.

**ASIA:** Azerbaijan, Bahrain, Bangladesh, Burma, British Indian Ocean Territory, Cambodia, China, Christmas Island, Cocos Islands, Honk Kong, India, Indonesia, Iran, Iraq, Israel, Japan, Jordan, Kazakhstan, Kuwait, Lebanon, Malaysia, Maldives, North Korea, Oman, Palau, Papua New Guinea, Philippines, Qatar, Russia, Saudi Arabia, Singapore, South Korea, Sri Lanka, Syria, Taiwan, Thailand, Turkey, Turkmenistan, United Arab Emirates, Viet Nam, Yemen.

**OCEANIA:** American Samoa, Australia, Fiji, French Polynesia, Guam, Kiribati, Marshall Islands, Martinique, Micronesia, New Caledonia, New Zealand, Norfolk Island, Northern Mariana Islands, Samoa, Solomon Islands, Timor Leste, Tonga, Vanuatu.

meadows in addition to impairing their ability to root due to the alteration of the plants' perception of gravity.

Noise exposure not only affected *Posidonia* health status and the plant's capacity to root itself, but also affected the plant's correct nutritional processes by decreasing the number of rhizome starch grains that store energy, as well as by degrading the specific fungal symbionts of *P. oceanica* roots and consequently altering the seagrass metabolism. Seagrass meadows considered an oceanic equivalent to primary forests rank among the most valuable biomes for the planet (Fig. 4) (den Hartog 1970; Boudouresque et al. 2006). This work revealed the sensitivity of aquatic plants to sound. Man-made noise could alter marine biodiversity and contribute to the fragility of seagrass meadows. More research is needed to determine if artificial noise affects seagrass in the juvenile stages, when the plant needs to use its ability to sense gravity in order to find soil and roots.

## Conclusion

This chapter provided current knowledge about the sensory capabilities of plants and their communication abilities above and below ground, as well as advances in plant acoustics, including responses to sound at behavioral, physiological, and molecular levels. In addition, it presented recent findings on acoustic impact on plants, specifically on marine species. Particularly, it was shown that anthropogenic noise can inflict ultrastructural damage on various *Posidonia oceanica* tissues, which could have implications at the whole marine ecosystem level.

More research is needed on acoustic emission and perception abilities in plants, including:

1) A better understanding of the molecular and cellular mechanisms of sound perception and signal transduction, specifically for aquatic plants.
2) Understanding the possible underground sound communication capacities in plants; understanding the intricate communication networks established between plant community individual roots as well as with other trophic levels.
3) Elucidating if marine communities, such as seagrass, possesses some communication system, chemical, or acoustic, to warn of the presence of damaging elements at physiological, ultrastructural, or behavioral level.
4) Assessing if the underground sophisticated root mesh is capable of transmitting other danger announcements related to stress factors caused by climate change, pollution, and overfishing.
5) Consideration must be given to the essential role of the root as "a brain" or point of sensory information input and organization, as well as a command center for decision-making.
6) Knowledge of damaging sound levels to develop criteria for evaluating the impact of sound on marine plants.

**Abstract**

Anthropogenic underwater noise is increasing in the oceans, making the establishment of sound exposure criteria for marine taxa imperative for protecting and managing a good environmental status of the seas. Zooplankton play a key role in the marine carbon cycle and act as linkage between phytoplankton and higher trophic levels. Still, studies of the effects of underwater noise on zooplankton are

limited. This chapter reviewed 21 studies that found positive, negative, and no responses of marine holo- and meroplankton to continuous and impulsive underwater noise from experiments conducted in the laboratory, field, or both. The majority of the examined effects were related to development (28%), mortality (25%), and orientation and settlement (19%). Meroplankton (68%) were the most investigated zooplankton group. These studies indicated that both lethal and sublethal effects are stage- and species-specific. Variations were found in the implemented sound exposures, and a standardized manner in reporting sound levels is needed. Further studies combining laboratory and field experiments are required to establish sound exposure criteria for marine ecosystems, which can be used as international directives for underwater noise.

**Keywords**

Zooplankton · Noise pollution · Anthropogenic noise · Mortality · Behavior · Development · Impulsive noise · Continuous noise

## Introduction

Anthropogenic underwater noise is an increasing source of environmental stress (Fritschi et al. 2011; Duarte et al. 2021). The goal of directives, such as the EU Marine Strategy Framework Directive (Directive 2008/56/EC 2008), is to monitor underwater noise and establish threshold values that do not adversely affect the marine environment. Typically, noise is divided into continuous and impulsive underwater noise, for which no threshold value has yet been integrated (Dekeling et al. 2020; Vasilakopoulos et al. 2022). Throughout the chapter, the term "sound exposure criteria" is used instead of "threshold values," which is defined as "sound levels, based on acoustic response thresholds, above which sound levels may have adverse effects on specified animals" (Hawkins et al. 2020).

Continuous underwater noise can be described as a constant or slowly fluctuating sound pressure over a long time interval, which neither is instantaneous nor involves (typically) pulsed characteristics. Continuous underwater noise is a broad term for several different sound sources, such as boat traffic or turbine sound from offshore wind parks (Kinneging and Tougaard 2021), that increases ambient sound levels, particularly at low frequencies. The sound levels are determined by the number and size of the boats and turbines, whereas boat noise levels are further controlled by the speed of the vessel (Kaplan and Solomon 2016; Tougaard et al. 2020). In contrast, impulsive underwater noise is defined as an instantaneous change in sound pressure, often of high amplitude, e.g., from air guns used in seismic surveys and from pile driving. During seismic surveys, air guns emit impulsive sound primarily at low frequencies by rapidly releasing compressed air (Hovem and Tronstad 2012). Pile driving emits intense broadband impulsive sound that can propagate far through the water and ocean floor (Stenton et al. 2022). Much of what is known about the effects

of anthropogenic underwater noise, such as altered or disrupted communication, orientation, feeding, and antipredator behavior, comes from studies investigating marine mammals and fish (Popper and Hawkins 2016, 2018; Duarte et al. 2021). Less is known about marine invertebrates (Hawkins and Popper 2017; Murchy et al. 2019), such as zooplankton.

Zooplankton are an essential link between primary producers and higher trophic levels; hence their fitness and mortality directly affect the path and storage of organic carbon in the food web (Steinberg and Landry 2017). They comprise a large group of animals that drift in the pelagic zone, either entirely (holoplankton) or partly (meroplankton), throughout their life cycle. Zooplankton differ in morphological and functional traits, e.g., size (Lindeque et al. 2013; Deagle et al. 2018; Evans et al. 2020), energy content (Chen et al. 2019), and behavior (Kiørboe et al. 2010; Almeda et al. 2017). Therefore, various groups or species may be affected by external stressors, such as underwater sound, in different ways and degrees.

By interpreting the results and methods of previous studies investigating the effects of anthropogenic noise on zooplankton, this chapter summarizes the previous findings and highlights the knowledge gaps for future studies.

## Methods

All studies included in this chapter were systematically selected by first creating an overview of marine zooplankton groups (Table 1). Note that ichthyoplankton, meroplankton consisting of fish eggs and larvae, were not included. This group contributes a relatively small proportion of plankton, and it is challenging to implement a systematic definition for different species at the transition stage of nekton. The second criterion used in the literature search was sound source. For continuous underwater noise, all low-frequency sound sources (independent of the sound exposure duration used in the studies) that were not impulsive by definition (see Introduction) were included in this chapter. Noise that did not originate from a real-life anthropogenic sound source found in the ocean was categorized as artificial low-frequency noise. For impulsive underwater noise, only two sound sources have been investigated for their effects on zooplankton: seismic air guns and pile driving.

Potential studies were searched using the phrase *noise effects on zooplankton*. The following terms were used for sources of noise: *underwater noise*, *low-frequency noise*, *continuous noise*, *boat/vessel/traffic noise*, *turbine noise*, *wind farm noise*, *air guns*, *seismic exploration*, *seismic surveys*, and *pile driving*. The groups listed in Table 1 were used to search for zooplankton species and (sub) phyla.

Three main types of information were extracted from the collected studies: (1) sound exposure, in which the sound sources and sound characteristics of various studies were presented, (2) study animals and developmental stages, and (3) study design and outcomes. For the latter, the outcomes of each study were categorized into lethal (mortality) and sublethal effects. The sublethal effects were further

**Table 1** Overview of marine zooplankton groups (Animalia)

The zooplankton groups reported in the chapter are marked in bold and with an asterisk (*). The table is adapted from the *Census of Marine Zooplankton*. Retrieved 10.11.2022: http://www.cmarz.org/species_pages/phyla/phyla.htm

divided into physiology (including oxidative stress and gene expression), morphology (including injuries to cells), development, orientation or settlement, and behavior (including swimming, feeding, and antipredator behavior). The responses for each outcome were then categorized as either negative (e.g., increased mortality),

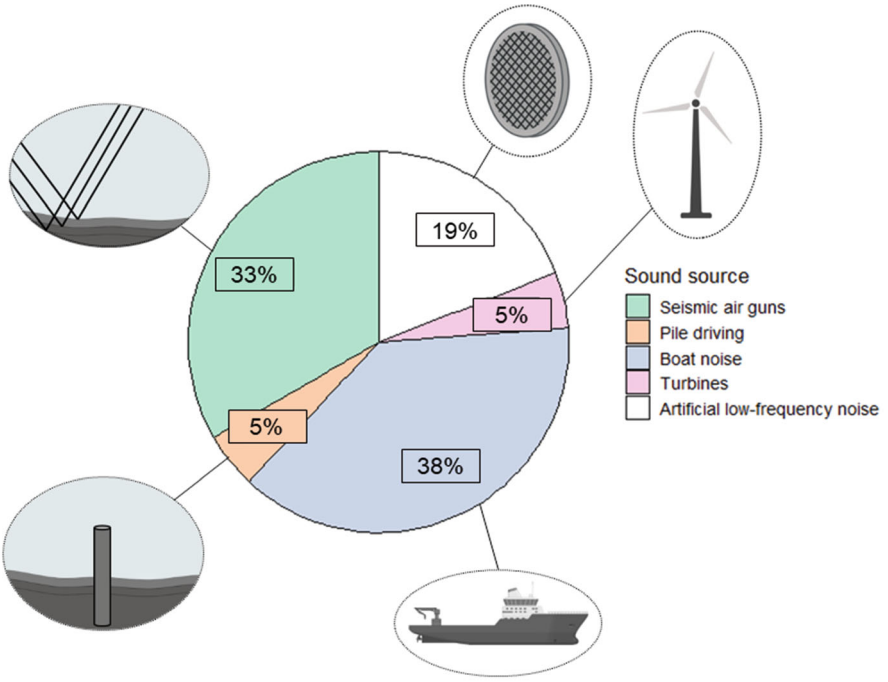

**Fig. 1** Schematic overview of the proportion of studies covering the five main sources of sound exposure ($n_{all\ studies} = 21$): seismic air guns, pile driving, boat noise, turbines, and artificial low-frequency noise. The legend is read counterclockwise through the pie chart. (Icons by biorender.com)

other (e.g., different patterns in the settlement but not clearly negative), or none (no response observed). Note that potential positive effects were categorized as "other," as it is with the present information not possible to determine whether, for example, increased settlement positively affects an individual or populations. All study animals were individually considered as either meroplankton or holoplankton. In addition, if a study presented several degrees of effects, for example, negative effects on mortality, but no effect on settlement, both outcomes were included. Therefore, the number (n) of each parameter differed among the graphical overviews (Figs. 1, 2 and 3).

## Sound Exposure

Of all the studies ($n = 21$), 13 (62%) investigated the effects of continuous underwater noise, and 8 investigated (38%) the effects of impulsive underwater noise on zooplankton (Fig. 1, Table 2).

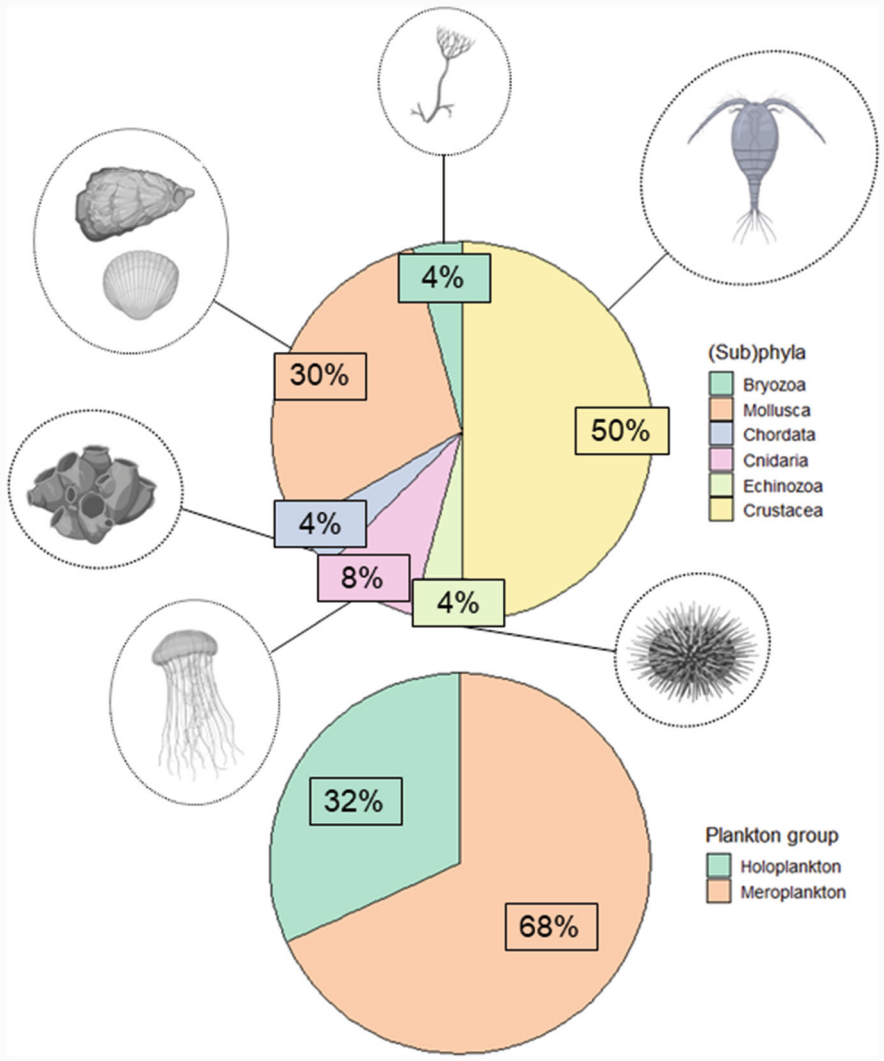

**Fig. 2** Schematic overview of the proportion of different zooplankton groups. Upper panel, groups of subphylum or phylum covered in the studies ($n_{\text{total reported (sub)phylum}} = 24$): Bryozoa, Mollusca, Chordata, Cnidaria, Echinozoa, and Crustacea*; and lower panel, plankton group ($n_{\text{total reported plankton groups}} = 22$): holoplankton and meroplankton. Note that one study could include several sub(phyla) or plankton groups. The legends are read counterclockwise through the pie chart. *In McCauley et al. (2017), in situ zooplankton samples were investigated. However, as the majority consisted of copepods, the study animals are categorized as Crustacea. (Icons by biorender.com)

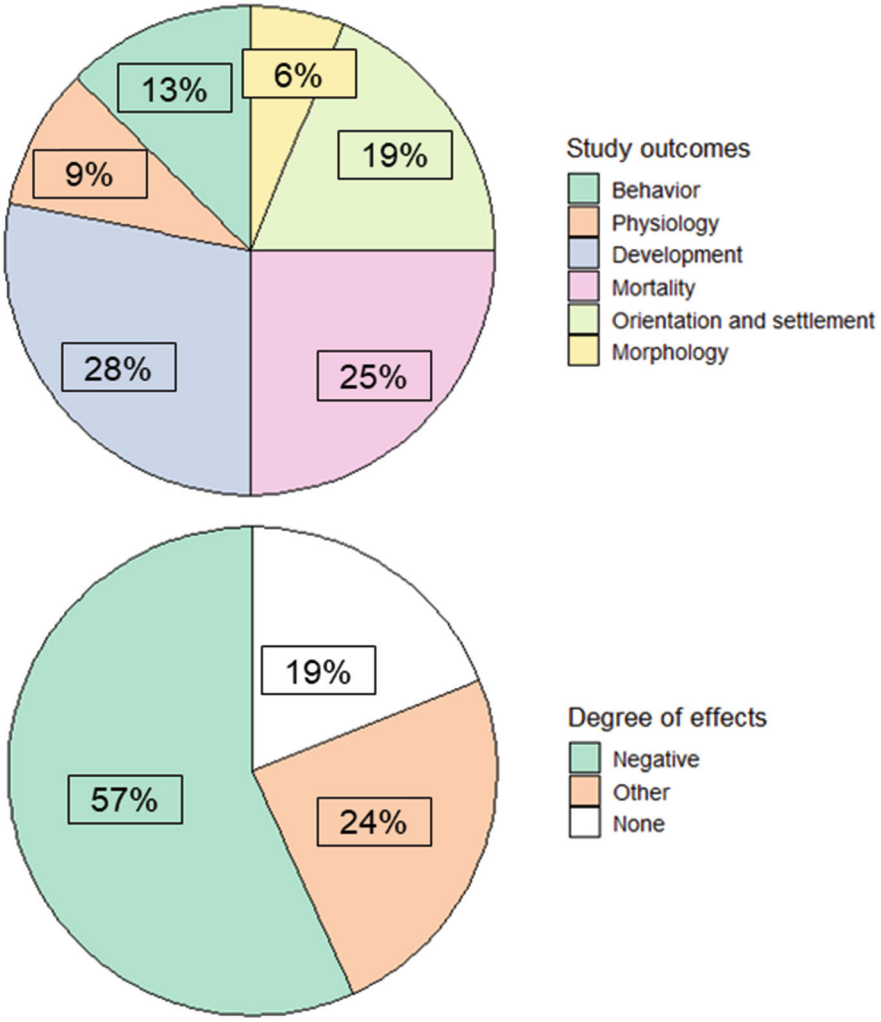

**Fig. 3** Schematic overview of the proportion of different outcomes and the degree of effects observed in the studies. Upper panel, categories of study outcomes covered in the studies ($n_{\text{total reported study outcomes}} = 32$): behavior, physiology, development, mortality, orientation and settlement, and morphology; and lower panel, the degree of effect ($n_{\text{total reported effects}} = 37$): negative, other, and none. Note that one study could include study outcomes or report different effects. The legends are read counterclockwise through the pie chart

**Table 2** Overview of the sound exposures from reviewed studies. Information is given on the sound sources, sound levels, and exposure durations

| Study | Sound source | Sound levels | Duration |
|---|---|---|---|
| Tremblay et al. (2019) | Artificial: Noise Egg (method, de Jong et al. 2017) | < 5000 Hz up to 20 dB (PSD) ↑ than ambient | 9 days |
| Solé et al. (2021) | Artificial: Playbacks of discrete frequencies of 100–1000 Hz and discrete and combined frequencies of 350 and 500 Hz | 160–195 dB (SEL) re 1 $\mu Pa^2$ | Few hours up to 2 weeks |
| Nedelec et al. (2014) | Boat noise: playback | 110 dB (PSD) re 1 $\mu Pa^2$ $Hz^{-1}$; 80 dB re 1$(\mu m\ s^{-2})^2$ $Hz^{-1}$ at around 100 Hz | 12-h cycle for 5 days |
| | | 20 dB ↑ than ambient | |
| Branscomb and Rittschof (1984) | Artificial: Discrete frequency playback at 15, 25, 30, 37, and 45 Hz | No information | 20 h |
| McDonald et al. (2014) | Boat noise: playback | 30–100 Hz 110–120 dB (RMS) re 1 µPa $Hz^{-1}$; 128–141 dB re 1 µPa | Loop of 2-min sequences: up to 26 h |
| Stocks et al. (2012) | Boat noise: playback | 100–300 Hz −30 dB re 1 $\mu Pa^2$ $Hz^{-1}$; 30–50 dB ↑ than control | 5 min |
| Pine et al. (2012) | Wind turbine: playback | 145 dB re 1 µPa; 20 dB ↑ than mudflat sounds | Every 6 h checked, up more than 200 h |
| | Tidal turbine: playback | | |
| Jolivet et al. (2016) | Boat noise: playback | 127 ± 3 dB re 1 µPa 100–1000 Hz; 20 dB ↑ than ambient | 67 h |
| Wilkens et al. (2012) | Boat noise: playback | 126 and 100 dB (RMS) re 1 µPa; 60 dB and 40 dB ↑ than ambient | 8–16 h |
| Sal Moyano et al. (2021) | Boat noise: playback | 129.5 dB (SPL RMS) re 1 µPa; 9 dB ↑ than ambient | 5 min |
| Solé et al. (2016) | Artificial: playback of 50–400 Hz sinusoidal wave sweeps | 157 ± 5 dB (not clear) re 1 µPa; peak 175 dB (SPL) re 1 µPa | 2 h |
| Lecchini et al. (2018) | Boat noise: playback | At 400 Hz and 900 Hz 90 dB (SPL) re 1 µPa; >10 dB ↑ than controls | 4-h playback track |
| Kühn et al. (2023) | Boat noise: playback | Peak at 130 Hz 150 dB (PSD) re 1 $\mu Pa^2$ $Hz^{-1}$; 174 dB PSD (RMS) re 1 $\mu Pa^2$ $Hz^{-1}$ one boat passing | 24-h loop of a 20-min recording |
| McCauley et al. (2017) | Seismic air guns: 1 air gun (150 $inches^3$) | SEL 156 (509–658 m) – 153 (1.1–1.2 km) dB re 1 $\mu Pa^2 s$ | App. 110 shots |
| | (13.8 MPa) | | |

(continued)

**Table 2** (continued)

| Study | Sound source | Sound levels | Duration |
|---|---|---|---|
| Fields et al. (2019) | Seismic air guns: 2 air guns*260 inches$^3$ (13–14.4 MPa) | SEL 221 dB re 1 μPa$^2$s (0 m), 183 dB re 1 μPa$^2$s (25 m) | Not given |
| Vereide et al. (2023) | Seismic air guns: 2 air guns*40 inches$^3$ (11 MPa) | SEL 180 (50 m), 166 (1100 m) dB re 1 μPa$^2$s | 2.5 h |
| Parry et al. (2002) | Seismic air guns: Air gun array (24) (total volume 3542 inches$^3$) | Max. source strength 211 dB/rel to 1 μPa at 1 m at frequency 50 Hz | Not given (but 2 km transect) |
| de Soto et al. (2013) | Seismic air guns: playbacks of an air gun array (6920 inches$^3$) | SEL from 161 to 165 dB re 1 μPa$^2$s | 24–90 h, 3 s intervals |
| Pearson et al. (1994) | Seismic air guns: Air gun array (7), total volume 840 inches$^3$ | Max. (1 m) 230 dB re 1 μPa | 10 s intervals |
| Day et al. (2016) | Seismic air guns: 1 air gun (3 setups): 45 inches$^3$ (2000 psi), 150 inches$^3$ (1300 psi), 150 inches$^3$ (2000 psi) | Max. SEL 186, 189, 190 dB re 1 μPa$^2$·s (3 setups) | 17.2–24.3 min, 11.6 s intervals |
| Stenton et al. (2022) | Pile driving: playback | 170 $dB_{pk\text{-}pk}$ re 1 μPa; 82.7 ± 3.4 – 84.6 ± 2.6 $dB_{pk}$ re 1 μm s$^{-2}$ | 5 days |

## Continuous Underwater Noise

The effects of boat noise on zooplankton were examined using playback sound exposure in a laboratory tank or field (Table 3), whereas only McDonald et al. (2014) used real-life observations to confirm the results of the playback exposure. Furthermore, all studies, except for Nedelec et al. (2014), conducted playback experiments in laboratory tank setups without additionally measuring particle motion. Note that Nedelec et al. (2014) conducted playback experiments in the field. These studies also differed in their control exposures, using silent or aquarium ambient sound controls (Stocks et al. 2012; Wilkens et al. 2012; McDonald et al. 2014; Jolivet et al. 2016; Kühn et al. 2023) or playback recordings from natural ambient soundscapes (Nedelec et al. 2014; Lecchini et al. 2018; Sal Moyano et al. 2021). The duration of the sound exposure ranged from 5 min to several days (Table 2). Lastly, the studies reporting spectral information on the original recordings measured similar sound pressure and particle motion levels for the playback exposures. However, sound levels varied between the studies due to different boat noise recording approaches and playback setups (Table 2).

Only one study examined the effect of turbine noise (Pine et al. 2012). Laboratory experiments were conducted to test the effects of tidal turbine noise (digital analog based on published spectra) and coastal wind turbine noise (playback) (Table 2). The maximum output sound exposure levels used in their experiments were 30 dB and 9 dB less than the published in situ sound levels from tidal and wind turbines, respectively.

Four studies used different approaches to generate artificial low-frequency noise: broadband noise, discrete frequencies, or specific combinations of frequencies (Table 2). Overall, the exposure sound levels, especially at low frequencies, were well above the ambient sound levels in studies that provided information on the measured sound spectra.

### Impulsive Underwater Noise

In seven studies that investigated the effects of air guns used in seismic surveys on zooplankton, variations were found in the number of air guns used, distance to the air guns, and exposure duration (Table 2). Therefore, the measured sound levels showed considerable differences between studies (Table 2). Furthermore, the studies differed in terms of exposing the animals to one or a series of shots (Table 2). One study used playback exposure from air guns (de Soto et al. 2013), while the rest conducted field experiments. Only one of these studies provided data on particle motion (de Soto et al. 2013).

Stenton et al. (2022) conducted two playback pile driving exposure experiments and reported the sound pressure and particle motion levels (Table 2). The measured playback sound levels resulted in a smaller proportion of sound at lower frequencies but increased at higher frequencies compared to the in situ pile driving recordings. The control playback consisted of ambient recordings made in the field, without anthropogenic sounds.

## Study Animals and Developmental Stages

Of all the included studies, 7 investigated the effects on holoplankton, and 15 investigated the effects on meroplankton. Furthermore, 50% of all study species were crustaceans (Fig. 2 and Table 3). Additionally, the reported effects on zooplankton varied between negative (57%), other (24%), and none (19%) (Fig. 3 and Table 3).

### Continuous Underwater Noise

Of the studies investigating the effects of continuous noise on zooplankton, 4 of the 21 species were holoplankton and the rest were meroplankton (Table 3).

#### Zooplankton Groups

Studies that focused on holoplankton ($n = 4$) examined the potential effects of noise on copepods and jellyfish. The physiology, morphology, and behavior of all copepods were negatively affected by noise (Table 3). Jellyfish were negatively affected by noise in their morphological structure (Table 3). Nine studies examined meroplankton (Table 3). In crustaceans, continuous noise had either negative or no effect on settlement or development (Table 3). Likewise, Cnidaria and Bryozoa were

**Table 3** Overview of the study animals and outcomes from reviewed studies

| Study | Lab/ field | Holo/mero (plankton) | (Sub) phylum | Species | Stage | Outcomes | Effect |
|---|---|---|---|---|---|---|---|
| Tremblay et al. (2019) | L | Holo | Crustacea | *Acartia tonsa* | Preadult | Physiology | Increased stress |

Information is given on whether the experiments were conducted in the laboratory or the field, plankton group (holoplankton or meroplankton), (sub)phyla, study species, development stages, study outcomes, and the degree of effects

[a]The adult females were exposed, but the effects were measured in hatched larvae

negatively affected by noise in settlement and swimming behavior, whereas Echinozoa species showed no behavioral response (Table 3). Other types of effects not categorized as negative were only found in studies that looked into sublethal outcomes in bivalves, chordates, and gastropods (Table 3). However, Nedelec et al. (2014) also found adverse effects of sound on the mortality and development of gastropods.

### Development Stages

For the holoplankton groups, copepodite and adult copepod stages and the medusa stage in jellyfish (Scyphozoa) were used in the experiments (Table 3). Most meroplankton studies looked into the developmental stages before metamorphosis and larvae settlement. For example, two studies investigated the effects of continuous noise on Malacostraca species (Pine et al. 2012; Sal Moyano et al. 2021) and looked into the last larval stage before settlement, megalopa, considered as an intermediate stage between planktonic and benthic. Nedelec et al. (2014) investigated the mortality of veliger stages after hatching and the development of eggs or embryos of sea hares when exposed to boat noise. Lecchini et al. (2018) looked into the coral larval stage, planulae.

## Impulsive Underwater Noise

Of the studies examining the effects of impulsive underwater noise, three out of eight looked at holoplankton, whereas more than half looked at the effects on meroplankton (Table 3).

### Zooplankton Groups

Studies on holoplankton have focused primarily on copepods. Two studies solely investigated copepods, reporting adverse but limited effects on mortality after air gun exposure (Table 3). McCauley et al. (2017) looked at the effects of air guns on copepods but as a proportion of a natural zooplankton community from in situ samples. The authors reported severe effects on mortality after exposure.

All included meroplankton species (Table 3) were crustaceans or bivalves, but none of them investigated the same species. Furthermore, only two studies have reported adverse effects, one from air gun noise on scallop larvae and the second from pile driving on lobster larvae. Interestingly, both studies reporting negative effects exposed the animals to sound in the laboratory, whereas the other six exposed the animals to impulsive underwater sounds in the field.

### Developmental Stages

Of the two studies examining the effects on copepods, one focused on adult stages and the other on naupliar stages (Table 3). In contrast, McCauley et al. (2017) tested the effects on in situ zooplankton samples and reported several species and stages in the same study. Regarding meroplankton, only the younger stages prior to the settlement of bivalves and crustaceans have been investigated.

## Study Designs and Outcomes

The majority of studies examined sublethal effects: behavior (13%), physiology (9%), development (28%), orientation and settlement (19%), and morphology (6%) (Fig. 3). A number of the studies investigated several outcomes, e.g., combining development and settlement (Fig. 3, Table 3).

### Continuous Underwater Noise

The exposure duration ranged from instant (5 min) to long time intervals (up to 8 days) when investigating sublethal outcomes. For meroplankton species, the focus was on orientation and settlement, development, and changes in swimming behavior (Tables 2 and 3). Two studies (McDonald et al. 2014; Nedelec et al. 2014) found additional lethal effects of long-term sound exposure (Table 3). For holoplankton, feeding behavior and physiological and morphological aspects, such as oxidative stress and cell injury, were investigated (Table 3). All outcomes were measured either during or directly after the end of the experimental sound exposure.

### Impulsive Underwater Noise

Studies have covered different outcomes, from mortality to sublethal effects, such as behavior, gene expression, and development (Table 3). In addition, studies have focused on both short- and long-term effects, from immediate and long-term mortality to direct and long-term effects on physiology and development. For example, McCauley et al. (2017) examined the effects on mortality directly after air gun exposure, whereas Fields et al. (2019) investigated mortality additionally 1 week after exposure. Similarly, Vereide et al. (2023) measured mortality every day for 6 days after air gun exposure in copepod nauplii.

## Discussion

Similarities, variations, and inconsistencies were found among existing studies on the effects of underwater noise on zooplankton, which are discussed in the following section. Additionally, general predictions are made regarding the potential effects of noise pollution on individual zooplankton and their subsequent effects on marine ecosystems.

### Sound Exposures

All the presented studies on continuous underwater noise were conducted in a laboratory or field setup, where no studies used real-life in situ sound sources (except

for the additional field observations by McDonald et al. 2014). In general, responses in zooplankton were found during sound exposure from 10 dB above ambient sound levels, which is concerning because continuous noise through shipping led to more than 30 dB elevated sound levels, especially in coastal areas (Kinneging and Tougaard 2021; Farcas et al. 2020). In addition, Pine et al. (2012) observed adverse responses to sound levels well below the in situ measurements of offshore turbines. Thus, the reported effects of boat noise, wind, and tidal turbines can be observed in high traffic, fairways, and operational areas (Kinneging and Tougaard 2021). Furthermore, the use of artificial low-frequency noise (Table 2) may provide information on the general frequency and sound-level characteristics that affect marine organisms.

The comparability among studies is complicated for impulsive underwater noise owing to the different setups and difficulty of simulating impulsive sound in experimental tanks. Several studies have reported varying effects despite implementing similar sound levels but often with different exposure durations and distances from the study animals (Tables 2 and 3). The sound pressure level from air guns depends on the number of air guns (often consisting of 18–48 air guns distributed in subarrays), operating pressure, and total gun volume (NDP 2021). The volume of air guns used in real seismic surveys ranges from 20 to 800 inches$^3$, which is within the range of air guns used in the included studies. On the other hand, yielding source levels have been calculated up to 260 dB rms re 1 μPa at 1 m output pressure, which is substantially higher than those reported in the included studies. In addition, the peak spectral levels for industry arrays are often in the 5–300 Hz range (Hildebrand 2009). Another important aspect of transferring reported results to a real-life setting is the natural movement and location of the zooplankton. Zooplankton move along with water currents and undergo diel vertical migration, which may affect the timing and duration of impulsive noise exposure. Therefore, although a real-life survey may cover 1000–3000 km$^2$ (Hovem and Tronstad 2012) and continuously shoot over weeks or months (Weilgart 2013), the animals will not be constantly exposed throughout that period. The duration of exposure in the reviewed studies lasted for a maximum of 3–4 days, which may even be considered too long to be transferred into a real-life setting, considering advection and migration. To transfer the results from field or laboratory studies to a natural environment, other potential factors that may alter the strength of noise exposure must be considered.

## General Anthropogenic Underwater Noise

Anthropogenic noise from, e.g., boat traffic and seismic surveys potentially overlap as low frequencies can travel several thousand kilometers in deep waters. Boat noise is predominant in coastal areas, in shallow waters where low-frequency noise propagation is limited (Kinneging and Tougaard 2021; Farcas et al. 2020). An overall increase in commercial shipping can be expected in the future, in combination with larger ships and increased shipping distances across the oceans (Kaplan and Solomon 2016). As wind turbines are a constant noise source, the increased construction of wind parks (often several 100 turbines) will lead to locally increased ambient sound levels (Tougaard et al. 2020). A model by Siebert et al. (2014)

indicated that noise from air guns would be impulsive to intermittent up to 1000 km but may change beyond continuous underwater noise. The model shows that ambient sound levels can increase by 45 dB between 500 and 2000 km from the source, particularly at low frequencies. Hence, the long-distance effects of air gun shots on zooplankton could be comparable to those presented here for continuous underwater noise (see Sound Exposure). Furthermore, seismic surveys may occur for several months over large distances; therefore, the spectrum of impacts on zooplankton based on near-field experiments may underestimate the full range of effects.

An overall challenge when investigating the literature on continuous and impulsive anthropogenic underwater noise is that many studies present the received sound and exposure levels in different and limited formats. Reporting the information in a standard manner would facilitate the interpretation of the relationship between sound levels and the degree of effects in the study animals, which is urgently needed for the integration of sound exposure criteria.

Future studies would benefit from reporting (1) sound levels in standard formats, such as PSD for continuous underwater noise for comparisons among calibrated hydrophones and SEL for impulsive underwater noise. The amplitude of the PSD is normalized over the spectral resolution, which makes it independent of hydrophone sampling rates. Further, studies should report (2) distances, (3) durations, (4) ambient or controlled sound levels, and (5), if possible, particle motion. Particle motion can injure animals, mask sound cues, induce stress, or alter the behavior of marine organisms (Nedelec et al. 2021). In addition, particle motion levels in noise-related laboratory tank experiments are higher than those in in situ recordings or playback experiments in the field (see data by Nedelec et al. 2014, 2015). Hence, the true exposure perceived by zooplankton cannot be predicted from the measured sound pressure levels.

## Study Animals and Developmental Stages

The degree to which marine animals are affected by anthropogenic noise is often species- and stage-specific. Furthermore, impacts may be linked to their perception of sound, physiology, and type of sound source used in the exposure.

### Perception of Underwater Sound

Despite the increasing use and knowledge of anthropogenic sound in the oceans, understanding how invertebrates affect and detect sound is limited. In particular, sound perception in zooplankton needs to be fully understood (Hawkins and Popper 2017). In contrast to marine mammals and certain fish species, zooplankton are incapable of "hearing" and may be affected in other ways by underwater sound, e.g., through mechanoreception or cell injuries.

Crustaceans, such as copepods, use mechanoreceptive setae to detect predators, prey, and potential mates. Mechanoreception requires relative physical movement, which can be produced by the hydroacoustic motion of a receptor-activating structure involving a stretch-sensitive ion-channel molecule (Yen et al. 1992; Lenz and

Hartline 2014). By detecting hydrodynamic stimuli, several copepod species, such as *Lepeophtheirus salmonis* (Heuch and Karlsen 1997) or *Calanus finmarchicus* (Weatherby and Lenz 2000), detect and avoid prey and obstacles. Thus, anthropogenic noise can disrupt the fitness-relevant processes in crustaceans. For example, anthropogenic noise may mask the acoustical cues from a soundscape that could alter the settlement choice for suitable habitats (Branscomb and Rittschof 1984) or potentially mask the hydromechanical cues from a prey (Kühn et al. 2023). Noise can also distract the animals and alter physiological processes, such as increased stress (Tremblay et al. 2019, Stenton et al. 2022), or lead to cell injury (Solé et al. 2021). For example, fusion of sensory cells was found in the parasitic copepod species *L. salmonis* (Solé et al. 2021). Solé et al. (2021) hypothesized that such changes in an animal's sensory organs may impair the detection of a potential host.

Bivalves may also detect and react to sound (Stocks et al. 2012; Wilkens et al. 2012; Jolivet et al. 2016). However, the underlying mechanisms are not yet well understood. For example, Eggleston et al. (2015) found an increased settlement rate in oyster larvae (*Crassostrea virginica*) during sound exposure compared to silent conditions, whereas clam (*Mercenaria mercenaria*) larvae showed no differences. Because bivalves lack gas-filled spaces, they are most likely unaffected by pressure changes (de Soto et al. 2013). However, studies have suggested specialized organs and statocysts as mechanisms that make them perceptible to sound particle motion (Hubert et al. 2022).

Other mollusks, such as gastropods, may also be capable of detecting sound via their statocysts. For example, Nedelec et al. (2014) hypothesized three mechanisms by which noise affects the development and survival of sea hares. First, the development might have been affected by tissue damage owing to strong molecular vibrations from boat noise, where a potentially similar mechanism was found by Solé et al. (2016, 2021). Second, the survival of sea hare veligers may have decreased due to barotrauma. Finally, they suggested that sea hares might suffer from stress when exposed to noise.

Jellyfish possess hair cell structures that respond to mechanical displacements (mechanoreceptors) from, e.g., vibrations and sound pressure waves (Solé et al. 2016). How noise causes cell damage in the two Cnidaria species is unknown. Solé et al. (2016) hypothesized that noise propagation vibrations could directly trigger the mechanical displacement of external sensory cells. Like jellyfish, other Cnidaria species, such as coral planulae, can detect sounds through cilia. Therefore, coral planulae can distinguish between soundscape habitats and boat noise, which may lead to the avoidance or masking of the signal needed from a suitable habitat (Lecchini et al. 2018).

In summary, the effects of anthropogenic noise may be either detection-dependent (mechanoreception) or detection-independent. First, if zooplankton detect noise with their sensory organs, it could increase stress, distract the animal, or mask acoustic signals from their surroundings. Second, strong vibrations from noise can cause morphological damage independent of their detection. However, knowledge still needs to be completed, and for many invertebrates, it remains to be seen if and how they detect sound (Stocks et al. 2012).

### Differences in Morphological Characteristics and Developmental Stages

The morphological differences between zooplankton groups may indicate that certain species are affected by one component of underwater sound, such as particle motion (Nedelec et al. 2016; Popper and Hawkins 2018), whereas others may be more affected by other components. For example, adult copepods, with a robust external layer and internal lipid sack of different densities than the surrounding water, may be affected by pressure changes from air guns. Similarly, de Soto et al. (2013) suggested that damage observed in scallop larvae after air gun exposure, because of their small size and absence of strong tissue density gradients, is more related to particle motion rather than pressure changes. These morphological differences may also explain the variation in the results of studies examining different zooplankton groups. For continuous underwater noise, contradictory results, namely, no response versus adverse effects, have been found in behavioral experiments in copepods (Tremblay et al. 2019, Kühn et al. 2023), whereas physiology and morphology were negatively affected in all investigated holoplankton groups (Solé et al. 2016, 2021; Tremblay et al. 2019). Contradicting results were also found in studies investigating the effects of impulsive noise (Table 3), although only two studies found negative effects on meroplankton, in contrast to the holoplankton studies that observed adverse effects in all studies (Table 3). Overall, the responses to the sound exposures were highly species-specific for holo- and meroplankton, but crustaceans seemed to be most often negatively affected. The sensitivity of crustaceans to sound may be due to their highly sensitive mechanoreception, as described above, and the reaction thresholds are stage-dependent (Fields and Yen 1997). In addition, only one study focused solely on the juvenile stages of holoplankton (Table 3). Regarding the importance of nauplii and their role in ecosystems, more knowledge is needed regarding earlier plankton stages. In general, the majority of studies focused on meroplankton in order to study benthic organisms (Table 3). Regarding the importance of zooplankton as a functional group, more studies focusing on holoplankton and their different developmental stages are needed.

## Study Designs and Outcomes

Continuous underwater noise can alter the sublethal processes and mortality after only a few hours of exposure (Tables 2 and 3). Note that the reported swimming activity and orientation effects were seen after 5 min of sound exposure (Stocks et al. 2012, Sal Moyano et al. 2021). Hence, continuous underwater noise alters behavioral responses to short-term exposure; however, there is no information about long-term behavioral responses in relation to physiological responses. More than half of the impulsive underwater noise studies either focused primarily on or included mortality but also on development and physiology. In general, there is an increasing trend in the combination of areas of biology and outcomes (Wale et al. 2021). This was also reflected in Wale et al. (2021), who examined the trends in methods and future directions of studies investigating the effects of anthropogenic noise on

marine invertebrates and reported that 39% of the studies in the same period covered a combination of biological outcomes. Combining investigations into physiological, morphological, and behavioral outcomes in noise research will facilitate unraveling the underlying mechanisms of noise impacts in different species.

Another important aspect to investigate is the effect of the experimental arena by comparing anthropogenic underwater noise studies done in the laboratory with studies done in the field. Several studies (e.g., Day et al. 2016) have previously highlighted this issue, which is highly relevant when translating possible effects into real-life effects. First, the studies included in this chapter presented and discussed contrasting laboratory and field results. For example, de Soto et al. (2013) conducted experiments in small tanks in the laboratory using air gun playbacks and reported negative effects on development in lobster larvae. However, Day et al. (2016) suggest that the long wavelengths produced by accurate sound sources, such as an air gun, cannot be emulated in a small tank. Also, the sound reflected from the surfaces in small tanks might result in an unrealistic picture and relationship between the sound pressure and particle motion of the sound (Parvulescu 1964, 1967; Rogers et al. 2015, Nedelec et al. 2016). Second, laboratory and field studies provide different possibilities regarding study design and outcomes. For example, when using a laboratory approach, the mechanisms behind potential damage to zooplankton can be easier isolated than out in the field. Furthermore, one can potentially exclude other impacts by keeping the study animals in a controlled environment. For example, when conducting field experiments, one needs to consider background mortality from, e.g., boat propellers or other physical disturbances, which are easier to control in the laboratory. In addition, a controlled environment is relevant when looking into long-term vs. immediate effects, as long-term effects may be challenging to detect in the field in a natural environment – but are highly relevant. For example, short-time experiments may miss the impact of potential habituation, as found in blue mussels' reduced responsiveness over several sound exposures (Hubert et al. 2022), and possible population effects.

## Potential Population and Ecosystem Effects

Based on the results of this chapter, any response of zooplankton to underwater noise can affect ecosystem functioning. For example, when zooplankton species are affected by noise, any positive or negative outcomes on mortality, physiology, or fitness-relevant behavior could lead to increased or decreased species abundance. In turn, these changes in abundance could lead to modifications in grazing and predation pressure on phytoplankton and other zooplankton groups (Lynam et al. 2017). As noise can alter fitness-relevant behavior at the individual level, it may also affect the strength and direction of intra- and interspecies interactions (Lagardère 1982; Schwarz and Greer 1984; McCauley et al. 2003). Therefore, a potential outcome in a system with low resilience may shift the phytoplankton and zooplankton abundance and community structure. Furthermore, higher trophic levels may be affected by an increase or decrease in energy transfer from lower levels. On the other hand,

zooplankton, especially copepods, are important for deep-sea carbon storage by fast-sinking fecal pellets (Shatova et al. 2012; Turner 2015). Hence, a change in abundance may increase or decrease the rate of this process.

## Conclusions

Underwater noise affects zooplankton, which is either detection-independent or detection-dependent. For the latter, interpreting the noise exposure in terms of particle motion is important, and a standardized manner of reporting sound levels is needed. However, several studies have reported no effects of underwater noise, indicating that the effects vary among sound sources, strength, and zooplankton groups. In order to understand how noise affects zooplankton and potentially establish sound exposure criteria, the interplay of the effects of noise on physiology, morphology, and behavior must be investigated simultaneously in different developmental stages. Information on the differences between short- and long-term exposure effects and potential habituation to various sound sources is largely missing. Further studies combining laboratory and field experiments are needed to predict future outcomes in the real world and, hence, the effect of noise on ecosystem functioning.

**Acknowledgments** This work was supported by the Research and Technology Centre West Coast, Kiel University (DE), and the project ZoopSeis (#302675), funded by the Research Council of Norway. The authors would like to thank the Aquatic Noise Committee 2022 for a successful, insightful, and social conference, where early career researchers were not just able but encouraged to take the stage. We would also like to thank Karen de Jong, Katja Heubel, and Anne Christine Utne Palm for their resourceful advice and support.

**Abstract**

Ecotoxicological studies mainly focus on chemical pollution, however, since past decades, there has been a growing interest for acoustic pollution. Previous studies on underwater acoustic pollution showed that noise affects vertebrates' behavior, like fish and marine mammals. However, little is known about

invertebrates and there is a huge lack concerning zooplankton species which are widely used as bioindicators in chemical pollution. Consequently, it could be useful to assess the impact of noise in terms of fitness (survival and fecundity). Here, isolated water fleas, *Daphnia magna*, were reared from birth to death in the presence or absence of motorboat noises. Effects on lifespan and clonal offspring production (e.g., clutch size, number of offspring produced along life, etc.) were measured and chronic exposure to boat noise did not affect *Daphnia*'s fitness. The spectral and temporal features of the sounds could explain the results. This study highlights the importance to integrate noise pollution into ecotoxicological research.

## Introduction

Freshwater ecosystems suffer seriously from all types of anthropogenic pollution (e.g., chemicals, light, radioactivity, nanopollution, and sounds) (see for instance Longcore and Rich 2004; André et al. 2011; Song et al. 2020; Jan et al. 2022) but the most documented to date remain chemical pollutions (e.g., industrial effluents, urban waste, pesticides, and drugs) (Truhaut 1977; Villeneuve and Garcia-Reyero 2011). Toxicological studies have documented, in a comprehensive and accurate way, the effects of different types of pollutants (e.g., ion, heavy metals, and drugs), exposure durations (acute or chronic), intensities (e.g., median lethal dose $LD_{50}$), and the interactions between them and with environmental parameters (temperature, acidity, humidity, etc.). Those results have contributed to the general knowledge allowing the evaluation of other types of pollution.

This study focuses on acoustic – or noise – pollution described as a pervasive and omnipresent pollutant found in all ecosystems (terrestrial, marine, and freshwater) (Shannon et al. 2016; Popper and Hawkins 2019; Kunc and Schmidt 2019), and which represents a growing research topic (Williams et al. 2015; Slabbekoorn 2019). Specifically, this study focuses on the effect of ship noise, an important noise disruption threatening aquatic systems (Rountree et al. 2020; Duarte et al. 2021). Moreover, studies on noise pollution have mainly focused substantially on behavior (Richardson et al. 1985; Duarte et al. 2021). Thus, contrary to many ecotoxicological studies since Truhaut (1977), it remains a gap in understanding how noise pollution affects individual fitness, i.e., survival and fecundity (Francis and Barber 2013; Read et al. 2014).

Although the effects of noise on large invertebrates, such as decapods or bivalves, have recently received substantial interest (see the reviews of Popper et al. 2001; Solé et al. 2023), research largely neglected zooplanktonic invertebrates

(Hawkins et al. 2015; Prosnier 2022; ▶ Chap. 96, "Effects of Anthropogenic Noise on Marine Zooplankton"), despite their ecological importance and general use as bioindicators in ecotoxicology (Parmar et al. 2016). Zooplanktons do not possess hearing structures, however, they present mechanoreceptors that allow them to detect particle motion, the other component of a sound with pressure (Gassie et al. 1993; Buskey et al. 2002). For instance, Gassie et al. (1993) found that marine copepods (*Acartia fossae*) can detect water vibrations, and Buskey et al. (2002) showed that vibrations can lead to an individual acceleration of *Acartia* spp. Marine zooplanktons (e.g., copepods) exposed to acute air guns show a reduction of their survival (McCauley et al. 2017; Fields et al. 2019; ▶ Chap. 96, "Effects of Anthropogenic Noise on Marine Zooplankton"). Copepods also show reduced foraging rate during boat noise exposure (▶ Chap. 96, "Effects of Anthropogenic Noise on Marine Zooplankton"). *Chaoborus flavicans* larvae, an important zooplankton predator, show more body rotations, interpreted as an antipredatory behavior, when exposed to boat noise for the first time (Rojas et al. 2021). These works highlight that noise could affect the fitness and behavior of zooplankton species. However, long-term exposure has not been investigated, yet except *D. magna* exposed to chronic broadband noise that showed a higher fitness and a lower speed (Prosnier et al. 2022b).

A particular acoustic parameter of noise is the temporal pattern that it can exhibit (Francis and Barber 2013) with chronic exposure at the one hand and acute exposure at the other (Duarte et al. 2021). Chronic exposure means a continuous or intermittent, regular or random sound (e.g., turbine or boat noise) whereas acute exposure represents a punctual sound (e.g., air gun) (Nichols et al. 2015; McCauley et al. 2017). The spectral (i.e., sound level of each frequency) and temporal patterns of noise are known to affect the behavior and physiology of organisms in different ways. For instance, in underwater chronic noise studies, fish are more affected by a random noise than by a continuous or regular one (Nichols et al. 2015). These results are interpreted as an ability for vertebrates to habituate to some predictable long-term noise exposition (Rojas et al. 2021). Consequently, it asks if some results with unrealistic noise, as continuous broadband noise (Prosnier et al. 2022b), could be extrapolated to real situation where organisms are exposed to boat noise, thus exposed to intermittent random noise (i.e., unpredictable) with high spectral variability.

The aim of this study was to investigate the effect of chronic exposure to motorboat noise (intermittent and random noise with spectral variability) on the fitness of the water flea *Daphnia magna*, a common zooplankton species widely used in ecotoxicology (Ebert 2022). Previous studies found no change in their mobility when exposed to acute noise (Sabet et al. 2015, 2019), whereas prior experiment with chronic exposure to broadband noise (i.e., a continuous noise) showed alterations in both fitness and behavior (Prosnier et al. 2022b). Consequently, motorboat noise should negatively affect *D. magna* fitness, by reducing survival, fecundity, or both, according to McCauley et al. (2017) and Solé et al. (2023). However, note that in numerous cases no effect was observed (Solé et al. 2023), and a positive effect was found for *D. magna* chronically exposed to broadband noise (Prosnier et al. 2022b).

## Material and Methods

### Collection and Maintenance of Organisms

*Daphnia magna* had been purchased from Aqualiment (Grand Est, France) and stored in a 20-L rearing aquarium, filled with aged tap water (physiochemical composition is available on Zenodo repository (Prosnier et al. 2022a)), for 1 month. They were reared at 18 °C under a 12:12 light:dark cycle. *Daphnia magna* were fed, every 2 days, with 0.05 g of algae (i.e., 736 mJ) with a mix of 80% of *Arthrospira platensis* and 20% of *Aphanizomenon flos-aquae* (Algo'nergy® Spiruline + Klamath).

### Fecundity and Mortality

Reproductive success and survival were measured during an experiment (similar as done in Prosnier et al. 2022b). Gravid *D. magna* were collected from the rearing aquarium and isolated in 50-mL, 0.3-mm jars containing Volvic® water. Newborns (< 24 h) were transferred individually into 150 mL (5.6 × 8.6 cm) glass microcosm, closed with a 0.3 mm mesh tissue allowing water flows and noise transmission (Fig. 1).

Eighteen glass microcosms were disposed at 20 cm of an underwater loudspeaker in four 150 L rectangular tanks (75 × 60 × 35 cm), filled with 90 L of aged tap water, at 20–22 °C and under a 12:12 light:dark cycle. Silence was broadcasted in the two control tanks and a daily boat noise playlist (see below) used as treatment was broadcasted in the two other tanks. For each *D. magna* mother, half of the newborns were exposed to the control treatment, and the other half to the noise treatment, therefore individuals were clones in the two acoustic conditions. Every day, survival and newborns production were controlled – if *D. magna* spawned, offspring were counted and taken off. Every 2 days, individuals were fed with 2 mL of algae (1 g/L), and water was changed once a week. During the first 8 days of the experiment (i.e., before the first hatching), dead *D. magna* were replaced by new newborns (isolated mothers were maintained in 50 mL jars during this initial period to be able to initiate new replicates with newborns) to increase the number of replicates. Experiments were performed with a total of 115 juveniles (58 in control and 57 exposed to noise) coming from 25 mothers; almost half of the juveniles in each condition (26 in control and 23 in noise) reached maturity. The experiment lasted 46 days, from the birth of the first individual to the death of the last one (the oldest *D. magna* survived 39 days).

Based on daily survival and daily clutch, populational data was analyzed using the Euler-Lotka equation ($\sum f_x m_x e^{-rx} = 1$), with $f_x$ the fecundity at age $x$, $m_x$ the survival at age $x$, and $r$ the intrinsic rate of increase. This equation allows to calculate the reproductive output $R_0$ ($R_0 = \sum f_x m_x$), the generation time $G_t$ $\left(G_t = \frac{\sum x f_x m_x}{\sum f_x m_x}\right)$, and the intrinsic rate of increase $r$ $\left(r = \frac{\log R_0}{G_T}\right)$ (Leung et al. 2007; Starke et al. 2021).

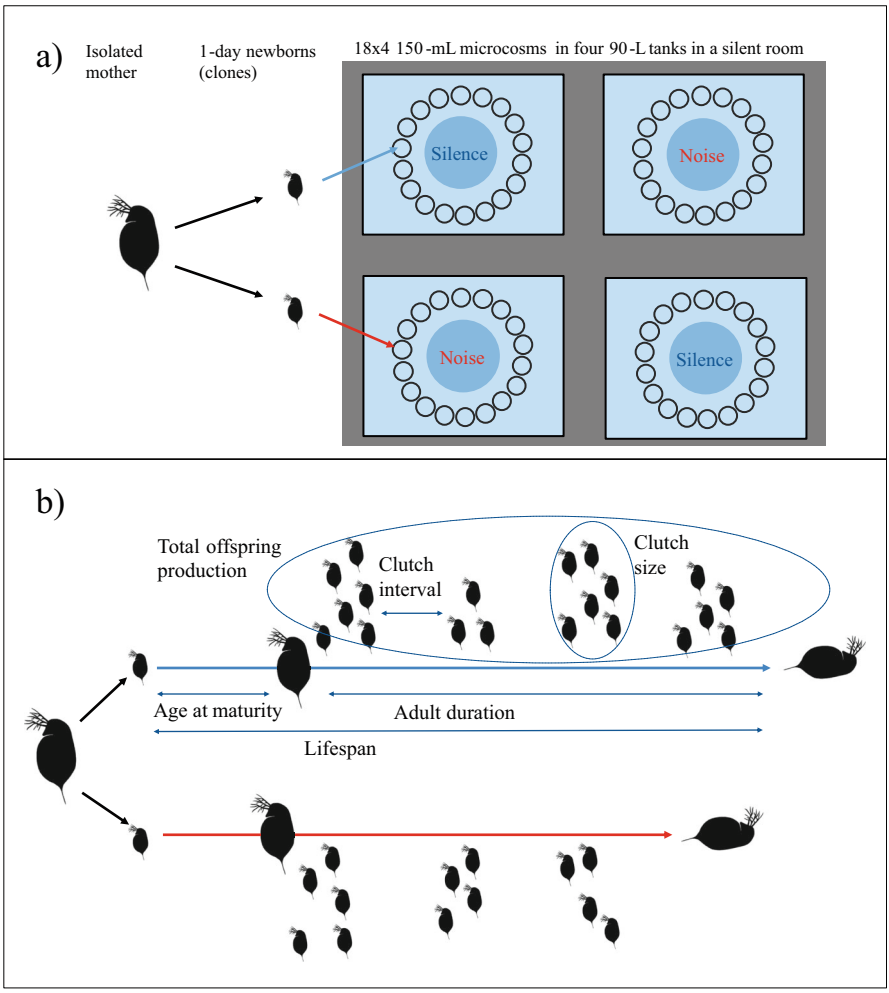

**Fig. 1** Setup. (**a**) Experimental design. In the four tanks blue circles are loudspeakers, dark small circles are microcosms closed with net. (**b**) Summary of all measures from birth to death of clonal individuals in the two treatments

## Acoustic Treatments

*Daphnia magna* were exposed to two acoustic treatments (see Rojas et al. 2021 for more details): a repeated 1 h playlist without sound for the control (i.e., only the ambient noise), or boat noise for the treatment with a playlist including 15 recordings of motorboat sounds previously made in the Grangent lake (45°45′07.54″N, 4°25′56.47″E, Loire, France). Their intensity was modulated from 0 to −25 dB Re 1 μPa by 5 dB to create 75 sounds from 103–150 dB RMS Re 1 μPa – a naturally occurring range of noise levels found in lakes (V. Médoc, pers. obs.) – that were

duplicated to obtain the total of 150 boat noises used in the experiment. Boat noise playlist was broadcasted from 9 a.m. to 6 p.m. (Fig. 2a). Both playlists (stereo WAV files) were generated using the software Adobe Audition 2020 (13.0.0.519, Adobe Systems Inc., Mountain View, CA, USA) and were played back using a Zoom® H4n recorder connected to an amplifier (DynaVox® CS-PA 1MK), and an underwater loudspeaker UW30 (Electro Voice®).

To check spectra and noise levels in both control and noise microcosms, recordings were made (Fig. 2b-e) with a Zoom® H4n coupled to a hydrophone (Aquarian Audio H2A-HLR Hydrophone, frequency response from 10–100 kHz) previously calibrated with a hydrophone (8104, Brüel & Kjær, Naerum, Denmark; sensitivity

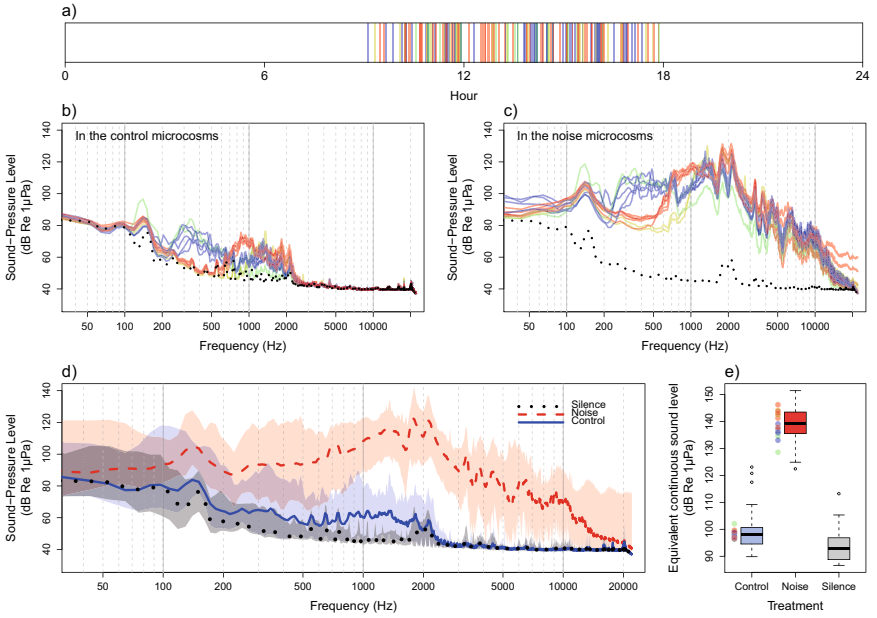

**Fig. 2** Acoustic treatments. (**a**) 24 h temporal sequence of the broadcasted motorboat noises, from 9 a.m. to 6 p.m. Each vertical line represents a boat. (**b**) Soundscapes of the control microcosms recorded in half microcosms with the records of the 15 boat sounds (solid lines), broadcasted at their maximal intensity in the noise tanks, and silence (dotted line). (**c**) Soundscapes in the noise microcosms recorded in half of the microcosms during the broadcast of the15 boat sounds at their maximal intensity (solid lines) and silence (dotted line). (**d**) Spectra in half of the microcosms. Thick lines are means for control (full blue line) and noise treatment (dashed red line) during the 15 boat broadcasts at their maximal intensity, and during the silence period (dotted black line). Shaded areas delimit the min and max sound pressure level. (**e**) Sound levels in half of the microcosms. Central bars represent the median, boxes the interquartile range, and dots the outliers (> 1.5 times the interquartile range). Colored dots are the sound levels in control and noise microcosms during the 15 boat broadcasts at their maximal intensity. The four colors (red, yellow, green, and blue) correspond to four noise structure spectra that were visually determined (for instance red and yellow have low energy between 200 and 700 or 1000 Hz compared to green and blue boat noises)

−205 dB re. 1 V µPa − 1; frequency response from 0.1 Hz to 180 kHz) connected to a sound level meter (Bruël & Kjaer 2238 Mediator, Naerum, Denmark). Emitted boat noises were firstly corrected to make their spectra closer to those of the initial 15 boat noise spectrums (Fig. 2). Boat noises were rerecorded only in half of the microcosms (in each tank) given that they were qualitatively and quantitatively similar due to the symmetry of the setup and after controlling with a broadband noise (Prosnier et al. 2022b). Note that the playback of boat noise was perceived in the control microcosms with intensities around 100 dB RMS Re 1 µPa, which was almost comparable to the sound level during the silence period (Fig. 2e), allowing to neglect noise transmission between the treatments. Particle motion cannot be measured due to the absence of adequate equipment, despite its importance for non-hearing species (Nedelec et al. 2016). However, Olivier et al. (2023) showed that results can still be qualitatively relevant when based solely on sound pressure level.

## Statistical Analyses

Statistical analyses were performed using R (version 4.2.2) with a significant threshold at 5%. Data allowed to analyze separately the effects on mortality (death age and adult survival) and fecundity (age at maturity, clutch frequency, mean clutch size, and daily clutch size). The combination of mortality and fecundity was used as a proxy of fitness and quantified through total offspring production. Data was also described at the population scale using the Euler-Lotka equation (but without statistical analysis due to absence of populational replicates). A survival analysis (log-rank test) was performed to compare survival (death age and adult duration) and age at maturity (first clutch age) between the control and noise treatments. For the fecundity parameters, only individuals that clutched at least one time (i.e., that reached maturity) were considered in the analyses. Clutch frequency (i.e., mean time between two clutches) and mean clutch size were analyzed using linear mixed-effects model, with tanks as random effect, thanks to the normal distribution of the data checked with a Shapiro test. The effect of both noise and age on daily clutch size was analyzed by a type II analysis of variance, completed with a pairwise Wilcoxon test between the treatments within each age. To test noise effect on the total number of clutches and offspring along life a generalized linear mixed-effects model was used, with tanks as random effect and a log function as the link function for Poisson distribution.

## Results

Chronic boat noise did not affect (Table 1) the survival of *D. magna* ($p$-value = 0.51, Fig. 3a) with a median survival of 4 days for the control and 5 days for the noise treatment. It did not affect fecundity parameters, with clutch interval around 2.5 days ($p$-value = 0.24, Fig. 3b), mean clutch size around 10 offspring ($p$-value = 0.74, Fig. 3c), and age at maturity around 8 days ($p$-value = 0.65). Daily clutch size was not influenced by noise (noise: $p$-value = 0.89, noise x age: $p$-value = 0.35,

**Table 1** Statistical results of chronic boat noises effects on fecundity and mortality of *Daphnia magna* (Fig. 3)

| | Mortality | | Reproduction | | | Fitness | |
|---|---|---|---|---|---|---|---|
| | Survival | Adult duration | Age at maturity | Clutch interval | Mean clutch size | Number of clutches | Number of offspring |
| df | 1 | 1 | 1 | 1 | 1 | 1 | 1 |
| $\chi^2$/W | 0.4 | 1.6 | 0.2 | 1.4029 | −0.54276 | 3.8197 | 1.8263 |
| *p*-value | 0.51 | 0.21 | 0.65 | 0.236 | 0.737 | **0.031** | 0.099 |
| $R^2$ | 0.0041 | 0.03 | 0.0046 | 0.03 | 0.007 | 0.096 | 0.327 |

pairwise: *p*-values $> 0.38$; Fig. 4), but changed with age (*p*-value $= 0.003$) with larger clutches at intermediate ages. However, taking into account the whole lifespan, there was an effect on the total number of clutches (*p*-value $= 0.003$) with five clutches for the control and six clutches for the noise treatment, and a tendency for higher total offspring production under boat noise exposure (*p*-value $=$ 0.099, Fig. 3d, e), with on average 60–70 newborns.

The populational analysis done with the Lotka-Euler equation confirmed the tendancy on total offspring production with a reproductive output ($R_0$) higher for the noise treatment with 63 offspring compared to the 54 offspring in control. Generation time ($G_T$) was longer in the noise treatment, with 16.6 days, compared to the 15.2 days in the control. The combination of both led to an intrinsic rate of increase of 0.25 $day^{-1}$ in the noise treatment compared to 0.26 $day^{-1}$ in the control.

## Discussion

This study investigated the effect of exposure to chronic boat noise on the fitness of the water flea *Daphnia magna*. Contrary to what expected, no effect on the survival and fecundity parameters was observed, which differed from results obtained with exposure to another type of chronic noise (Prosnier et al. 2022b). Such difference in the results might result from variations in the temporal and spectral features of the noise. Moreover, as one of the first experiments on chronic noise, it raises questions on the interactions with other pollutants, and on the effects on complex communities.

Chronic boat noise had no effect on *Daphnia magna*'s fecundity and survival. These results are opposite to those on acute exposition of copepods to air gun: After passing a boat with air gun, McCauley et al. (2017) observed a high mortality for numerous marine zooplankton species, as copepods; and Fields et al. (2019) showed that air gun exposure leads to an increased mortality in *Calanus finmarchicus* within an hour. In addition, results are opposite to those of Prosnier et al. (2022b), where an exposition to a continuous broadband noise leads to a surprising increase of *D. magna*'s fitness due to higher survival and clutch size. Here, although boat noise had no statistical effect on the survival and fecundity parameters, there was a tendency for a higher total offspring production with noise, which would be consistent with the results of Prosnier et al. (2022b). However, at a population scale, the

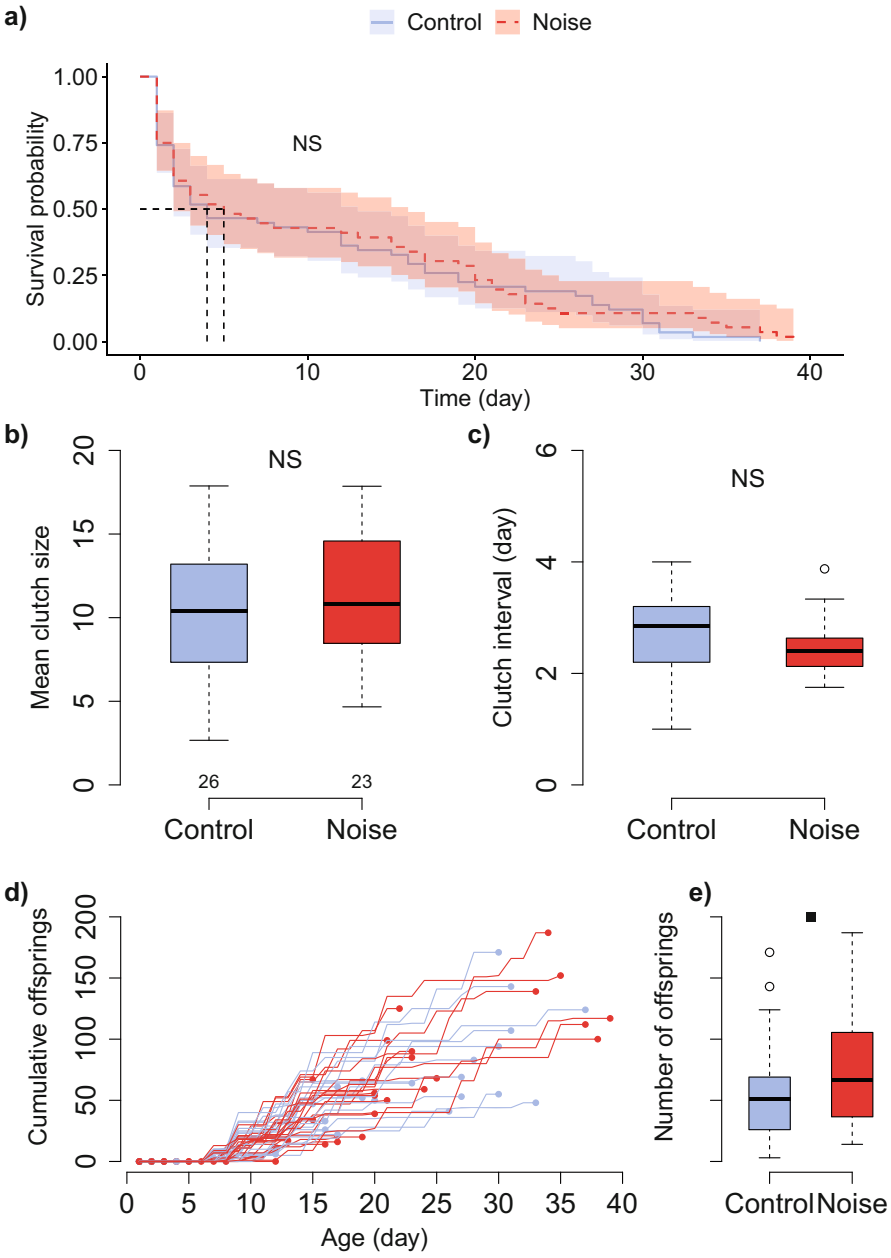

**Fig. 3** Effects of noise treatments on *Daphnia magna* survival and fecundity. (**a**) Survival of *D. magna*; (**b**) mean clutch size; (**c**) clutch frequency; (**d**) cumulative offspring production along life; and (**e**) total number of offspring during lifetime. Numbers in **b**) are the numbers of *D. magna* for the two treatments for **b**, **c**, and **e**. **a**) Representation according to the Kaplan-Meier method; **b-e**) central bars represent the median, boxes the interquartile range, and dots the outliers (> 1.5 times the interquartile range). Statistical analysis: dot *p-value* < 0.1, * *p-value* < 0.05; ** *p-value* < 0.01; NS *p-value* > 0.1. See Table 1 for statistical values

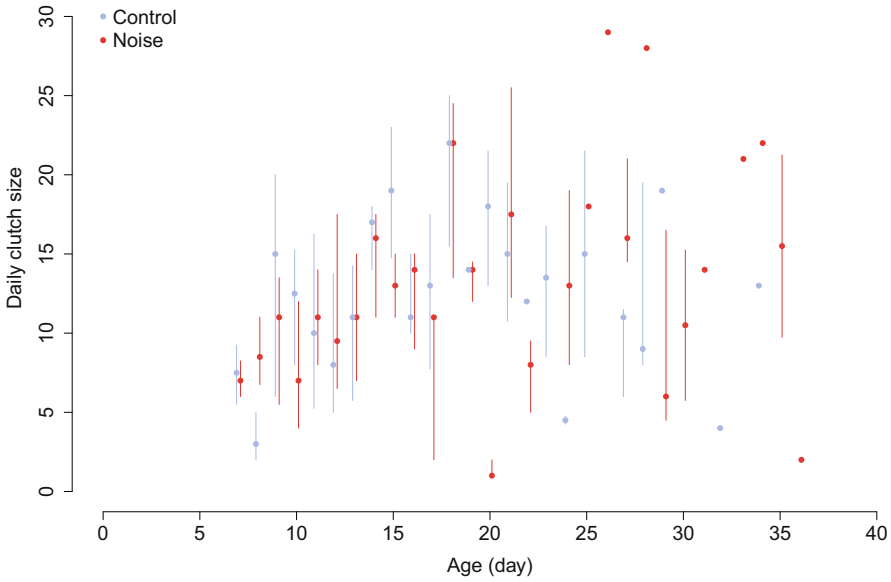

**Fig. 4** Effects of noise treatments on *Daphnia magna* daily clutch size. Dots represent the median of the daily clutch size and lines are interquartile ranges. See Fig. 3a, d as complement for the number of individuals at each age. Note that there could be only one clutch for an age (i.e., no interquartile lines) or clutches only for one treatment (i.e., only one point for an age)

Euler-Lotka equation suggests a tendency for a lower growth when exposed to boat noise due to a shorter generational time. These differences, or at least these lower intensities of effects, suggested that the effect of chronic noise pollution, on zooplankton species, could depend on the temporal and spectral structure of noise. Indeed, in Prosnier et al. (2022b), the broadband noise broadcasted was continuous, at high level (130 dB RMS re 1 µPa) for all frequencies (from 0.1–20 kHz), whereas, in this study, irregular sounds (a total of 2 h of noise per day) were used at various intensity levels (from 108–136 dB RMS re 1 µPa) and various frequencies (some boat noises with low intensity between 200 and 800 Hz). It is already known that in hearing vertebrates (i.e., with dedicated organs to detect as inner ear sound pressure variation) animals respond differently to chronic noise pollution if there are, or not, temporal variations (continuous, regular, and irregular) or spectral variations (i.e., variation in the frequencies), thus predictable or not (Francis and Barber 2013). Nichols et al. (2015) showed that fish were more stressed (higher cortisol concentration) with a higher noise level (from 126–141 dB RMS re 1 µPa), and with an intermittent random noise (i.e., unpredictable) compared to a continuous noise. However, the review of de Jong et al. (2020) on noise effects on fecundity revealed that continuous noise with spectral variations, such as boat noise, was more prone to impact physiological markers (cortisol level, ventilation rates, and metabolic rate) and behavior (startle and freeze responses, and horizontal and vertical avoidances). Another study on zebrafish larvae showed a higher negative effect of a continuous

white noise on survival and a higher cortisol concentration (Lara and Vasconcelos 2021). Thus, it seems that for hearing vertebrates, depending on the developmental stage and the considered characteristic, both temporal and spectral characteristics need to be considered. For zooplankton, little is known about the importance of noise patterns. Here, the comparison with Lara and Vasconcelos (2021) and Prosnier et al. (2022b) suggests that, contrary to what is reported with fishes, negative effects seem higher with a continuous noise.

Despite there was no effect on fecundity, it would be necessary to focus on the offspring coming from mothers exposed to noise. Here, there was no qualitative effect reported during the current experiments, i.e., all the offspring produced seemed viable and mobile, and Prosnier et al. (2022b) observed no effect on size. This would be consistent with the study of Day et al. (2016) where the exposure to air gun did not affect the embryonic development of the spiny lobster *Jasus edwardsii* (Decapodae). However, air gun exposition reduces growth and development stage of *Acartia tonsa* nauplii (▶ Chap. 96, "Effects of Anthropogenic Noise on Marine Zooplankton"). This aspect seems important as it is known that mother and early stress could affect daphnia's development (Mittmann et al. 2014; Mushegian et al. 2016) and that stress effects could differ across generations (Campos et al. 2016). Consequently, impact studies on noise should focus on embryonic development and perform multigenerational experiments to determine long-term effects of chronic noise, possibly due to embryonic misdevelopment (Mushegian et al. 2016), maternal effects (Radersma et al. 2018), and acclimatation or adaptation (Ringot et al. 2018; Abdullahi et al. 2022).

An interesting question is to consider the effect of noise as part of cocktails of pollutants. It is now a common question in ecotoxicology to ask how stressors (e.g., pollution, temperature, and food quality) act synergistically (Altshuler et al. 2011). For instance, Starke et al. (2021) showed that food quality impacts more *D. pulicaria* at some higher temperature due to the increased metabolism. Prosnier et al. (2015) studied the antagonistic effect of copper and nutrient enrichment on the *Daphnia* – algae interaction with modeling methods. Regarding noise, Stenton et al. (2022) showed both synergetic and antagonistic effects of noise and cadmium exposure on Norway lobster larvae (*Nephrops norvegicus*), depending of the considered parameters (survival, development, oxidative indicators). Another, McMahon et al. (2017) studied interactive effects of both light and noise pollutions on a frog-parasite interaction. Moreover, it could be also useful to better understand experimental results. Many controlled setups (light, temperature, and nutrient controlled) produce uncontrolled noises (L. Prosnier, pers. obs.), but their potential interactions with the stressors studied are unknown. For instance, here, there was a very high mortality in juvenile compared to similar studies (Parisot et al. 2015; Prosnier et al. 2023b) that suggests suboptimal condition for *D. magna* (i.e., other stressor than the noise) that potentially affects outcomes through the masking of effects, for example. However, on the other side, suboptimal conditions could make individuals more prone to be affected by an additional acoustic stress. Note that, despite the same suboptimal conditions, Prosnier et al. (2022b) obtained a difference between the control and noise treatments. The recent *Larvosonic* system, developed by Olivier et al. (2023),

could be useful to study the impact of noise on zooplankton with a better control of the environmental conditions.

This study is a first step in our understanding of the importance of noise patterns for invertebrates (i.e., predictable versus unpredictable noise) in comparison with vertebrates. It is mandatory to better understand how noises could affect complex communities with both vertebrates and invertebrates (Francis et al. 2009; Slabbekoorn and Halfwerk 2009; Slabbekoorn 2019). For instance, Rojas et al. (2023) experimented boat noise effects on a freshwater community. In this experiment, (1) unpredictable noise should affect more fishes, at top trophic levels, than invertebrates and (2) bottom-up effects could also be expected due to various reactions of zooplanktonic species. About effects on invertebrates, the diversity of responses by various zooplanktonic species is still lacking (► Chap. 98, "Response of Freshwater Zooplankton Communities to Chronic Anthropogenic Noise") – for instance if zooplanktonic predators are affected in the same way than their zooplanktonic prey. Moreover, indirect effect could be expected in a community (Read et al. 2014). For instance, noise do not affect frog abundance but reduce their parasite's one (McMahon et al. 2017). This interest for invertebrates, in particular arthropods, raises also for terrestrial communities (Morley et al. 2014). Thus, a more general overview of the impacts of anthropogenic noises on all invertebrates should be beneficial to prevent them (Francis and Barber 2013).

**Acknowledgments** The authors would like to thank all the people who contributed to the success of this experiment: Nicolas Boyer and Aurélie Pradeau for *Daphnia* rearing and providing material, Léo Papet, Joël Attia, and Jérémy Rouch for the acoustic treatments and analysis and for providing material, Olivier Valéro for sound recording, Marilyn Beauchaud and Paolo Fonseca for acoustic calibration, Théophile Turco for help in the analyses, and the EYD (ENES Young Discussion) for the useful discussions. Authors also thanks Marie-Agnés Coutellec and the anonymous reviewer for their useful comments, and Cosio (2023) for its recommendation. A preprint version of this chapter has been peer-reviewed and recommended by PCI Ecotox Env Chem (https://doi.org/10.24072/pci.ecotoxenvchem.100103).

Data, script, and code are available on Zenodo. https://doi.org/10.5281/zenodo.7339910 (Prosnier et al. 2022a).

**Abstract**

Man-made sounds are now recognized as a pervasive pollutant, and impacts on wildlife have been researched for many years. However, less knowledge is available on certain species, particularly small freshwater invertebrates, which are abundant, highly diversified, and occupy key positions in food webs. Also, it is not clear whether the responses to noise observed at the level of individuals have consequences on communities. A mesocosm investigation was performed to assess the response of a freshwater planktonic community to chronic motorboat noise. Noise was expected to disturb trophic links within the community and particularly the consumption of cladocerans by dipteran larvae. To test this hypothesis, the functional response of *Chaoborus* larvae feeding on *Daphnia* was derived, and their behavior during the foraging process was recorded in microcosms (aquariums). Although noise did not induce obvious alteration in the community composition, a significant increase in the abundance of cladocerans was found that was not supported by the results of the microcosm investigation, showing no difference in *Chaoborus* functional response or behavior between the noisy and noiseless conditions. The results of this chapter suggest that the composition of freshwater zooplankton and particularly cladocerans is likely to be altered by chronic noise, with further investigations needed to understand the mechanisms. They also illustrate how scaling up the effects of noise from individual responses to community remains difficult.

**Keywords**

Freshwater zooplankton · Motorboat noise · Functional response · Trophic links · Daphnids · *Chaoborus* larvae

## Introduction

Threats to freshwaters include habitat degradation, flow modification, over-exploitation, invasive species, and disease (Dudgeon et al. 2006; Williams-Subiza and Epele 2021), and result in a decline in biodiversity at rates that exceed what is reported in most terrestrial and marine habitats (McRae et al. 2017). Anthropic pressures on freshwaters are not expected to ease given the growing human needs and also because people seek to reconnect with nature, a need reinforced by the recent crises like the Covid-19 pandemic. Managers of freshwater socio-ecological systems worry about the rise of recreational motorized activities and their associated noise emissions (Reid et al. 2019) that can disturb the various populations of users as well as wildlife.

Noise pollution has recently been categorized as an emergent threat to freshwaters (Reid et al. 2019), with motorized boats as the most widespread source of noise. Impacts of noise on fishes are well documented with physiological stress responses and alterations in communication, reproduction, mobility, foraging, and predator

avoidance (reviewed by Mickle and Higgs 2018; Popper 2003; Slabbekoorn et al. 2010). Although invertebrates are highly diverse, widespread, and possess statocysts or external sensory hairs that allow them to perceive sounds through particle motion (Popper and Hawkins 2018), interest in their response to noise pollution came later compared to vertebrate species, and 77% of the impact studies on invertebrates are less than 10 years (Wale et al. 2021). While cephalopods, large crustaceans (crabs, lobsters, and shrimps), and bivalves are among the most common model species studied (Fernández Robledo et al. 2019; Smith et al. 2018), little is known about small zooplankton despite its pivotal role in the functioning of aquatic food webs, maintaining energy flow between primary producers and higher trophic levels (Turner 2004; Vargas et al. 2010).

Available evidence on zooplankton shows a diversity of effects. While very loud emissions from seismic surveys have been found to cause mortality in both larval and adult stages of marine zooplankton (McCauley et al. 2017), vessel noise can act as a positive cue for larval settlement in the blue mussel *Mytilus edulis* (Jolivet et al. 2016). Exposure to low (30 Hz) and high (20 KHz) frequencies seems to promote grazing in the marine copepod *Acartia tonsa* (Yiwei and Berggren 2018). The water flea *Daphnia magna* (Cladocera) shows no alteration in mobility when exposed to either continuous or intermittent 300–1500 Hz band-pass filtered white noise (Sabet et al. 2016). More recently, it was found that larvae of the phantom midge *Chaoborus* (Diptera) made more body rotations in response to motorboat noise (Rojas et al. 2021).

In addition to the imbalance between vertebrates and invertebrates in the very rich literature on the impacts of noise pollution, there is also a discrepancy between the biological integration levels with a lack of research on ecosystems compared to behavioral and physiological outcomes (Sordello et al. 2020). Although a few empirical evidences from terrestrial systems illustrate how noise-induced changes in behavior can propagate through nested ecological interactions (Francis and Barber 2013; Phillips et al. 2021), scaling up the effects of noise from individuals to populations and communities without any experimental validation might overestimate impacts.

In this chapter, the effect of chronic motorboat noise on the dynamics of a freshwater zooplankton community was investigated, bringing together cladocerans, copepods, ostracods, and dipterans. Noise was expected to alter the structure of the community through changes in abundance and/or changes in the activity of the predators. To test this hypothesis, the response of the community was evaluated in mesocosms over 6 weeks, and, as a second part, it was assessed how the *per capita* predation rate of *Chaoborus* larvae (dipterans) varied with cladoceran density (the functional response) under control and noisy conditions. *Chaoborus* larvae are a relevant dominant predator of large filter-feeder zooplankton (cladoceran species) known to be a main structuring force within the community (Castilho-Noll and Arcifa 2007; Vanni and Findlay 1990). *Chaoborus* larvae have been found to make more body rotations in response to motorboat noise (Rojas et al. 2021), which could be associated with reduced foraging. Noise might therefore alter community dynamics through the modulation of the trophic pressure by *Chaoborus* larvae.

## Materials and Methods

### Mesocosm Experimental Design

The mesocosm experiment lasted 6 weeks from September to October 2021 and was carried out on the PLANAQUA platform of the CEREEP-Ecotron Ile-de-France research station (48° 16′10.92 N, 2° 43′50.879 E, Seine et Marne, France). Two acoustic conditions (with or without boat noise, see section "Playback Tracks") were applied in 16 outdoor plastic enclosures (diameter: 1.40 m, depth: 1 m, volume: 1 $m^3$, n = 8 replicates *per* condition) positioned in two lines and distributed in a systematic way to balance the effect of spatial distribution between the two conditions. All mesocosms included a 15-cm layer of Loire sand and were filled 2 months before the experiment with water from the littoral zone of one of the two storage lakes from the PLANAQUA platform, to reach a 70-cm water column. An underwater loudspeaker (Electrovoice UW30, 0.1–10 kHz) was fixed 10 cm below the water surface in the middle of each mesocosm. It was connected to an amplifier (Dynavox CS-PA 1MK), itself connected to an audio player (Handy's H4n zoom), both placed inside a waterproof electric box next to the mesocosm. One week before starting the experiment, temperature loggers attached to a ballast were positioned in the sunniest part of each mesocosm. The water temperature was 24 °C at the beginning of the experiment and decreased with some small fluctuations over time to reach 18 °C at the end of the experiment.

### Zooplankton Dynamics

At day 0, +10, +26, and +42, 8 L of water were sampled with a 2-L sampling bottle at four different positions and depths in each mesocosm. Water was filtered with a 50-µm mesh size nylon filter to collect zooplankton species, which were immediately fixed in 15 mL of 90% ethanol. Species identification and classification on day 0 and day +42 were performed by the engineering office © 2021 SAGE Environment (Annecy, France). To save costs, accurate classification was done for all the mesocosms at day +42, while the data *per* noise condition at day 0 was pooled. At day +10 and day +26, only the numbers of cladocerans and *Chaoborus flavicans* larvae were quantified, as they were the most structuring trophic links expected in the communities. At the end of the experiment, a multiparameter probe (YSI ExO-2) was used to assess the main physicochemical parameters (temperature, pH, conductivity, turbidity, and chlorophyll).

### Functional Response and Behavior of *Chaoborus* Larvae

The functional response (FR) of *Chaoborus* larvae feeding on five densities (3, 6, 12, 24, and 48) of *Daphnia* sp. coming from the storage lake has been derived with four replicates *per* density and *per* noise condition. To account for potential

habituation to the noise condition and better explain what happened in the mesocosms, larvae from the control and noisy mesocosms were collected and exposed to the same noise condition (see section "Playback Tracks") during the FR tests. The experiment took place in two 90-L rectangular tank (75 × 60 × 20 cm, one *per* noise condition) filled with filtered (50-μm mesh size) water from the storage lake. A UW30 underwater loudspeaker was positioned in the center of each tank 20 cm above the bottom. A single larva was presented to the water fleas at one of the five densities (3–48) for 8 h in a 150-mL glass beaker (height = 7.2 cm, diameter = 7 cm) covered with a 0.03 mm mesh allowing water flow only. A total of 20 beakers *per* mesocosm were used and placed at 10 cm all around the loudspeaker. At the end of the experiment, each larva was removed and put into 90 °C alcohol to be measured under a binocular loop and using a rule. The number of remaining prey was counted to determine the number of prey eaten.

The behavior of the *Chaoborus* larvae was studied in a 50-L aquarium (length×width×height: 60 × 25 × 35 cm) filled with filtered water from the mesocosms and equipped with an UW30 underwater loudspeaker in the center and 20 cm above the bottom. A 150-mL glass beaker containing 20 larvae and covered with a mesh allowing water flow only was positioned inside the aquarium at 10 cm of the loudspeaker. The number of body rotations performed by each larva was counted over a 20-min period of ambient noise (recorded in one of the mesocosm) or ambient noise supplemented with motorboat noise (see section "Playback Tracks").

## Playback Tracks

An Aquarian Audio H2A-XLR hydrophone (frequency response from 10 Hz to 100 kHz) connected to a ZOOM H4next Handy recorder was used for all the recordings and a UW30 underwater loudspeaker (Electrovoice) connected to a Dynavox CS-PA 1MK amplifier itself connected to a ZOOM H4next Handy player for all the playbacks.

Natural background noise did not differ between the mesocosms and was around 90 dB re 1 μPa. In the control mesocosms, a 1-h audio track of silence was looped continuously. To make the audio tracks of the noisy mesocosms, 25 sounds from commercial vessels and recreational boats were recorded from the river Seine after the lock of Champagne sur Seine (48°22′1.348 N, 2°29′37.401 E) at 1 m depth. The 25 original sounds were duplicated, changing a bit the intensity between the two replicates, and the resulting 50 sounds were distributed over 14 consecutive 1-h audio tracks of silence so as to mimic the mean daily activity of the Champagne sur Seine lock (Table 1). The boat sound audio tracks were broadcasted from 6 a.m. to 8 p.m. and silence the rest of the time. The intensity of each boat sound was modified with the Audacity 2.2.1 software to obtain realistic signal-to-noise ratios (SNR) ranging from 25 to 30 dB (Fig. 1a), calculated after re-recordings in the mesocosms and using the *SNR* function of *Seewave* R package (Sueur et al. 2008) with:

**Table 1** Composition of the 14-h playback track broadcasting silence supplemented with motorboat sounds during the mesocosm experiment

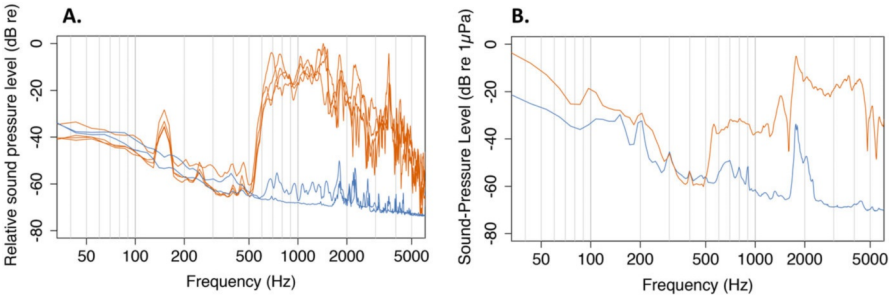

**Fig. 1** Sound spectra of the two noise conditions (ambient noise in blue and boat noise in red) in: (**a**) the mesocosms used for the community investigation (each orange line corresponds to a recording of the same boat noise made in four noisy mesocosms and each blue line corresponds to a recording of 3 min of ambient noise made in two control mesocosms) and (**b**) the aquariums (50-L rectangular tanks) used for functional response derivation

$$\mathrm{SNR} = 20 \log_{10}(\mathrm{RMS}_{\text{boat sound}}/\mathrm{RMS}_{\text{ambient noise}})$$

where RMS corresponds to the root-mean-square sound pressure level.

For the control condition of the FR experiment, an 8-h (playlist 1) audio track of natural background noise previously recorded in one of the mesocosm and whose level was adjusted to match that in the mesocosm around 90 dB re 1 µPa (Fig. 1a) was broadcasted. For the boat noise treatment, an 8-h recording (playlist 2) from a noisy mesocosm (Fig. 1a) was broadcasted using the same process than for control condition.

Concerning the behavior of the *Chaoborus* larvae, a 20-min period of playlist 1 was randomly selected to be used for the control condition and a 20-min sequence of playlist 2 corresponding to the period with the largest number of boat sounds was used for the noisy condition (Fig. 1b).

## Data Analyses

The R software version 4.0.3 (R Core Team 2018) was used for all the statistics with a significance level of 5%. A chi-square test of independence was performed to assess the homogeneity of taxa at day +0 between both noise treatments. A generalized linear mixed models with a quasi-Poisson distribution (GLMMTMB) was performed to explain the dynamic of cladocerans as a function of three fixed factors and their interactions: the noise condition (ambient or motorboat noise), the

abundance of *Chaoborus flavicans* larvae, the sampling date, and considering the tank identity as random factor to account for repetitive measures. A quasi-Poisson (or quasi-likelihood) distribution was used because it is recommended to consider the overdispersion (variance exceeding the mean) often found in count data (Ver Hoef and Boveng 2007). A Wilcoxon test was used to test for significance the difference in physiochemical parameters between the two noise conditions at day +42.

For the FR experiment, a one-way ANOVA test was performed to detect heterogeneity in the size of *Chaoborus* larvae between the two noise conditions as the data met the normality and homoscedasticity assumptions. FR analysis was done with the *Frair* R package (Pritchard et al. 2017). The three main categorical FR types (linear type I, Rogers' type II, and Hassel's type III) were modeled by maximum likelihood estimation (Bolker 2008) with the *frair_fit* function, and the fits were compared using the second-order Akaike information criterion (AIC). This allowed to exclude the types II and III whose AIC values were always the highest ($\Delta AIC > 2$ with the type I). A type I FR is characterized by a linear increase of consumption rate as a function of prey density (Holling 1959). Both FRs being of type I, the delta method implemented by the *frair_compare* function was used to perform pairwise FR comparison from parameter estimates with the null hypothesis that the difference in attack rates (D*a*) between the two FRs does not differ from zero (Pritchard et al. 2017). In addition, the overlaps of the 95% confidence intervals (BCa CIs) which correct for bias and skewness in the distribution of bootstrap estimates (*a* and *h* parameters) were inspected using the *frair_boots* function (bootstrapping method, $n = 2000$) (Pritchard et al. 2017).

Concerning the behavior of the *Chaoborus* larvae, the total number of body rotations was compared between the two noise conditions using a generalized linear mixed model with a negative binomial distribution with the noise condition (ambient or motorboat noise), the sampling date as predictors, and the tank where they came as a random factor to account for repetitive measures.

## Results

At day +0, communities between ambient noise and ambient + motorboat noise did not differ in taxa density (chi-square test = 63.333, df = 56, p-value = 0.2336). At day +42, no significant differences in the physicochemical parameters between the two noise conditions (Tables 2 and 3) were found.

The zooplankton communities of the noisy and noiseless mesocosms included cladocerans (*Daphnia* sp., *Bosmina* sp., *Chydorus* sp., and *Ceriodaphnia* sp.), copepods (especially Calanoïda and Cyclopoïda), ostracods, and dipterans (especially *Chaoborus* larvae). Cladocerans species and more particularly *Daphnia* sp. were the most abundant at the beginning and at the end of the experiment in the control mesocosms (57.31% and on average 52.11%, respectively), whereas in

**Table 2** Physicochemical parameters (mean ± SD) in the control (ambient noise) and noisy mesocosms (boat noise) at the end of the experiment, with the results of the Wilcoxon tests performed to test the difference between the two noise treatments

| Parameters | Ambient noise (mean ± SD) | Boat noise (mean ± SD) | W | p-value |
|---|---|---|---|---|
| **pH** | 7.60 ± 0.59 | 7.70 ± 0.37 | 266.5 | 0.665 |
| **Temperature °C** | 15.66 ± 0.08 | 15.66 ± 0.13 | 257.5 | 0.536 |
| **[Chlorophyll] µg/L** | 1.49 ± 0.87 | 1.71 ± 1.68 | 331 | 0.38 |
| **ODO mg/L** | 9.64 ± 0.32 | 9.62 ± 0.33 | 277.5 | 0.836 |
| **Conductivity uS/cm** | 165.32 ± 8.11 | 167.66 ± 5.74 | 212.5 | 0.121 |

the noisy mesocosms, copepods and cladocerans were more abundant at day +0 (48.25% and 39.84% respectively) but cladocerans increased to reach 71.24% of the whole community at the end of the experiment (Table 4, Fig. 2).

The abundance of cladocerans was significantly increased by noise (p-value = 0.044, Table 5, Fig. 3a) but was not influenced by the abundance of *Chaoborus*, the date, and the interactions between predictors. The abundance of *Chaoborus* larvae did not differ between the two noise conditions (GLMMs, Estimate = 0.026, Std. Error = 0.501, z-value = 0.050, p-value = 0.960, Fig. 3b).

Concerning the FR experiment, there was no difference in the size of the *Chaoborus* larvae between the two noise conditions (one-way ANOVA: $F_{1,18}$ = 0.269, p-value = 0.61). Irrespectively of the noise condition, the FR was a type I (linear increase of *per capita* consumption rate in function of prey density). No significant difference in attack rate (fixing the slope) was found between the two noise conditions (Estimate = 0.087, Std.Error = 0.108, z-value = 0.817, p-value = 0.413) supported by a strong overlap of the 95% BCa CIs, suggesting similar FRs (Fig. 4a).

No significant difference in the number of body rotations was found between the two noise conditions (noise: Estimates = 0.2957, Std.Error = 0.4268, z-value = 0.693, p-value = 0.488, Fig. 4b). However, interindividual variability in both FR and behavior was greater with boat noise than for controls.

## Discussion

In this chapter, a mesocosm investigation was conducted to assess the effect of chronic motorboat noise on the dynamics of freshwater zooplankton. Predation tests were also performed in microcosms through the functional response (FR) derivation to test the prediction that in case of a noise-induced alteration in community dynamics, this would be linked with a change in the foraging behavior of invertebrate predators, focusing on *Chaoborus flavicans* as the main predator within the zooplanktonic community.

No marked effect of chronic motorboat noise on the zooplankton community was found except for water fleas (*Daphnia* sp.), which represented the most abundant

taxon and were significantly more numerous in the noisy mesocosms. This apparent positive effect could be indirect, considering that noise has no or a very limited direct negative effect on water fleas but negatively influences their natural enemies. Although no investigation on the response of water fleas to noise was made, the absence of direct effect is partially supported by the little literature available. Sabet et al. (2016) did not find any alteration in mobility in *Daphnia magna* exposed to either continuous or intermittent 300–1500 Hz band-pass filtered white noise, a result that was also obtained working on motorboat noise (Rojas et al. unpublished

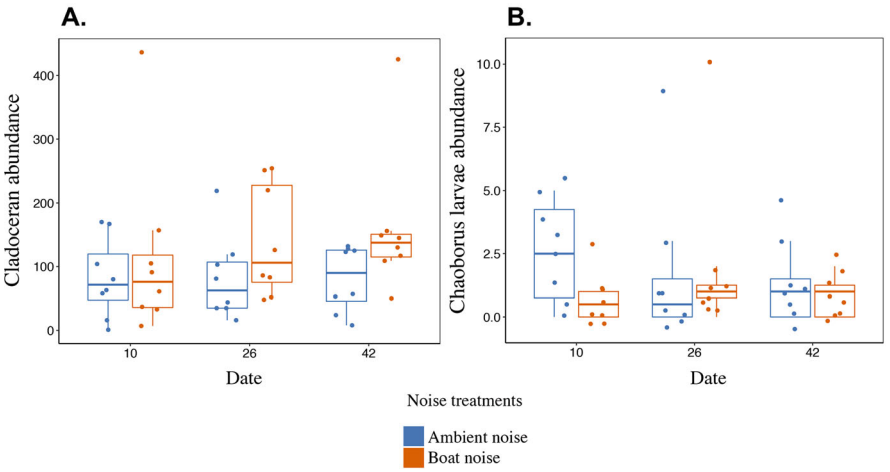

**Fig. 3** Variation in the abundances (median and interquartile range) of Cladocerans (**a**) and *Chaoborus* larvae (**b**) in the control (ambient noise, blue) and noisy mesocosms (ambient noise supplemented with boat noise, orange) at days 10, 26, and 42

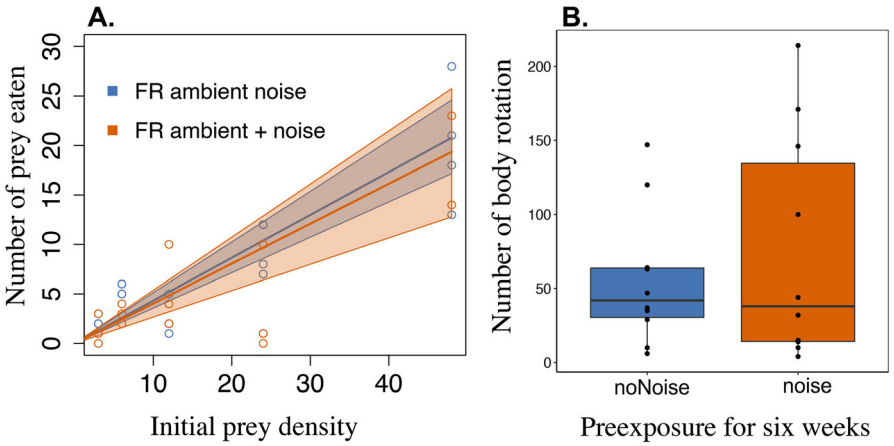

**Fig. 4** (**a**) Number of water fleas eaten by single *Chaoborus* larvae as a function of initial water flea density (functional response) under ambient noise (blue) or chronic motorboat noise (red). Dots indicate the raw data and shaded areas the confidence intervals. (**b**) Number of body rotations (median and interquartile ranges) made by the *Chaoborus* larvae exposed to recordings of ambient noise (blue) or chronic motorboat noise (red)

data). More recently, Yağcılar and Yardımcı (2021) found that exposure to 432 Hz and 440 Hz frequency sounds resulted in lower egg numbers and heartbeats in *D. magna*. However, the use of pure tones that do not refer to any kind of noise pollution in nature as well as the absence of information on sound levels make these

results difficult to compare with the results of this chapter and also difficult to extrapolate to natural populations.

Concerning water fleas' natural enemies, it was reasonable to expect from the FR results that water fleas had experienced predation by *Chaoborus* larvae in the mesocosms. However, contrary to this assumption, noise did not alter the FR of *Chaoborus* larvae nor their behavior assessed through the number of body rotations. The main difference between this chapter and the study by Rojas et al. (2021), where *Chaoborus* larvae displayed more body rotations with motorboat noise, is that this study accounted for repeated exposure (i.e., chronic noise), what Rojas et al. (2021) did not. So, it might be that *Chaoborus* larvae show more body rotations when exposed to noise for the first time and then resume normal behavior with repeated exposure, a phenomenon also referred to as "habituation" that has not been addressed in the present chapter as the response of "naïve" larvae was not tested. Habituation to noise has been reported in many species including fishes (Johansson et al. 2016; Kusku 2020; Rojas et al. 2021) and aquatic invertebrates (Hubert et al. 2022), and could result from sensory or motor fatigue, or associative learning between the repetition of a given stimulus and the absence of any threat.

Similar FRs irrespectively of the noise condition does not support the hypothesis that the water fleas of the noisy mesocosms benefited from a noise-induced reduction in *Chaoborus* predation. Surprisingly, the FR of *Chaoborus* larvae was of type I (linear increase of *per capita* predation rate with increasing prey density), while they were found to display a type-II FR (decelerating rise to an asymptote) in previous studies (Cuthbert et al. 2019; Krylov 1992; Spitze 1992; with *Daphnia pulex*, *D. longispina*, and *Culex pipiens* as prey, respectively). Regarding the *Chaoborus* and *Daphnia* populations used in this chapter, the highest prey density used ($n = 48$) was not enough to reach saturation, and it is not possible to exclude an effect of noise at higher prey densities. Another reason why it was difficult to use the behavior of the *Chaoborus* larvae to explain the increase in cladocerans in the noisy mesocosms could be that predation tests in small and highly controlled experiment units are not representative of the foraging patterns occurring in more complex systems (i.e., the mesocosms used in this chapter). For instance, many zooplanktonic species including *Chaoborus* larvae and *Daphnia* show vertical migrations (Dawidowicz et al. 1990; Haupt et al. 2009). Noise might disturb trophic links within zooplankton through alterations in the species-specific spatial patterns. In other words, the tests performed in aquariums might have underestimated the negative effect of noise on *Chaoborus* predation.

To understand how noise influenced the zooplanktonic communities of the mesocosms, a focus was made on the trophic link between *Chaoborus* larvae and *Daphnia*, and no work was made on the other ecological interactions, in particular competition. Cladocerans are known to compete with rotifers and copepods for common food resources (Gilbert 1988; Lehtiniemi and Gorokhova 2008), copepods being the second planktonic group (after cladocerans) in terms of abundance in the mesocosms. The response of freshwater copepods to noise remains unknown, but a negative effect could make the competition even more asymmetric in favor of cladocerans. The three groups are also engaged in apparent competition by sharing

*Chaoborus* larvae as predator (Elser et al. 1987; Swüste et al. 1973). An interesting perspective would be to assess their respective contribution to *Chaoborus*' diet under chronic noise.

To conclude, this chapter suggests that chronic motorboat noise is likely to disturb the composition and dynamics of freshwater zooplankton without providing evidence for any alteration in the trophic link between *Daphnia* sp. and *Chaoborus* larvae. The effects of chronic motorboat on freshwater zooplankton probably involve the modulation of ecological interactions, but this remains to be further investigated. This chapter also illustrates how scaling up individual responses obtained in highly controlled conditions to the level of communities remains tricky. Additional research on the long-term effect of noise on freshwater zooplankton, as well as on fish-dominated planktonic communities, is needed.

**Abstract**

The Fehmarnbelt Fixed Link consists of an immersed tunnel connecting Denmark and Germany in the western Baltic Sea. Marine sediments are excavated to create the tunnel trench. The importance of the Fehmarnbelt for the harbor porpoise is recognized and managed in German waters through a Natura 2000 area. The authorities defined two indicators to safeguard its function. The first threshold demands that not more than 20% of the cross-section between Lolland and Fehmarn shall be exposed to construction Sound Pressure Level exceeding 144 dB ref. 1 μPa. The second threshold states that not more than 1% of the Natura 2000 area shall be exposed to construction Sound Pressure Level exceeding 140 dB ref. 1 μPa from June to September.

Measurement of dredging sound does not allow to assess the compliance with these thresholds since public shipping sound regularly exceeds them already. Therefore, a hybrid approach combining real-time modeling and continuous measurements has been developed, using measurements for continuous calibration of the model.

Results of the first and half construction year revealed an average deviation between the model and measurements less than 1 dB. Compliance with the thresholds is assessed with confidence and reliability despite the interference of sounds introduced by other maritime activities.

## Introduction

Anthropogenic underwater noise is recognized as a threat to marine wildlife, and there are growing needs to monitor, mitigate, and regulate it. Underwater noise may be harmful to cetaceans through interfering with their acoustic communication, orientation, and prey capturing abilities and – at high doses – might even lead to auditory damage. While much knowledge has accumulated about the responses of marine mammals to impulsive sounds from offshore pile driving or seismic surveys (Richardson et al. 1995; Southall et al. 2007; National Marine Fisheries Service 2018), much less is known about their reaction to continuous sound from shipping or dredging (McQueen et al. 2020). Although ships are not the loudest sources of underwater noise, their sheer abundance makes shipping sound a very important

source of chronical anthropogenic noise in the oceans (Hildebrand 2009; OSPAR Commission 2009). Ambient noise levels have been rising in some regions along with an increase in shipping activity (Anderson et al. 2008; Andrew et al. 2011; Miksis-Olds et al. 2013; Kaplan and Solomon 2016). In the context of overall rising underwater noise levels, also dredging noise receives growing attention and the Central Dredging Association also addressed the issue (CEDA 2011). CEDA acknowledged that dredging involves a variety of activities, which produce underwater sounds but also concluded that appropriate management practices lack standardized monitoring protocols. Dredging sound is diverse but usually only of moderate intensity except for Trailing Suction Hopper Dredgers, which emit relatively high underwater noise levels (Robinson et al. 2011). As dredging operations may include a variety of vessels, an assessment of underwater sound cannot simply focus on the dredgers but must assess the whole operation.

The construction of the Fehmarnbelt Fixed Link as an immersed tunnel involves extensive dredging operations for an extensive period of time and space. The Fehmarnbelt Fixed Link will consist of a 17.6 km long, immersed tunnel connecting the Danish Island of Lolland and the German island of Fehmarn in the western Baltic Sea (Fig. 1). For the first time in Germany, the relevant authorities have imposed restrictions to underwater sound from dredging and associated activities to preserve the habitat of the population of 2000–4000 harbor porpoises staging and nursing in the Fehmarnbelt (FEMM 2013). These restrictions induce an obligation to monitor, manage, and limit the overall sound levels according to requirements defined in the plan approval decision. The first restriction demands that not more than 20% of the cross-section between Lolland and Fehmarn shall be exposed to construction Sound Pressure Level exceeding 144 dB ref. 1 μPa. The second restriction states that not more than 1% of the Natura 2000 area shall be exposed to construction Sound Pressure Level exceeding 140 dB ref. 1 μPa from June to September.

In this study, we outline a hybrid approach that combines continuous sound modeling and in situ underwater sound measurements as the most suitable and robust method for assessing the compliance with regulatory metrics. The continuous assessment of the compliance with two sound thresholds defined by the regulatory authorities is described and the uncertainties assessed.

## The Sound Exposure Issue Related to the Tunnel Construction

### Activities Involved in the Tunnel Construction

For the construction of the tunnel, marine sediments need to be excavated to create a tunnel trench about 90 m width and 16 m depth for the subsequent immersion of the tunnel segments. The construction includes extensive dredging operations. The dredging will result in around 19 million cubic meters of sand, stone, and soil.

Different types of dredging vessels conduct the dredging operation at sea (Fig. 2). In the coastal areas, backhoe dredgers are deployed. Further offshore, in deeper

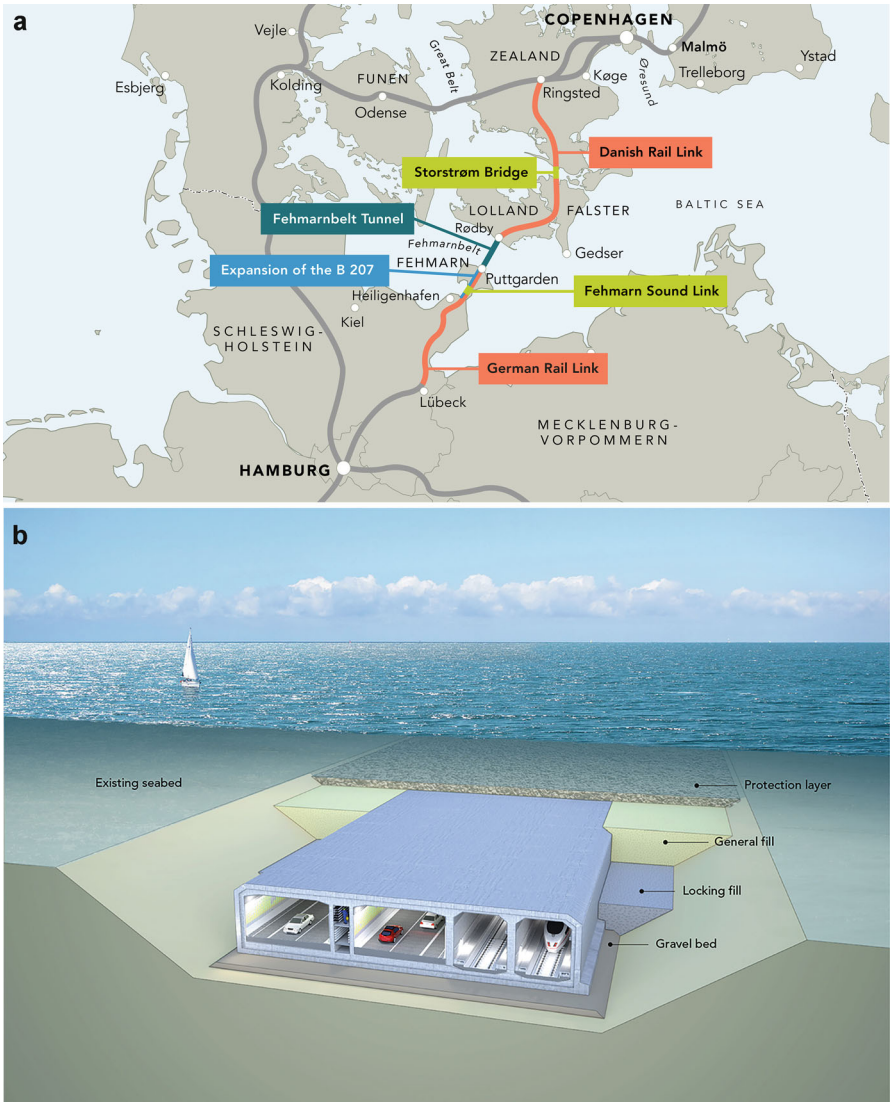

**Fig. 1** The Fehmarnbelt tunnel project. (Copyright: Femern A/S)

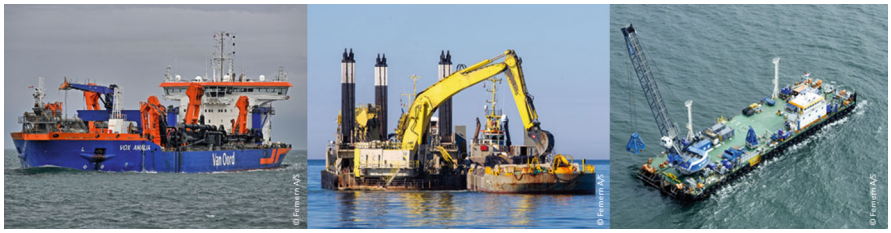

**Fig. 2** Example of different dredgers involved in the tunnel construction. (Copyright: Femern A/S)

waters so-called grab dredgers and trailing suction hopper dredgers are used. In total, more than 100 vessels have been involved 24 h per day during the first and half year of construction, including Trailing Suction Hopper Dredgers, Backhoe Dredgers, Grab Dredgers, Tugs, Barges, Survey vessels, etc.

## Sound Exposure for Harbor Porpoises

The Fehmarnbelt is a natural habitat of the harbor porpoise (*Phocoena phocoena*), a small odontocete whale which is the only cetacean species regularly reproducing in the Baltic Sea. Harbor porpoises of the Fehmarnbelt belong to the population of the western Baltic Sea which comprises about 20,000–40,000 individuals. The wider Fehmarnbelt area has a function as a staging and nursing area for 2000–4000 individuals with highest numbers during spring and early summer (FEMM 2013). During spring and autumn, porpoises are migrating through the Fehmarnbelt which is the main connection between the Danish Belt Sea and the Baltic Proper. In the center of the Fehmarnbelt, a marine protected area as part of the European Natura 2000 network has been established in 2007 to protect harbor porpoises.

As harbor porpoises show aversive responses to underwater sound, it has been extensively discussed with German authorities and NGOs whether the construction of the tunnel may negatively affect the function of the Fehmarnbelt for this species. The environmental impact assessment concluded that porpoises are less sensitive to continuous noise and that the construction of the tunnel will not impair harbor porpoise population in the Fehmarnbelt (Femern A/S and LBV SH 2013).

## Sound Indicators and Thresholds to Prevent Impacts

For the first time in Germany, the relevant authorities have imposed restrictions to underwater noise from dredging and shipping as well as a demand to monitor and manage noise according to the following requirements:

1. Not more than 20% of the cross-section between Lolland and Fehmarn shall be exposed to construction Sound Pressure Level exceeding 144 dB ref. 1 μPa to avoid creating a barrier effect that may impede porpoise migration (indicator 1).
2. Not more than 1% of the protected Natura 2000 area shall be exposed to construction Sound Pressure Level exceeding 140 dB ref. 1 μPa during the reproductive period of harbor porpoises from June to September to minimize the impact on the protected area and on reproducing porpoises (indicator 2).
3. The compliance to these thresholds shall be monitored continuously as part of the environmental construction monitoring.

## The Hybrid Model-Measurement Approach

### The Maritime Context of the Fehmarnbelt

The Fehmarnbelt is a strait connecting the Bay of Kiel and the Bay of Mecklenburg in the western part of the Baltic Sea between the German island of Fehmarn and the Danish Island of Lolland (Fig. 3). Ferries connect Puttgarden and Rødby on the two islands. The strait features a 10 nautical miles wide area with depths of 20–30 meters. Currents in the strait are weak and mostly dependent on wind.

The Fehmarnbelt is one of the busiest waterways in Europe. Figure 4 is representing the cumulative time when the ambient sound exceeded 140 dB ref. 1μPa (dominance map) before the project activities in the marine environment started. This dominance map shows that the sound of the shipping route connecting the North Sea and the Baltic Sea and the ferry line between Germany and Denmark cause levels of ambient sound pressure levels that may overcast construction sounds above 140 dB ref. 1μPa up to about 10% of the time (Fig. 4).

### The Model-Measurement Hybrid Approach

Since the commercial shipping and the ferry vessels generate sounds that already regularly exceed 140 dB ref. 1μPa and 144 dB ref.1 μ Pa, monitoring construction sounds in the Fehmarnbelt, the monitoring of construction sound and compliance with the thresholds, i.e., the two noise indicators, cannot be achieved by sound

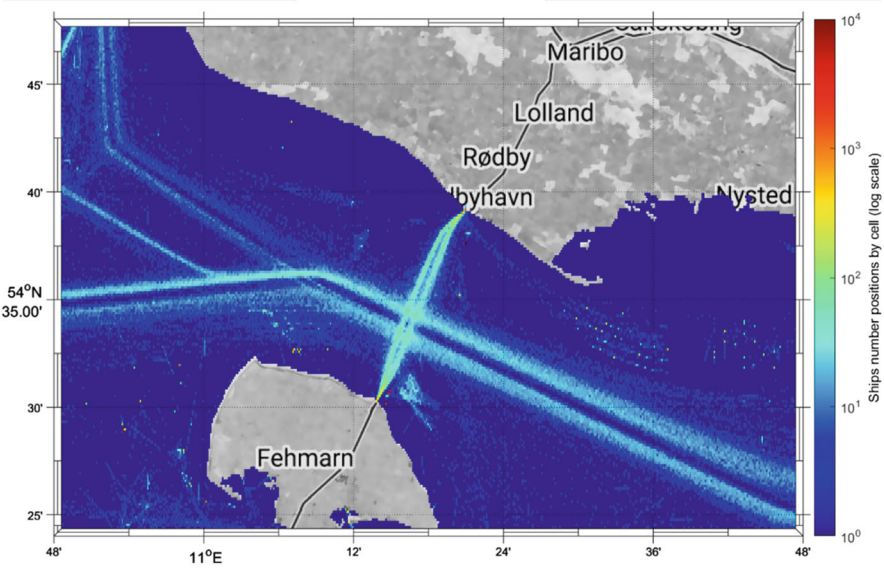

**Fig. 3** Maritime traffic density map in the Fehmarnbelt before the tunnel construction started in 2020

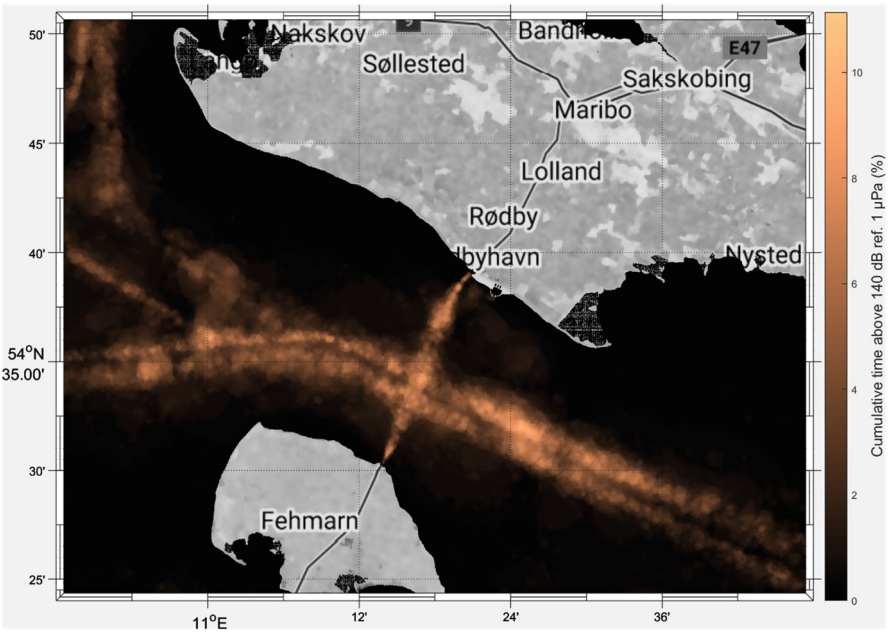

**Fig. 4** Proportion of time when the shipping sound exceeding 140 dB ref. 1 µPa before any tunnel trench dredging started in 2020

measurements alone. Indeed, direct measurement of the sound in the Fehmarnbelt would include sounds from all sources, commercial shipping, ferry vessels, etc., mixed with the sounds of the tunnel construction activities. The analysis of measured only values it would not be conclusive whether any excess of the thresholds is originated from the construction activities or from the other vessels. By nature, the sound measurement records all sounds, and it is not possible to separate contributions from the construction with sounds from the overall traffic. In addition, the spatial nature of the indicators, calculated along the cross-section and into the Natura 2000 area, cannot be assessed with only hydrophones.

A method to handle this intrinsic characteristic of the measured data for model calibration has been developed and is detailed hereafter. The construction sound monitoring follows a hybrid approach which enables the cumulative sound from construction activities and the ambient sound from the usual maritime traffic being assessed separately. The hybrid nature of the approach is combining near real-time modeling, continuous sound measurements along the construction sites, and dedicated measurements of underwater radiated noise (URN) of most of the vessels involved in the project (Fig. 5).

## Sound Measurement Strategy

A dedicated protocol has been defined to perform the sound measurements in order to ensure that the data would be suitable for the implementation of the hybrid approach.

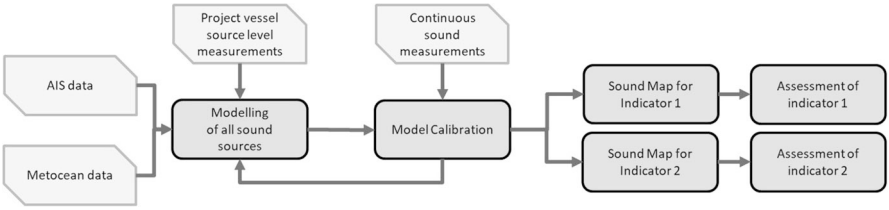

**Fig. 5** Overview of the hybrid methodology to model, calibrate, and assess both regulatory indicators

Three categories of measurement have been defined: category A consists of the measurement of the source levels (underwater radiated noise – URN) of the vessels involved in the construction. Category B consists of measurements at the vicinity of the construction site. Category C consists of long-term measurement at a distance from the construction areas.

Category A measurements are dedicated to the source-level measurements of various construction vessels involved in the tunnel construction. Levels are measured individually or representatively per vessel type. The processing of the URN takes into account the environmental conditions of the measurement site (such as sediment grain size) and the configuration of the measurement (such as the range between the hydrophone and the vessel). Source levels are estimated for different representative activities such as dredging and disposal by backhoe dredger (BHD), grab dredger (GD), and trailing suction hopper dredger (TSHD), steaming, anchoring, etc., including also tugs and service vessels operating under various activities. The source levels obtained, which includes the measurement of the source directivity, are integrated in the sound model.

Underwater sound is also continuously measured along the offshore working sites and used to validate and continuously recalibrate the model. Four mobile underwater sound measuring devices (Fig. 6) per offshore working site are deployed within a few hundred meters of the construction-related work. These mobile measuring devices are maintained weekly, i.e., the position is adjusted according to the construction progress and the measuring data are retrieved for subsequent data analysis.

In addition to the mobile underwater noise measuring devices in the near field of the offshore working areas, two permanent measuring stations are deployed at some distance to the construction areas (Fig. 7). These monitoring positions are maintained bimonthly.

For the mobile and the fixed measuring stations, standardized underwater noise measuring recorders are used that meet all requirements of the measuring regulations for underwater sound measurements (BSH 2011) (Verfuß et al. 2015) and are also calibrated regularly. The measurements are performed continuously with a sampling rate of at least 48 kHz so that the frequency range between 20 Hz and 20 kHz is covered. Measured sound pressure levels are processed into 20-s windows data in 1/3-octaves.

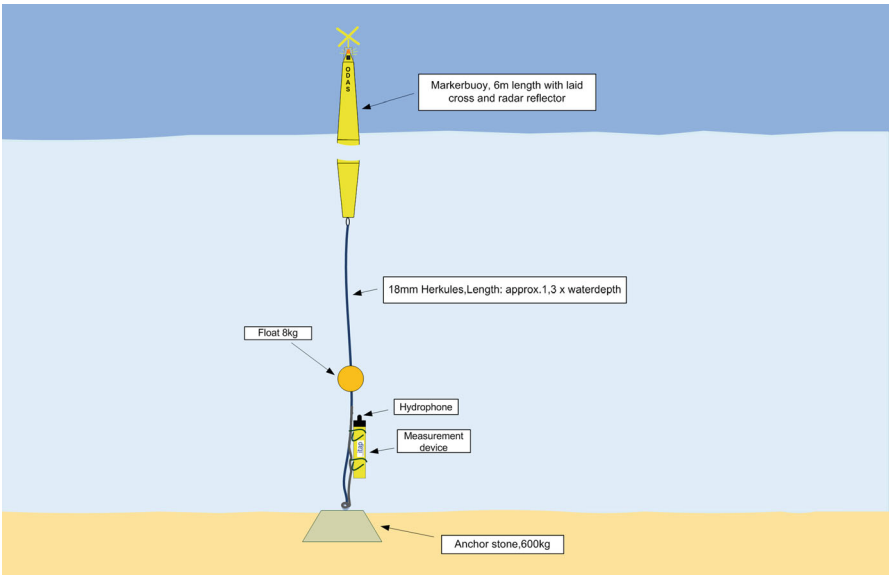

**Fig. 6** Sketch of the acoustic moorings

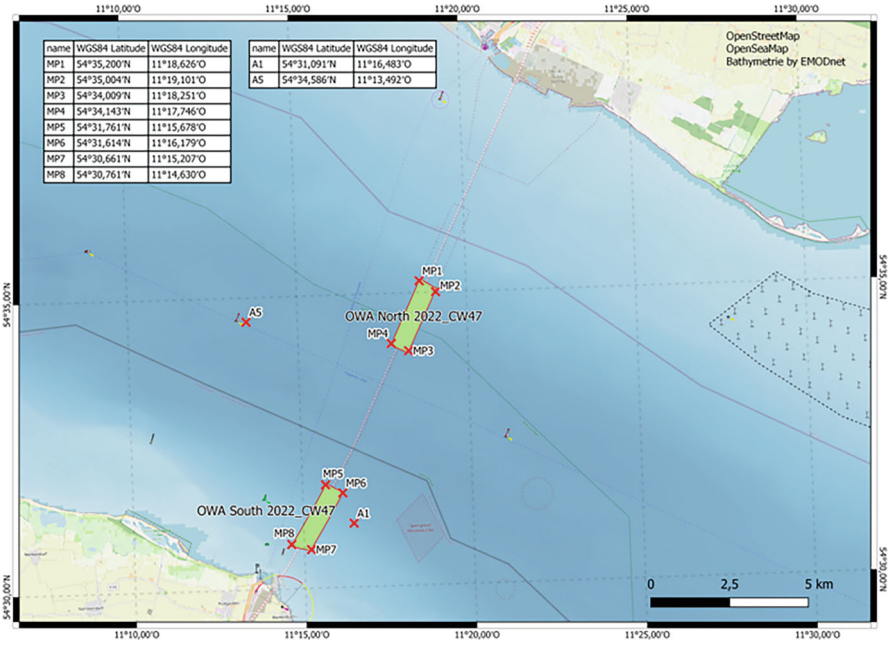

**Fig. 7** Example of the design of the sound measurements done in the construction sites and the long-term measurements at a distance of the construction activities

Noise measurement devices measure the entire total noise including natural noise from waves, splashes, and rain as well as other shipping sounds than that originating from construction activities. Sound measurements thus do not allow a direct assessment of construction sound. Therefore, the recorded underwater sound measurements.

## Sound Modeling

Sounds are modeled with the web-based Quonops© Online Services modeling platform (Folegot 2009, 2011). Although Quonops© supports other modeling techniques, in the framework of this project, Quonops© is solving the sound propagation Helmholtz equation by using the parabolic equation approximation parabolic modeling (Collins 1994; Collins et al. 1996). Broadband modeling is done in 1/3 octave bands from 16 Hz to 4 kHz for each sound source independently. Automated Identification System (AIS) data provides the near real-time position of all vessels continuously. Project vessel and related activity sounds are derived from the category A measurements, while the source levels from the non-project vessels are estimated from vessel size and sailing speed based on the RANDI 3 model (Wagstaff 1973; Ross 1976; Breeding et al. 1996).

The modeling of sound propagation is done for each sound source by a series of cylindrical vertical planes (Nx2D technique) with azimuths around the sound source spaced by 3°.

The oceanographic context is considered in the modeling: the sound speed profiles in water are derived from water temperature, salinity, and pressure (or depth) provided by operational oceanographic services and updated every hour. The main effect of these non-homogeneities in sound speed distributions is to create propagation channels. These complex phenomena are, however, predictable by numerical simulation.

The sediment properties and the changes of the bathymetry of the marine environment are also taken into consideration in the resolution of the Helmholtz Equation by considering the propagation in the marine substrate and the reflections from the water-sediment interface. These characteristics of the marine environment induce absorption, reflection, and diffusion of the sound through the soil and in the water column. The descriptive data of the bottom and bathymetry are taken from available local data.

The model calculates the sound originating from natural sources derived from the wind field data (Ainslie 2010) and all non-construction vessels – which in combination equates the so-called background noise – and construction vessels separately.

The model predicts the project vessel-based cumulative sound by integrating the individual source levels measured for the vessels involved in the construction activities and their near real-time positions provided by the AIS stream. This provides modeling of the background sound (i.e., the sum of all non-project-related sounds) and project-related sounds in near real time, separately as well as combined to form the total sound field (Fig. 8).

This approach allows for calibration of the model from cumulative sound levels recorded from non-project and project sounds, on the one hand, and the assessment of both conditions to verify compliance every 15 min, 24/7, on the other hand.

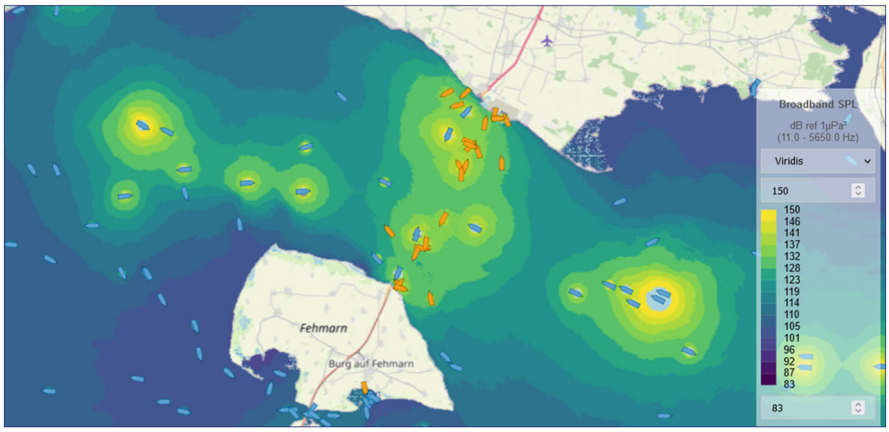

**Fig. 8** Instantaneous total sound map. Project and non-project vessels are displayed in orange and blue, respectively

## Model Calibration

The hybrid approach combines near real-time modeling provided by the Quonops© Online Services platform and the sound measurements. The modeling results are validated by recurring category B and C underwater noise measurements during the construction activities, allowing the model to be recalibrated periodically with the most recent underwater noise measurements. This procedure ensures that the model provides the best estimate of the overall sound at each measurement position.

The comparison of measured and modeled data is based on the total sound composed of construction sounds and background sounds. However, neither a detailed analysis of different situations for different time periods of the recordings nor a complex individual consideration of individual activities is possible.

The calibration methodology has been initially developed during the BIAS project (Folegot et al. 2016). The Cumulative Density Function (CDF) is used to overcome the difficulty that the measurement and the modeling are not performed at similar time resolutions by defining a common robust metric. The CDF describes the statistical content of the sound for the period considered similarly for both the measurement and the modeling, regardless of the technical characteristics of the measurement or the modeling. The CDF expresses the relationship between the sound level and the percentile, e.g., the proportion of time a given level occurs.

The calibration process consists of finding the best set of model parameters that minimize the difference between the CDF provided by the measurement and the CDF provided by the model at the position of the measurement and for the same period. The calibration is performed by minimizing the differences between both measured and modeled CDF by considering the following uncertainties:

- Wind: the wind fields are converted into sound of natural origin. The measurement provides a ground truth of natural noise and help to consider the local conditions that influence the natural noise generated by wind.

- Sediment: it is acknowledged that uncertainties in the description of the soil parameters need to be addressed. Therefore, we use a calibration process that will enable to model to decide on a set of geo-acoustic parameters that make the model fit best the natural noise component of the measurements.
- Non-project source levels: it is acknowledged that the diversity of commercial vessel designs, propellers, sizes, and hulls introduce uncertainties in the estimation of the source levels of the vessels. The RANDI 3 source-level model provides an a priori assessment. The calibration process accounts for this uncertainty and uses the measured ambient noise levels to adjust the source levels of the non-project vessels.

The assessment of the quality of the calibration is quantified by the calculation of the root mean square of the absolute difference between both measured and modeled CDF between the 5th and 95th percentiles (Fig. 9, left) and is updated on a weekly basis for all available measurement positions. From the start of the dredging in July 2021 to April 2022, more than 300 calibrations have been performed and the model-measurement mismatch has never exceeded 2 dB and is usually around 0.7 dB (Fig. 9, right).

## Model Validation

To validate the model, the modeling of the total sound (project and non-project activities in the Fehmarnbelt) is regularly compared with the acoustic measurement. An illustration of the comparison is provided in Fig. 10. The figure reveals a good agreement between the model and the sound measurements. It is important to note that there is a discrepancy between the continuous measurements of the total sound that are processed in 20-s windows and averaged on 15-min windows (black lines). The model on the other side provides a snapshot every 15 min (blue dots for the total sound, orange dots for the sound not related to the project activities). The gray area in the background explicit the variability of the measurement between the 1st and 99th

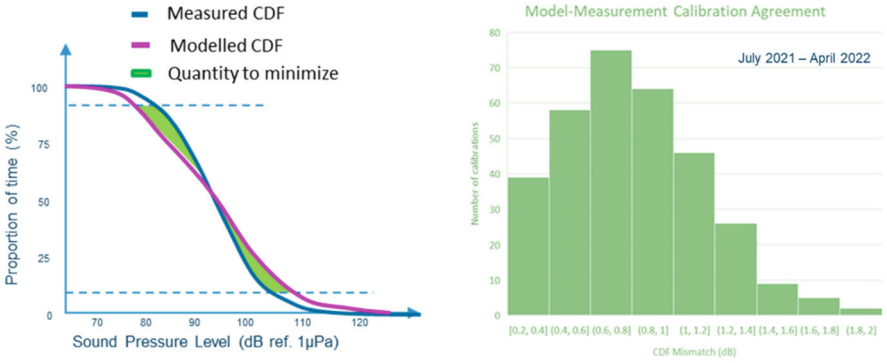

**Fig. 9** Left: The calibration of the sound modeling is based on the minimization of the difference between the measured and modeled Cumulative Density Functions (CDFs). Right: Distribution of the model-measurement statistical mismatch from July 2021 to April 2022

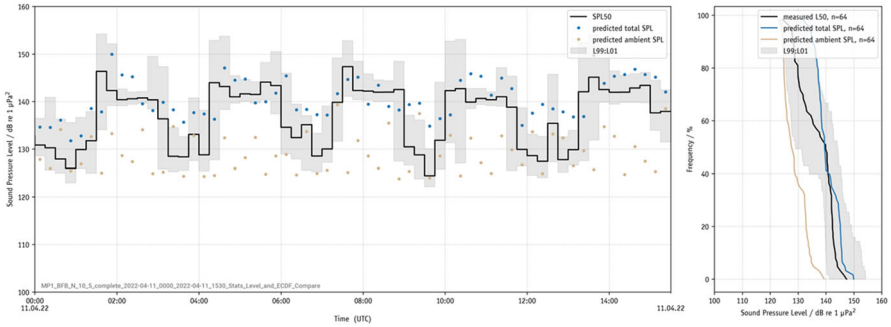

**Fig. 10** Course of the modeled and measured sound levels in April 11, 2022, at the measuring station MP1. The sound pressure level data are processed in 20-s windows and then averaged in 15-min windows (black line). The blue and brown dots represent the total and background sound, respectively, as predicted by the model. The gray background represents the 1–99% excess level of the measured values for the 15-min averaging intervals. The figure on the right is the Cumulative Function representation of the data

percentiles. There is a good agreement between the total sound levels modeled (in blue) that are close to the higher percentiles of the measurements. On the other hand, the modeled background levels not related to the construction activities are minimizing the lowest percentile measured. This is an expected result which highlights that the total sound is a mixture of construction and non-project sounds that cannot be reported by the measurement.

## Compliance with the Noise Indicators

### Indicator 1: Prevent a Barrier Effect

Indicator 1 attempts to represent the blocking effect potentially induced by the noise of the project on the passage of underwater fauna in the Fehmarnbelt channel. It is assumed that this effect becomes significant when more than 20% of the cross-section between Lolland and Fehmarn is exposed to sound levels above 144 dB ref. 1 µPa at all times.

To assess indicator 1, only the project's stationary activities near the site of the future tunnel are taken into account: this concerns project vessels sailing at speeds less than 3 knots (limit for considering vessels engaged in noisy dredging, towing, unloading, etc.) and which are located less than 300 meters from the cross-section (imaginary line of 17.6 km between Germany and Denmark, drawn at the location of the future tunnel) (Fig. 11).

The cumulative noise of these activities is calculated by the Quonops model every 15 min (Fig. 12), and their sound footprint beyond 144 dB ref. 1µPa is projected on the cross-section: the value of the indicator is given by the proportion of cross-

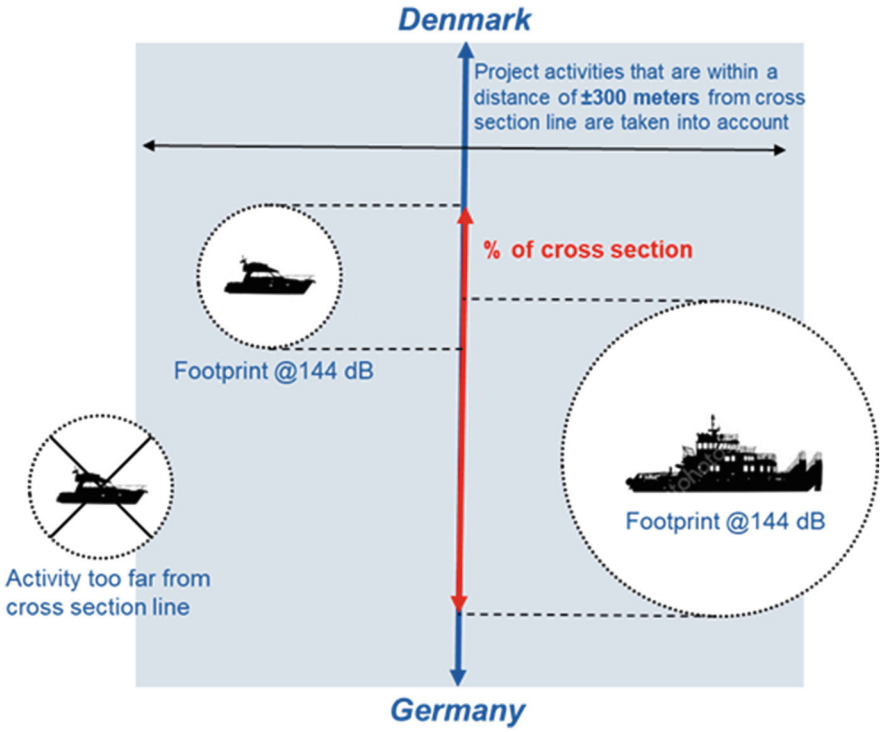

**Fig. 11** Overview of the methodology to assess indicator 1

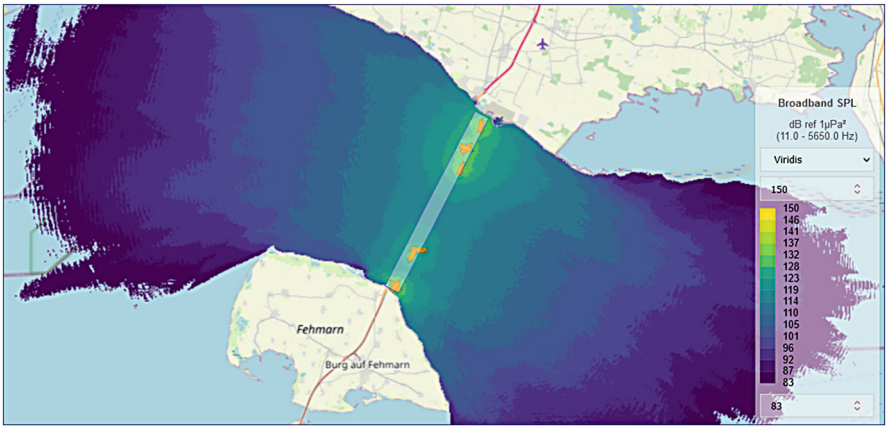

**Fig. 12** Example of sound map used for the calculation of indicator 1

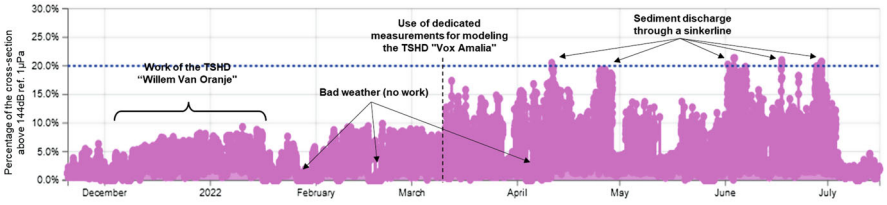

**Fig. 13** Percentage of the cross-section of the Fehmarnbelt above 144 dB ref. 1µPa (indicator 1)

section subject to a sound level greater than 144 dB ref. 1µPa compared to the total length of the cross-section.

The project shall not exceed the 20% limit imposed on indicator 1: this means that the noise generated at the construction site beyond 144 dB ref. 1µPa must not occupy more than 3.6 km (cumulative length) of the width of the channel between Germany and Denmark.

Figure 13 shows the evolution of the values for indicator 1 from December 2021 to July 2022. The fluctuations give a history of the project: highest values testify the local dominance of sound from project activities along the cross-section. More specifically, the Trailing Suction Hopper Dredgers such as "Willem Van Oranje" and "Vox Amalia" are among the loudest project vessels and contribute significantly to the values of indicator 1. The lowest values of indicator 1 can be attributed to periods of bad weather which caused the work to stop and in fact the emission of noise by the project in the channel Fehmarnbelt.

Following the use of dedicated measurements of the TSHD "Vox Amalia" in the modeling, the values of indicator 1 increased significantly from the end of March 2022. In April and June, the values briefly exceeded the 20% threshold, during the discharge of sediments by the TSHD into a sinkerline, the blocking effect of which is taken into account by the model. In such situations an investigation is performed, and a solution shall be found to reduce the noise level.

## Indicator 2: Limit Sound in the Marine Protected Area

For indicator 2 (1% of the Natura 2000 site), all construction vessels, irrespective of their speed and position, are considered by determining the construction-related noise levels. The project site intersects a Natura 2000 marine area where porpoises are protected during their summer breeding period (from the beginning of June to the end of September). Indicator 2 attempts to represent the proportion of this protected area exposed to loud project noise set to 140 dB ref. 1µPa by the authorities.

The cumulative sound of these activities (Fig. 14) is calculated by the Quonops model, and the value of indicator 2 is defined by the proportion of the marine protected area exposed to sound levels higher than 140 dB ref. 1µPa, compared to its total surface (280 $km^2$) (Fig. 15).

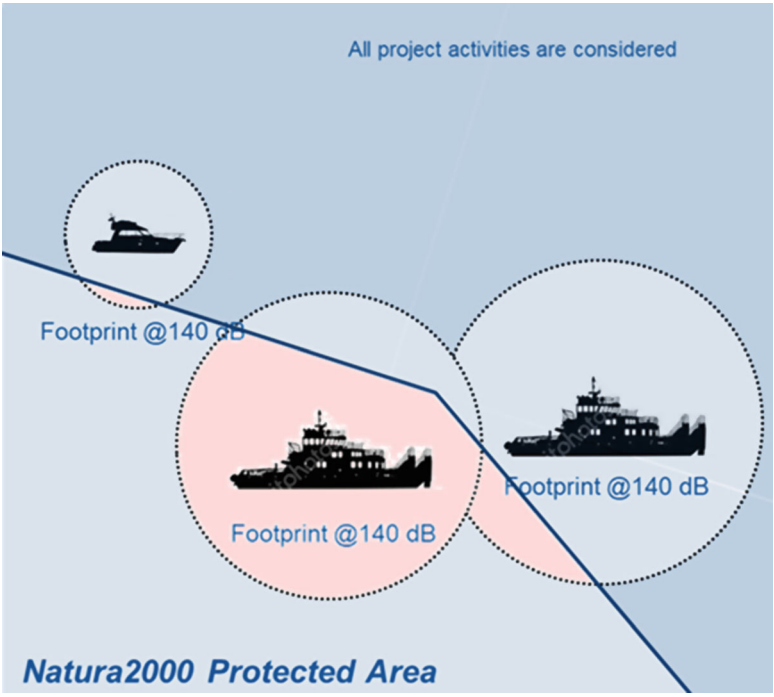

**Fig. 14** Example of sound maps used for the calculation of indicator 2

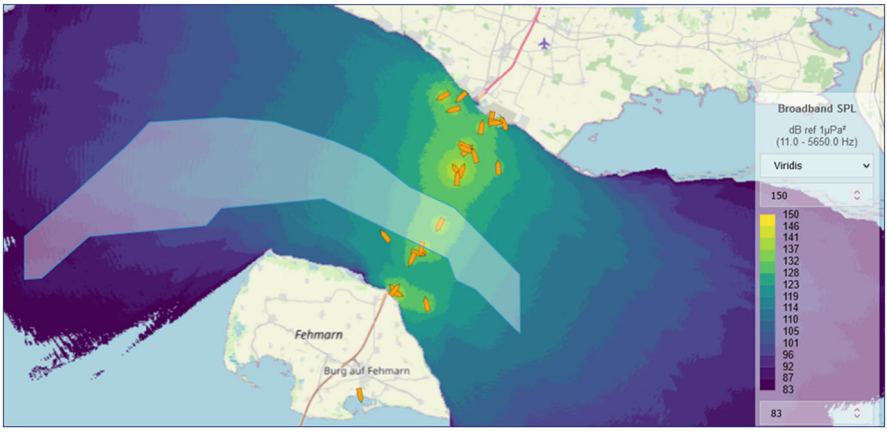

**Fig. 15** Overview of the methodology to assess indicator 2

The project shall not exceed the 1% limit imposed on indicator 2 from June to September: this means that the noise generated by the construction site beyond 140 dB ref. 1µPa must not occupy more than 2.8 $km^2$ of the surface of the Natura

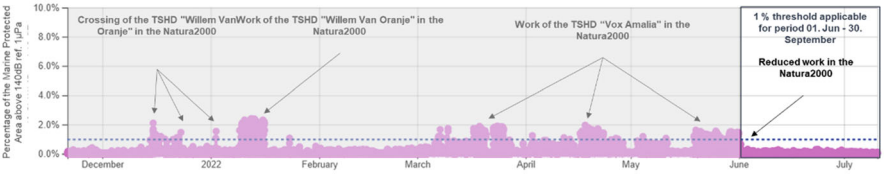

**Fig. 16** Percentage of the Natura 2000 area above 140 dB ref. 1µPa (indicator 2)

2000 marine protected area during this time of the year. Outside this period, the limit is raised to 10%.

Figure 16 shows the evolution of indicator 2 between December 2021 and July 2022. Similar to indicator 1, the fluctuations of indicator 2 can be attributed to particular events in the construction project: some high and isolated values correspond to occasional passages of project vessels crossing the Natura 2000 protected area, while the lower values correspond to localized works in the area or in the vicinity of the area. Outside the porpoise reproductive season in summer, the threshold for indicator 2 may not exceed 10%. However, from June to September, the threshold is 1%: the active management of the project has led to a reduction of vessel activities from the first of June 2022 to comply with the threshold.

## Conclusion

The regulatory thresholds defined to protect the marine environment from the sound generated by the construction project of the tunnel across the Fehmarnbelt aim at preventing a barrier effect and maintaining a quality of the habitat in the Natura 2000 area "Fehmarnbelt."

The busy maritime context of the Fehmarnbelt generates a large amount of ambient sound that may overcast construction sounds more than 10% of the time. Therefore, a hybrid approach that combines in situ measurement with modeling was therefore mandatory to enable the assessment of the sound originated from the construction independently from the sounds of all other human activities. The method developed has led to an operational solution, providing near real-time monitoring of the regulatory thresholds continuously every 15 min.

The results of the first year and half year of real-time modeling and measuring underwater noise of the dredging work revealed a good fit of modeled underwater noise with the measurements. Therefore, project-related sound across the Fehmarnbelt can be predicted confidently and with sufficient accuracy to assess compliance with the regulatory thresholds for underwater sound despite the interference with the sounds introduced by the heavy commercial traffic.

Although the real-time assessment is fully automatized, it proved to be essential to have precise knowledge of the construction activities and the specifications of the construction vessels and their source levels. Though source levels can be calculated

from available sources, it is recommended to measure source levels of specific activities at the construction sites to reduce the uncertainties of the model as much as possible.

Underwater noise modeling was accompanied by extensive noise measurements which allowed routine calibration of the model. The stability of the model has been achieved thanks to the numerous measurement stations.

The monitoring of the sound indicators is actively used by the project management to plan and organize the operations of the project. The compliance achieved since the start of the project has proven to be successful to protect the marine environment and the approach can be recommended to other projects where the occurrence of protected species may require managing underwater sound.

**Abstract**

The Marine Strategy Framework Directive (MSFD) (Directive 2008/56/EC) promotes sustainable use of the seas by requiring member states to achieve and maintain Good Environmental Status (GES), including underwater noise as one of of the eleven specific criteria for evaluating GES. In 2022, the EU established quantitative threshold values for addressing the consequences of impulsive underwater noise input into the marine environment. In this chapter, a data-driven stepwise approach is introduced for the implementation of an MSFD compatible assessment methodology. Corresponding standardized practices are presented. For the data-driven evaluation of regional requirements and of the applicability of harmonized methodologies within EU regions, exemplary regional case studies were performed for the Baltic Sea, North Sea, and Mediterranean Sea. Further, the estimation of effect ranges and corresponding risks of adverse effects is important for an impulsive noise assessment. Regional differences in the marine environment were addressed. Main challenges of impulsive noise propagation modelling were identified based on both numerical and analytical/empirical propagation modelling. Finally, recommendations for the impulsive noise registries are presented.

Impulsive underwater noise · Regional assessment · Noise registries

## Introduction

The EU Marine Strategy Framework Directive (MSFD) (Directive 2008/56/EC) provides an important framework for a sustainable use of the seas within the European Union, which explicitly includes the effects of underwater noise in an assessment of the state of the marine environment. The MSFD was adopted to protect the marine ecosystem and biodiversity and obliges EU member states to achieve and maintain *Good Environmental Status* (GES). Descriptor 11, underwater noise, is one of the eleven specific descriptors for Good Environmental Status. Descriptor 11 (D11) comprises two criteria, with the first criterion (C1) relating to *Anthropogenic impulsive sound in water* (Commission Decision 2010/477/EU). In 2022, the EU introduced MSFD-related quantitative threshold values for underwater noise, including impulsive noise (D11C1), for the first time. The focus of these thresholds is on the protection of habitats of noise-sensitive marine species.

*Commission Decision (EU) 2010/477/EU* provides relevant criteria and methodological standards for the Descriptors of GES. For the assessment of GES in relation to D11, the temporal and spatial distribution of impulsive underwater noise (loud, low and mid frequency impulsive sounds) was identified as a primary criterion (D11C1). It is specified as *proportion of days and their distribution within a calendar year over areas of a determined surface, as well as their spatial distribution, in which anthropogenic sound sources exceed levels that are likely to entail significant impact on marine animals (Com. Dec. 2010/477/EU).* Commission

Decision (EU) 2017/848 detailes further criteria elements for the 11 qualitative descriptors and specifies methodological standards for the scale of the assessment, for standardized methods of monitoring and assessment and for units to evaluate the criterion. However, the criteria definitions and methodological standards must be further developed and specified with regard to the practical implementation and assessment of GES within the different EU regions and subregions.

Since the introduction and propagation of anthropogenic underwater noise is of transboundary nature, the assessment is relevant to all marine regions and sub-regions under the MSFD. Given the diversity of ecosystem characteristics and the various species affected by underwater noise in different regions, the assessment methods under Criterion D11 must take account of the regionally diverse conditions. Nevertheless, to ensure consistency and coherence of assessments in the marine regions and subregions, Commission Decision (EU) 2017/848 requires the definition of methodological standards and harmonization of the application of criteria for assessing the extent to which GES is achieved by Member States.

Since the adoption of the MSFD, a number of different assessment approaches for impulse noise have been proposed or used by different regions and Member States individually (Dekeling et al. 2020). This chapter describes results from the EU project HARMONIZE (see project report for details) (Müller et al. 2021), which was funded by the General Directorate (DG) Environment of the European Commission under the DG ENV/MSFD 2020 Call to support the preparation of the next 6-year cycle of implementation of the MSFD with respect to the level of anthropogenic impulsive underwater noise introduced into the marine environment. Against this background, HARMONIZE conducted the first cross-regional attempt to examine the applicability of assessment approaches for D11C1 to the diverse marine areas, to identify immediately applicable methods for assessing impulsive noise based on regional impulsive noise registries and to analyze the different assessment requirements in different EU regions and sub-regions. Thus, the project supported the definition of thresholds and evaluation of GES regarding underwater noise to fulfil upcoming MSFD reporting obligations of EU Member States.

HARMONIZE used a data-driven stepwise approach to recommend harmonized methodologies and standardized practices to be integrated in an D11 assessment that is applicable in practice, scientifically justified, comparable, and replicable across regions, sub-regions, and Member States. Key activities of this stepwise approach were the sourcing of assessment data, the identification of best available practices, and regional and sub-regional requirements as an important basis for harmonization. Another key activity was the investigation of regional case studies. These tested the practicality of the harmonized, data-driven assessment methods against regional requirements.

## Handling of Impulse Noise in the EU Employing Noise Registries

As part of the implementation of the MSFD, regional noise registries have been established in cooperation between EU Member States and regional marine conventions since 2015. They provide the database for the MSFD assessment of Good Environmental Status with respect to impulsive underwater noise. EU Member

States have to report impulsive noise events annually to these regional noise registries. D11C1 requires the consideration of three main aspects: the spatial distribution, the temporal extend, and the levels of impulsive underwater noise. The regional noise registries were developed to be able to include these aspects accordingly, but they use simplified concepts (i.e., source strength classes and anthropogenic activity categories). The most common reported time resolution of impulsive noise events is on a daily basis, but an even lower reporting resolution is also accepted by the registries. The spatial information on events spans from the exact source location of an activity, to within standardized geographic polygons of different sizes. Finally, noise registries classify impulsive noise event according to five noise level categories.

The evaluation of noise registry data provided the basis for determining the practicable level of accuracy that can be achieved, which largely depends on both the availability and resolution of data collected in the regional noise registries. For this analysis, three publicly available regional databases were used that currently include datasets on impulsive underwater noise: the ICES noise registry for OSPAR and HELCOM regions (International Council for the Exploration of the Sea (ICES) n.d.), the QuietMed noise registry for the Mediterranean Sea region (Enguix et al. 2019), and the EMODnet database (EMODnet n.d.) with subsets of data from different regions (Fig. 1).

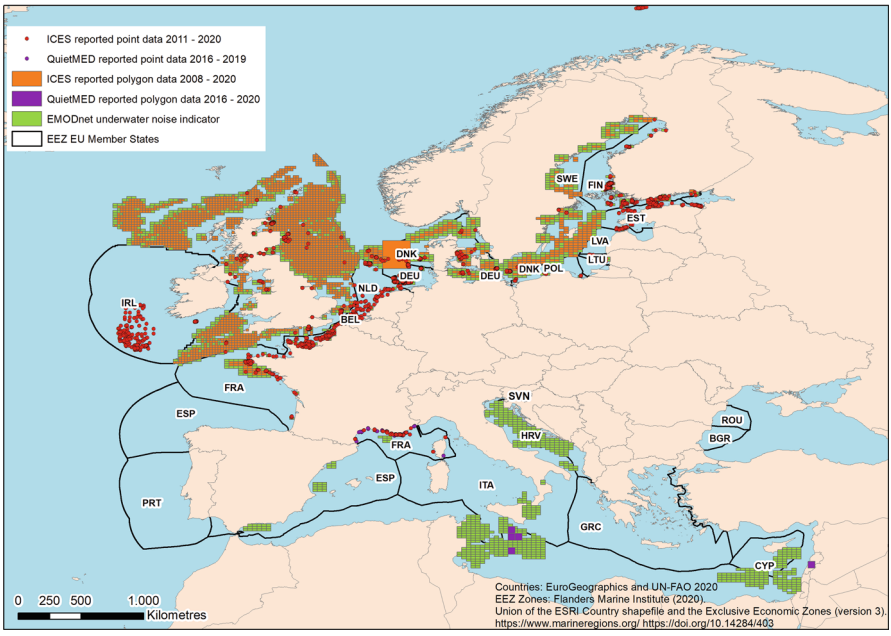

**Fig. 1** Visualization of publicly available data reported to regional noise registries

The analysis of available data in the noise registries has shown that a major insufficiency with respect to a quantitative assessment of impulsive noise arises from the incompleteness or non-reporting of impulsive noise data. Likewise, the heterogeneous level of details associated with reported impulsive noise data and corresponding parameters, i.e., differences in temporal and spatial information detail of events as well as the representation of the source strength, have a significant impact on the accuracy and reliability of a quantitative assessment. An essential prerequisite for the regional assessments, using the database provided by the registries, is data harmonization and quality assurance. Further, the temporal and spatial coherence and overlap between physical data on impulsive noise emissions on one hand and biological data on the other hand were identified as fundamental condition for the success of any assessment of the environmental status regarding D11C1.

## To Assess Impulsive Noise According to the MSFD

### Assessment Approach

Noise registries were designed based on MSFD-related guidance by the EU and were intended as a fundamental tool for a joint monitoring on regional or sub-regional level (Dekeling et al. 2014a, b, c). Over the past years, several decentralized assessment methodologies were developed by regions and member states. The introduction of quantitative EU threshold values motivated a harmonization of these approaches, taking the specifics of the different marine regions into account.

Four different assessment methodologies were included into the harmonization process for D11C1. These methodologies were reviewed with respect to various relevant aspects (e.g., required data, required resources, expert knowledge, and applicability to EU regions and sub-regions). They were further classified into several characteristic categories, as shown in Table 1 (adapted from Table 1 in Müller et al. (2021)).

An analysis of these assessment methodologies demonstrated that different components of the approaches were comparable to each other and included elements that could be adjusted to design a harmonized assessment framework for immediate application within the next MSDF cycle. Importantly, all assessment methodologies followed a common overall structure and were based on the common monitoring programm for D11C1, i.e., the regional noise registries. However, it became apparent that the four methodologies required a different accuracy and extend of input data.

For the purpose of evaluating the possibility to integrate the methodologies into a harmonized methodology, four *Harmonization Criteria* were identified, with corresponding minimum requirements (Müller et al. 2021):

1. *Suitability*: available data and information allow for an evaluation of the environmental status, uncertainties are well delimited, and results can be practically translated into regulation if needed.

**Table 1** Comparison of different assessment methodologies

| Main aspects | A: Mixed approach (Dekeling et al. 2020; Merchant et al. 2017) | B: Population-based approach (Dekeling et al. 2020; Heinis et al. 2015) | C: Habitat-based approach (Dekeling et al. 2020; Müller et al. 2020) | D: Habitat-based approach (Dekeling et al. 2020) |
|---|---|---|---|---|
| Baseline | Disturbance | Disturbance | TTS/disturbance | Disturbance |
| Source data | Noise registry | Noise registry | Noise registry | Noise registry |
| Effect ranges | Observations for species (based on specific adverse effect e.g. disturbance related to a specific activity) | Propagation model | Empirical propagation model/ measurements | Propagation algorithms/ predefined buffers |
| Assessment areal focus | MA, e.g., OSPAR II, MPAs | MA | MA (EEZ) and MPA | MA and PUHA |
| Adverse effect | Population (density) | Population (decline in density) | Habitat affected (quality loss) | Habitat affected (quality loss) |
| Assessment metric/ parameter to evaluate/ interpret | Exposure curve (index) | Population dynamics (model-based) | Adaptable percentage of area over time (based on sensitive periods) | Percentage of area and time exposed |
| Options for threshold for GES | Change in the form of the exposure curve (or change in index) | Change of population based on a model result, perhaps x % reduction in population | Percentage of area (x % EEZ or MPA) exposed over time | E.g., x % area exposed (MA and MPA) and y % time exposed |

*MA* management area, *MPA* marine protection areas, *PUHA* potentially usable habitat area

2. *Applicability*: assessment methods are well defined; uncertainties can be estimated by each Member State and the method can be applied for setting regulatory measures and evaluating the sufficiency of measures.
3. *Reproducibility*: methods applied are transferable to sub-regions and regions, results are non-ambiguous and allow for comparison of GES at union level.
4. *Feasibility*: assessment effort is such that each Member State is able to implement the methodology with own resources and capabilities.

The four assessment approaches included in Table 1 were analyzed against the four *Harmonization Criteria* established for the purpose of harmonization. Emphasis was placed on the applicability by each Member State at national level taking into account the available capacities. Furthermore, emphasis was placed on the unambiguity of the assessment results in light of the available input data. Minimum

requirements to be fulfilled for the implementation of a methodolody were stipulated for each of the four *Harmonization Criteria* as follows (Müller et al. 2021):

1. Minimum requirements for criterion *Suitability*: Data availability concerning species and habitats.
2. Minimum requirements for criterion *Applicability*: (2a) Methods available are widely accepted and well tested in case studies for as many EU regions as possible and are transferable between regions, (2b) uncertainties are defined and delimited, and (2c) monitoring may be used and integrated into the assessment to evaluate the effect or sufficiency of measures, which aim at improving the status of the marine envionment.
3. Minimum requirements for criterion *Reproducibility*: Assessment methodology and monitoring actions allow to compare results and efficiency of measures among regions and member states.
4. Minimum requirements for criterion *Feasibility*: Each member state should be able to participate with financial capacity and with resources currently available, without depending on expertise that exists only in some Member States or specialized institutes.

As basis for the recommendation of a robust assessment and for the estimate of realistic uncertainties and options for their reduction, these minimum requirements were considered as worst-case scenario for a regional assessment. Overall, the availability of input data required for a habitat-based assessment of the temporal and spatial exposure of regions and sub-regions within marine waters of most EU Member States was rated as high. One reason for this high rating is probably the fact that many Member States are involved in transnational long-term surveys on species and habitatsand have good access to environmental data within their national waters such as bathymetry, currents, and temperature profiles. Contrasting this, data required for predictive models in the context of population-dynamic modelling was rated as scarce for most EU Member States. A likely reason for this is the fact that the acquisition of physiological, demographic, or telemetry data at the necessary temporal and spatial resolution requires extensive monitoring efforts leading to increased financial ressources.

The criteria showed that a practicable and robust assessment approach must be based on a comparatively large, empirical database that isavailable to the Member States.

Another important aspect identified was the possibility to identify areas that are most severely affected by impulsive noise and to be able to formulate measures in response to this information. Thresholds compatible with the concept of habitat-conservation approaches were rated as capable of providing transparent results to be used for an effective handling of measures by the regulatory authorities in the Member States.

In the light of the structure and completness of available input data for the current MSDF cycles, an in-depth analysis of individual and heterogeneous datasets (as common practise in, e.g., certain Environmental Impact Assessments) was

rated to be not in line with current assessment priorities and the regional focus of the MSFD. Hence, a quantitative assessment of marine habitats and marine regions exposed to impulsive noise on the basis of available data in noise registries was evaluated to be directly applicable and feasible for all EU regions and sub-regions. Further, an assessment of the environmental status regarding D11C1 on different time scales, i.e., ranging from days to years, was identified as realistic ambition level for a harmonized assessment approach in all marine areas within EU MSFD responsibility.

The general procedure of an immediately applicable assessment approach is described by the following steps (Müller et al. 2021):

- Definition of the Management Area (MA), e.g., Marine Reporting Units (MRU).
- Determination of the assessment area/habitat of the indicator species.
- Evaluation of completeness and quality of the data.
- Determination of Level of Onset of Biological adverse Effect (LOBE).
- Selection of a propagation model to estimate sound pressure fields, effect ranges, or scientifically justified effect ranges (predefined ranges).
- Determination of the temporal and spatial noise pressure.
- Calculation of exposure using assessment/habitat area and noise pressure and determining the exposed habitat (% area and time exposed).
- Assessment of the environmental status based on threshold values for tolerable temporal and spatial exposure.

## Decision Scheme for Noise Propagation Modelling

The general objective of the noise propagation modelling in the context of the D11C1 assessment is to quantify the spatial exposure of noise-sensitive species in marine habitats due to one or more impulsive sound events. Sound propagation from a sound source to a receiving point is largely determined by various parameters including the source location and duration, the source depth, the type of source, the source spectra and distribution of energy, the bathymetry and seabed, the oceanographic conditions (such as temperature and salinity), currents, tides, the weather conditions such as wind and waves and the receiver location.

An important prerequisite for harmonization was that the determined exposed areas (in 2D) or the volume (in 3D) are comparable, i.e., lie in the same result range, regardless of the sound propagation modelling approach used. To achieve such comparable results, also the input data have to be well defined and accurate. For the selection of appropriate propagation models in a regional assessment, a decision scheme was developed as illustrated in Fig. 2. The decision scheme follows four interlinked steps (Müller et al. 2021), which are summarized in the following.

*Scope of application*: Depending on indicator species and marine region, the approach for the noise propagation modelling needs to consider that:

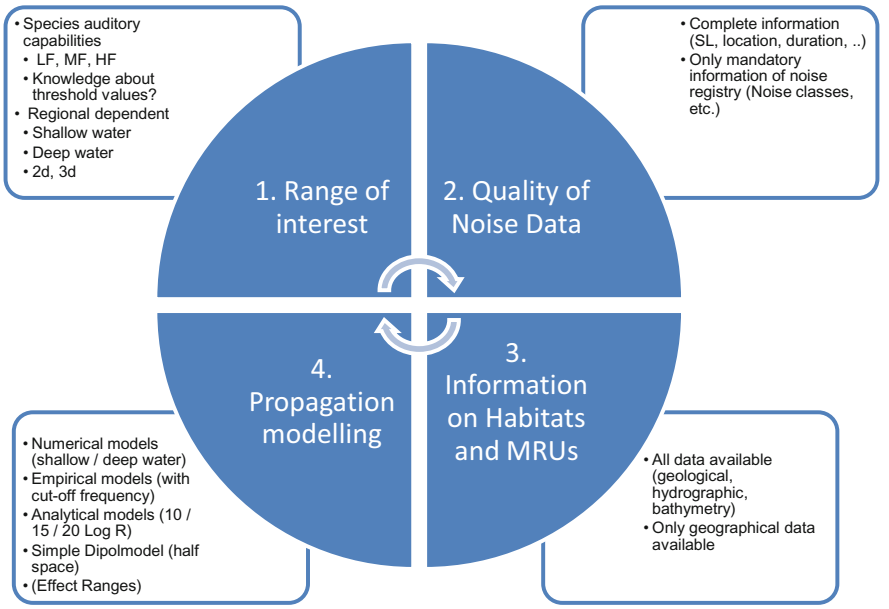

**Fig. 2** Decision scheme for the selection of appropriate propagation models as proposed in Müller et al. (2021)

- Each habitat or MRU has different physical and biological characteristics;
- Each indicator species or groups of species react differently depending on auditory capabilities (e.g., low frequency, mid-frequency, or high frequency), sound source frequency, and sound levels;
- Sound propagation in shallow waters, e.g., in the North Sea, differs from propagation in deep waters, e.g., Mediterranean Sea.

*Quality of noise data in registries*: Ideally, a complete dataset of the source event should be available for determining the sound levels using propagation modelling (source type, source level, location, duration). In addition to the mandatory data reported to noise registries, additional data, e.g., frequency distributions, specified source level, and measured levels, would significantly improve the quality of the noise propagation modelling. Irrespectively, the quantity and quality of available noise data should be evaluated carefully prior to an assessment.

*Selection of Habitat/Area of Assessment*: Habitat or area relevant for assessment should be defined with respect to environmental (bathymetry, topography, currents) and biological (species spectrum, occurrence) characteristics. For regulatory purposes, the selection of administrative sectors could be a suitable choice, which allows Member States to regulate and monitor activities and to define measures to achieve GES, if required.

*Information on geographical, geological, and hydrographic data for habitats or MRUs*: Hydrographic and geological information is important for the quality of the

noise propagation modelling. Sound propagation conditions depend on several parameters such as soil properties, stratification of the water column, and sound velocity profiles, which may change seasonally. There may be situations where required input data may or may not be available, which must be included in the decision-making process when selecting the appropriate modelling approach.

These interlinked steps should be considered for the selection of a noise propagation modelling approach. Based on the results of each step, the most appropriate choice may correspond to advanced numerical simulations, an empirical model, an analytical model, or even an effect range.

The decision-making process is based on a cycle scheme, since input data and selected procedures at all four levels influence the assessment of the environmental status and thus the assessment of GES. Additionally, uncertainties within each step influence the quality of the final assessment. On one hand, this can be seen as a disadvantage, but on the other hand it allows the process to be optimized.

Based on current experience with regional impulsive noise assessments, given the number of events, the accuracy of reported data and the current knowledge of habitats, populations, and species, simple propagation models are in most cases sufficient for the purposes of regional assessments. However, if more detailed input information is available, more complex propagation models can be used if the appropriate resources are available. Due to its EU-wide applicability for all marine regions, empirical approaches are universal and easily accessible in terms of implementation. However, acoustic wave fields are complex and for determining uncertainties in the assessments, a comparison between different propagation models is crucial.

## Numerical Modelling of Impulsive Noise

Both structure and information subject to annual reporting by Member States to the regional impulsive noise registries were defined by the EU-TG Noise during the beginnings of the MSFD. The requirements for reporting were kept low to encourage an active reporting on impulsive noise by EU Member States. The aforementioned requirements include obligatory parameter such as information on the date and location of impulsive noise introduced in the marine environment and other voluntary parameters. The description of the sources and sound propagation plays a key role in converting impulsive noise source information reported in the registry to effective representations of noise levels expected to occur in the marine environment.

Numerical simulations were performed to support the assessment strategies regarding the evaluation of effect ranges. The sound fields were estimated by numerical simulation involving the use of “range-dependent” models taking the previously mentioned parameters (bathymetry, sound speed profile, meteo-oceanic data, sound sources, sedimentology, etc.) into account. For frequencies above 1 kHz BELLHOP ray tracing was used (Jensen et al. 2011). The RAMSurf model using parabolic equations was used for frequencies below 1 kHz (Collins and Kuperman 1994). However, the choice of the model also depends on the modeling context, e.g.,

a ray-tracing method is not appropriate for the description of narrow waveguides (Küsel and Siderius 2019). Modeling was performed in two-dimensional planes (distance x depth), considering a single sound source described as a monopole. The data used as input for the numerical modelling was the data available in regional noise registries, hosted at ICES. To consider important regional differences, the North Sea, the Baltic Sea, and the Ligurian Sea in the Mediterranean Sea were selected as areas for case studies. For each of the case study regions, a sound-intensive activity was selected that represents a realistic impulsive noise event reported in the region. In addition to the regional perspective of each case study, a specific technical focus was given to challenges of quantitative assessments for each of the case studies.

Test case study 1 addressed seismic airgun arrays in the Mediterranean Sea. Airgun blasting is an activity commonly used by the oil and gas industries to locate reservoirs deep beneath the seafloor, involving high levels of impulsive sound. The context of the Mediterranean Sea requires modeling in very deep waters. An objective of this test case was to assess the sensitivity of acoustic propagation with respect to regional variability in bathymetry and bottom type, as well as seasonal variability in sound propagation conditions in water as detailed in Table 2.

The seasonal variation of oceanographic conditions had a strong impact on sound propagation with up to 20 dB difference in broadband level in the surface layer between the summer and winter season based on results from the modeling of scenarios 01A and 01B. The effect of sound speed variability between summer and winter concerned mainly frequencies above 1000 Hz in the upper water layer (up to 30 dB difference at 1000 Hz). This is related to the proximity of the source to the surface (with a source depth of 6 m), as well as by the fact that only the surface layer is affected by seasonal variations in sound speed. The depth-dependent gradient of sound speed in water depends on the temperature, pressure, and salinity of the water.It causes an oriantation of the wavefront by refracting the sound rays toward the surface or toward the seabed. Hence, sound propagation becomes affected by the state of the sea at the surface, or by the geo-acoustic properties of the seabed and its varying reflectivity. This phenomenon adds uncertainty to the estimation of sound levels at the receiving point, and requires that the environment is accurately described. Figure 3 shows an example of seasonal differences in the sound propagation at 500 Hz in the deep water context of the case study region in the Mediterranean Sea. Based on the modelling scenarios 01C and 01D, representing two different propagation directions from the same sound source, the bathymetry and variability of the seafloor properties have a strong impact on sound propagation. One one hand, the propagation of sound may be limited or interrupted in shallow water, e.g., when the sound field reaches the coast. On the other hand, the interaction of sound with the seabed increases for decreasing water depth and the sound propagation becomes affected by the geo-acoustic properties of the bottom. This caused an increase in sound levels of up to 5 dB based on the scenario results.

In order to study the influence of frequency discretization on the modeling results, the scenario 01C for a distance of up to 30 km was repeated by multiplying the frequencies in the calculation of the frequency range between 32 and 1000 Hz. To

estimate the influence of the frequencies discretization on the accuracy in the modelling, three frequency schemes were tested. First, one central frequency was modelled per octave band (i.e., 6 calculated frequencies). Secondly, the calculation was repeated by modeling one frequency per third octave band (i.e., 18 frequencies calculated). Thirdly, one frequency per tenth octave band was modelled (i.e., 60 frequencies calculated). The results from these three schemes were then averaged to yield a single value of transmission loss per octave band to be able to compare the results. The comparison was then carried out by taking the tenth octave band calculation as a best possible case, assuming that the calculation with the finest discretization results corresponds tothe best representation of the real conditions. Table 3 shows the difference of the median values at the 50% percentile of the transmission losses (averaged error ± standard deviation over the range) calculated for each octave band of the one octave band calculation and the third octave band calculation.

The choice of the frequency discretization during the calculation of the propagation had a significant impact on the precision of the calculation. While the average deviations observed were close to zero, differences of up to 20 dB appeared locally. It is possible that these deviations affect the surface layers and the deep layers more frequently. The choice of an appropriate frequency discretization for sound propagation calculations hence corresponds to a compromise between the desired accuracy of the results and the time allocated to the calculation.

Test case 2 addressed underwater explosions in the Baltic Sea. Underwater explosions occur in different contexts (e.g., civil engineering such as rock excavation or fragmentation before drilling, military activities such as detonations of unexploded ordnance or ship shock trials) and are among the noisiest man-made activities in the seas. The objectives of this test case were to analyze the effect of sediment variability, the effect of bathymetry, the influence of source profiles, and the frequency dependence of underwater propagation as described in Table 4.

The joint influence of sediment variability and bathymetry has a strong impact on sound propagation, as demonstrated by the choice of two different bottom types (rock or sand) and two different bathymetric profiles for the modeling of scenarios 02A-B-C-D. Figure 4 shows the influence of the bottom properties on the acoustic propagation in a shallow-water context at 63 Hz. Overall, the rocky-type sediment was found to be more favorable for sound propagation, especially at low frequencies. The difference in transmission loss with respect to the sandy-type sediment reaches 80 dB for the lowest frequency of 32 Hz. This causes a difference on the broadband level received at 100 km from the sound source of up to 35 dB. These results highlight two strong influenceing factors on the propagation of sound: the cutoff frequency onone hand, which has the effect of blocking the propagation of energy below the cut-off frequency. The value of which depends on the water level and the type of sediment. The second phenomenon is the interaction of the acoustic wave field with the seabed. The reflection coefficient determines the proportion of energy that is reflected back into the water column and thus not lost in the sediment. At long distance, the repeated interactions of sound and the seabed make the effect of the reflection coefficient significant. Further, comparison of two different modeled source profiles has highlighted the importance of including the frequency distribution of the acoustic energy emitted by the source in the assessment.

Test case 3 addressed pile driving activities in North Sea, which involves repeatedly pounding long steel pipes into the ocean floor to support other structures, such as bridges, piers, and wind turbines (Table 5). A large hammer is used to strike the top of the pile, generating vibrations in the air, water, and sediment. The objectives of this test case were to study the effects of different technical noise abatement measures and their effectiveness depending on the source profile used. Details on technical noise mitigation solutions and examples of their associated mitigation effectiveness as observed at specific sea sites as also used in this case study are described in a cross-project experience report for offshore windfarm construction projects in Germany (Bellmann et al. 2020).

The considered source spectrum has a large effect on the modelled distribution of the underwater noise generated at the pile. Mainly because piling is performed in

shallow water, which exhibits a strong influence by the cutoff frequency. It has an even larger effect on the modelled efficieny of mitigation systems. The efficiency of the mitigation strongly depends on the source profile, since the attenuation is frequency dependent, with maximum reduction at mid frequencies (300–4000 Hz). Using a different source profile derived from Bellmann et al. (2020) altered the results. Further issues that add to the uncertainty of results result from the interaction with the seabed, which is site specific and influences the contribution of the sea-bottom thus altering the performance of the mitigation system. Using unrealistic source spectra potentially introduce deviations of about 10 dB in the estimate of the efficiency of the mitigation system.

## Conclusions

As result from the data harmonization, regional case studies, and quality assessment, it was demonstrated that a quantitative assessment of exposed marine habitats by impulsive sound based on available data in noise registries would be directly applicable for all EU regions and sub-regions. Further, a time-dependent assessment of the environmental status regarding D11C1 for different time-scales was identified as a realistic goal for a harmonized assessment approach in all marine areas within EU MSFD responsibility.

A key characteristic of the habitat-based approach identified as basis for harmonization was its potential to assess and limit impacts due to underwater noise by setting spatial and temporal thresholds for noise in certain habitats or parts of habitats (e.g., national reporting units, subregional units). Furthermore, the approach can be applied in line with the precautionary principle. For preventing impacts on marine

life due to impulsive noise the approach enables the protection of habitats by safeguarding the availability of a minimum proportion of undisturbed habitat at all times. Hence, the approach may ensure that relevant populations sensitive to underwater noise are able to use their habitat for vital functions despite being subjected to noise.

Priority targets for a successful implementation of such a harmonized assessment in the next MSFD cycles were identified as follows:

- Implement a robust area-based assessment methodology. This conclusion is supported by the fact that uncertainties are introduced by the regional registries that do not support a high-resolution assessment.
- Focus has to be directed to achieve data completeness in the noise registries. An assessment based on data, which islacking the majority of noise events would introduce uncertainties that are not acceptable.
- Focus on the improvement of the quality, reliability, and completeness of biological input data.
- Identify and agree on the biological component addressed in the assessment, such as at least one relevant species per region.
- Establish biological thresholds for species, species groups, or habitats of interest for the assessment in order to quantify the area affected by sound.
- Acquire information on the occurrence of species and their spatial and temporal distribution.
- Analyze impulsive noise characteristics, including spatial and temporal variations and differences between noise generating activities.
- Document and acquire additional information on impulsive noise occurances, such as results from measurements or results from the application of mitigation measures (e.g., technical noise abatement, spatial/temporal restrictions, and deterrence protocols).

Future objectives to be addressed after Member States and regions have gained experience with the evaluation of the current environmental status are how to use the assessment to determine the good environmental status (GES). In addition, a future task will be to identify targets and measures to be applied if the assessment shows that GES has not been achieved.

**Abstract**

Invasive bigheaded carps (*Hypophthalmichthys molitrix* and *H. nobilis*) are two aquatic invasive species that are expanding their range throughout the Mississippi River Basin. These carps display negative phonotaxis to broadband sound, and thus, acoustic deterrents have shown promise for managing their populations. Numerous dams block direct upstream access for the carp; however, fish can bypass these physical obstructions by swimming through navigational locks. Nonphysical acoustic deterrents have the advantage of not effecting navigation, are relatively inexpensive, and could be tuned above the hearing range of non-ostariophysian fishes. Fish also react negatively to high levels of carbon dioxide, and it has been proposed to combine these two stimuli into one deterrent system to reduce potential habituation to long-term acoustic playbacks and increase barrier efficacy. Here, the possible synergies of combining these two stimuli into integrated deterrent systems are evaluated.

## Introduction

A species introduced to a new range by humans is considered invasive when it reaches densities that can negatively affect native species and the environment. Historically, invasive species were considered second only to habitat loss endangering native species in the United States (Wilcove et al. 1998). Over a third of the species federally listed as threatened or endangered are imperiled primarily due to predation by, or competition with, non-native species (Pimentel et al. 2005). Indeed, non-native species are the second most common cause of extinction, after biological resource use, for all species worldwide since 1500 CE (Bellard et al. 2016). Invasive species are a growing problem caused by human introductions and will require active management to mitigate or prevent damages.

Two aquatic invasive species of recent concern in North America are the bighead carp (*Hypophthalmichthys nobilis*) and silver carp (*H. molitrix*). These carp species were first introduced to the United States from China in the early 1970s as a non-chemical method for plankton control in public water treatment facilities (Kelly et al. 2006). By 1975, silver carp had escaped and established wild populations in Arkansas waterways (Kolar et al. 2007). Their spread into open water systems was accelerated by extensive flooding of private sector aquaculture operations in the 1990s (Kelly et al. 2006). Common names for non-native species can have unintended social consequences (Larson 2005), such as fostering xenophobia. For this reason, although the common name of "Asian carp" for these species persists colloquially, hereafter the two species of silver and bighead carp will be collectively termed bigheaded carps.

Bigheaded carps are currently expanding across the United States (Noatch and Suski 2012). There is concern that these invasive carps will travel from the tributaries of the Mississippi River Basin where they have currently established populations and ultimately colonize the Laurentian Great Lakes (Kolar et al. 2007). After establishment, extirpation is nearly impossible, so prevention is the most efficient and cost-effective method to control highly invasive species (Lodge et al. 2006). Research on new barrier technology aims to prevent further range expansion into yet uninvaded ecosystems (Putland and Mensinger 2019; Vander Zanden and Olden 2008; Vetter et al. 2017a). The general goal of these selective barriers is to prevent the passage of undesirable species while simultaneously allowing the natural migration of native fish (Rahel and McLaughlin 2018).

Bigheaded carps have caused ecological damage where they have established large breeding populations, including inducing declines in native fish condition (Irons et al. 2007), and alteration of zooplankton communities (Sass et al. 2014). Currently, bigheaded carps account for 70% of fish biomass in the lower Illinois River (Garvey et al. 2012). There are concerted efforts underway to prevent

upstream passage into Lake Michigan through the Chicago Area Waterway System (Kolar et al. 2007). An electrical barrier in a lock chamber near Chicago prevents fish passage; however, it has numerous disadvantages: high maintenance expenses including energy costs, continual power usage with susceptibility to outages, potential lethality to humans, and reduced efficacy against small fish (Davis et al. 2017; Noatch and Suski 2012). Additionally, no single behavioral barrier is likely to stop all fish, and redundancy in deterrent systems would be necessary to achieve 100% efficacy (Davis et al. 2017).

To reduce economic costs such as impeding or stopping commercial vessel traffic, there is interest in developing nonphysical carp barriers, meaning they do not disrupt the flow of water or boat traffic (Noatch and Suski 2012). Besides electricity, broadband sound has been effective in deterring carp swimming (Vetter et al. 2015; Vetter et al. 2017b) and even prevented schools from passing through a narrow channel (Murchy et al. 2017). However, there is concern that habituation would occur in naturalistic environments and over longer exposure periods.

In addition to acoustic deterrents, fish can sense carbon dioxide ($CO_2$) through gill receptors (Perry and Gilmour 2002) and exhibit negative chemotaxis when $CO_2$ concentrations exceed certain levels. Bigheaded carps are known to exhibit various aversion behaviors to carbon dioxide including negative chemotaxis (Cupp et al. 2017; Cupp et al. 2018b; Donaldson et al. 2016; Tix et al. 2018). Future studies will need to demonstrate whether changes in carp movement responding to nonphysical deterrents over time are due to habituation, fatigue, or a combination of factors.

Dams and adjacent lock chambers offer pre-existing infrastructural pinch points to reduce the movement of bigheaded carps. A vessel traveling upstream through a lock and dam structure enters the lock through a gate, which then closes behind the vessel. Fish may also enter the lock chamber simultaneously with the vessel. The water level in the lock is adjusted to meet the level of the river upstream, raising the vessel. Then, the upstream gate opens so the vessel and any fish that remain in the lock chamber can pass upstream. Nonphysical deterrents may be able to encourage fish to move out of lock chamber before the downstream gate closes or prevent fish from passing through the downstream gate in the first place (Fig. 1).

In addition to moving through the lock chamber during vessel passage, fish may be able to pass upstream through other parts of a dam structure. During periods of unusually high water in the upstream reservoir or river segment, it may be necessary for infrastructural security or to reduce upstream flooding to open additional spillways that are typically closed during normal river conditions. Two design elements for dam spillways found on the Illinois River are wickets and gates (Coulter et al. 2018). To allow increased water flow past a dam, gates can be raised, and wickets lowered. In gated dam designs, a gate is raised above the water level to allow increased flow. In contrast, slabs called wickets are hinged to a foundation on the river bottom and can be laid flat onto the riverbed. In wicket-style dam designs, wickets are lowered to allow increased water discharge downstream. The design differences of each dam type may influence the ability of fish to pass through the structure.

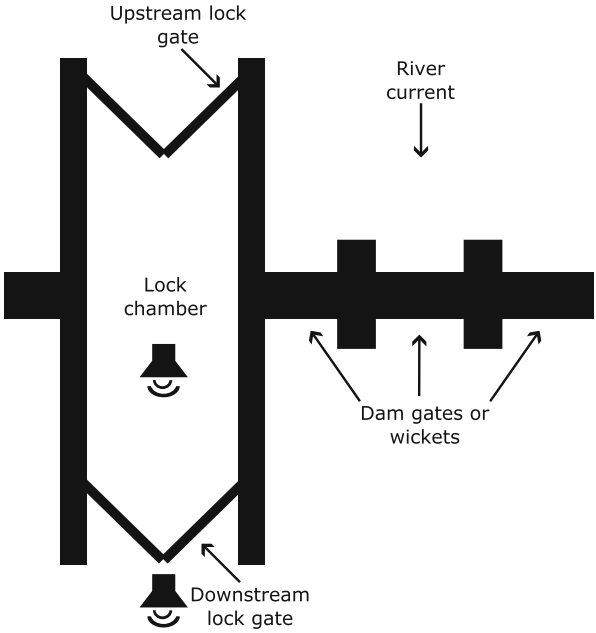

**Fig. 1 Lock and dam structure**. A lock chamber allows vessel and fish passage through the dam. Acoustic deterrents could be placed in the lock to encourage fish to exit before the downstream gate closes or outside the lock to prevent entry. Potential locations for acoustic deterrent placement are indicated by speaker icons

Characterizing current movement trends through physical lock and dam barriers will inform best practices for nonphysical barrier placement. Bigheaded carps were found to travel more frequently through wicket-style dams in the lower Illinois River than through gated-style dams found upriver (Coulter et al. 2018). Some dam designs present higher risk for carp transmission than others and may be better candidates for nonphysical deterrents. In gated-style dams on the Illinois River, bigheaded carps were found to travel through the dam gate more often than through the lock along with transiting vessels (Lubejko et al. 2017). Therefore, it may be useful to place behavioral deterrent systems near dam gates or wickets as well as near lock chambers (Fig. 2).

The majority of carp crossings may occur during open-river conditions when the dam gates are either completely open or overtopped, compared to normal river conditions (Lubejko et al. 2017). Overtopping presents a serious threat to physical barrier efficacy due to the uncontrolled river state during floods. For example, the Starved Rock Lock and Dam (Illinois River, USA) has been overtopped six times between 1933 and 2017 (Lubejko et al. 2017), and this condition is expected to occur more often with increasing precipitation in the Midwest due to climate change (Dai et al. 2016). In addition to strategic deployment near locks or dam gates selected for high risk of carp passage, secondary deployment above dam structures for use during overtopping events may be another potential application of behavioral barriers. In this way, nonphysical acoustic and/or $CO_2$ barriers could potentially extend the effective dam head height for invasive carp during flood conditions. However, future

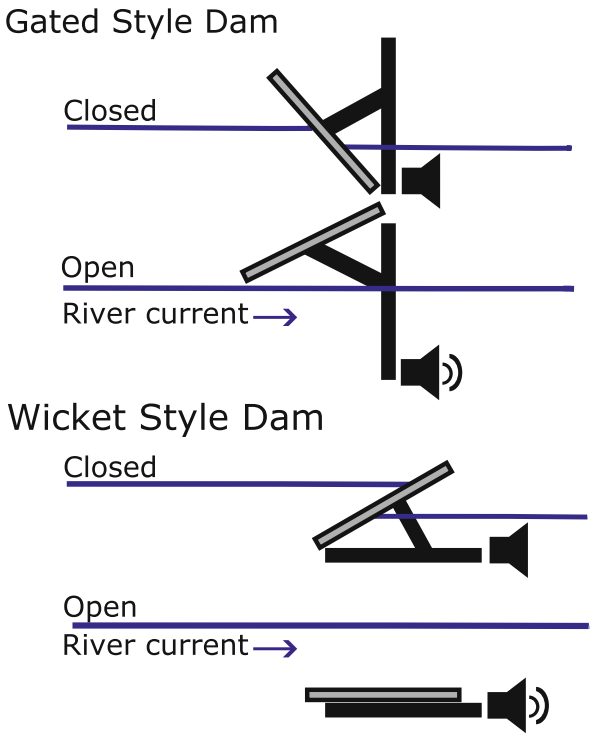

**Fig. 2 Gated- and wicket-style dams.** Fish may be able to pass under raised gated-style dams or over lowered wickets. Acoustic deterrents could be placed near any downstream spillway that is periodically open during periods of high water and activated strategically

research would be necessary to determine the possible efficacy of behavioral barriers placed above dams to reduce invasive fish passage during overtopping. Reaching the dissolved $CO_2$ concentrations necessary to elicit avoidance responses may be difficult at the high-flow speeds associated with open-river conditions. Other deterring stimuli like sound would be less limited by flow rate than dissolved $CO_2$. Like any integrated pest management solution, different modalities that may be limited individually can provide synergies when combined (Barzman et al. 2015). Future research should determine the combination of deterrents that is appropriate for the full suite of possible river conditions at deployment sites.

## Response of Invasive Bigheaded Carps to Nonphysical Deterrents

The current literature has shown bigheaded carps avoid both acoustic signals and $CO_2$, although there are various limitations and strengths to each stimulus. Here, limitations for each are reviewed, and the case for developing an integrated deterrent system using both stimuli is presented. In many cases, the weaknesses of one deterrent, such as lacking species selectivity, are covered by the other. Further,

synergies from combining two stimuli may develop, such as reduced habituation to any one modality alone.

## Acoustic Deterrents

Since accidental introduction in the North American Mississippi River, bigheaded carps have negatively affected resident ecological communities. Reducing range expansion will require finding new methods to block upstream migration. A promising method is the use of acoustic carp deterrents at lock chambers to allow vessel traffic to pass freely through dams (Putland and Mensinger 2019). As ostariophysians, carps have specialized bones called Weberian ossicles that directly connect the swim bladder and inner ear. These bones allow for sound pressure detection, giving the fish a greater bandwidth of frequencies detected (up to 5 kHz, Vetter et al. 2018) than many native species that do not possess morphological specializations thought to aid in enhanced hearing.

The historical distinction between species as hearing generalists and specialists is overly simplistic (Popper and Fay 2011). Instead, a continuum of hearing ability is more appropriate, where interspecific variation in hearing is largely dependent on the specialization of structures to assimilate sound pressure into the sense of hearing with the more basally evolved sense of particle motion (Popper et al. 2021). Fishes without known specialized hearing structures, such as the Weberian apparatus, can generally detect frequencies in the range of approximately 100 Hz to 1 kHz at threshold levels around 78–150 dB re 1 μPa (Ladich and Fay 2013). Comparatively, fishes with hearing specializations generally have much lower sound pressure thresholds for detection and respond at higher frequencies (200 Hz to 3 kHz, Ladich and Fay 2013).

Studies on fish hearing can be completed with behavioral experiments and by measuring auditory evoked potentials (AEP), a noninvasive technique to record electrophysiological activity in response to sound. As determined by AEP using high-frequency sound, bigheaded carps can detect frequencies from 100 Hz up to 5 kHz (Vetter et al. 2018). Since hearing as the perception of sound is both sensory and behavioral, behavioral studies of fish hearing thresholds may be more accurate than electrophysiological experiments alone (Popper and Hawkins 2021; Popper et al. 2019; Sisneros et al. 2016). A behavioral audiogram of bigheaded carps would be useful to develop acoustic deterrents finely tuned to their assimilated sense of hearing, although this data is not available at this time. Regardless of whether current AEP data underestimate the upper range of bigheaded carps' hearing, the high end of bigheaded carps' auditory frequency range exceeds that of most native fishes in the Mississippi River Basin. This sensory difference presents ample opportunity to increase the selectivity of acoustic deterrents for invasive bigheaded carps and minimize the effects on native species by using higher-frequency sound (e.g., 1–5 kHz).

## Species Selectivity

Well-designed acoustic deterrents should affect target invasive species while mitigating off-target effects on native species. The same acoustic deterrent could differentially affect species based on interspecific acoustic sensitivities (Jesus et al. 2019). Therefore, acoustic deterrents composed primarily of frequencies above the hearing range of non-ostariophysans could better target bigheaded carps. However, frequency sensitivities alone may not provide complete species selectivity in application at locks and dams. Some frequency detection overlaps with native species, and bigheaded carps are expected. Other native cyprinids and siluriformes (superorder *Ostariophysi*), as well as clupeids (order *Clupeiformes*), would likely still be able to detect high-frequency signals. In a behavioral screening of native and non-native ostariophysan responses to an acoustic deterrent, bigheaded carps were found to demonstrate repeated negative phonotaxis unlike most native species tested (Murchy et al. 2022). While a native cyprinid, bigmouth buffalo (*Ictiobus cyprinellus*), also responded to the acoustic stimulus, fewer consecutive reactions were observed compared to bighead carp. High-frequency acoustic deterrents may be able to target bigheaded carps' hearing while mitigating off-target effects on native species (Murchy et al. 2022).

Bigheaded carps share key behavioral and invasion history similarities (Kelly et al. 2006), which may allow acoustic deterrents to manage both species simultaneously. However, bigheaded carps are distinctly different from common carp (*Cyprinus carpio*), and studies using common carp as a proxy for bigheaded carp have limited value (Murchy et al. 2016). Silver and bighead carps frequently hybridize in the wild, and post-$F_1$ hybrids are not sterile, raising the possibility in the near future of a hybrid being the dominant genotype over parental genotypes (Lamer et al. 2010). In behavioral response to acoustic deterrents, silver (Vetter et al. 2015) and bighead (Vetter et al. 2017b) carps demonstrate consistent negative phonotaxis from complex sounds, but habituate more quickly to pure tones. To date, most studies have demonstrated similar responses between the two, suggesting they can be co-managed by one broadband sound stimulus. Further, broadband sounds will likely be more effective at providing species selectivity, possibly by reducing habituation to any one frequency or spanning a larger swath of the target species' hearing sensitivity (Jesus et al. 2019).

## Limitations of Acoustic Behavioral Barriers

In general, excess anthropogenic sound has the potential to disrupt native fishes' information about the soundscape, to communicate, find prey, or avoid predation (Slabbekoorn et al. 2010). For example, excess noise could mask native fish acoustic communication by reducing the area in which a fish seeking a mate can be heard by conspecifics. Alternatively, masking could reduce the quality of information communicated such as when a signal recipient can no longer detect and/or discern mate quality due to attenuation of the signal. While these concerns for excess anthropogenic noise are generally valid, they are not especially relevant when considering the application of acoustic deterrents for bigheaded carps. Concern about anthropogenic

masking is spatial scale dependent, and the proposed locations of deterrents are highly localized, such as immediately adjacent to dam or lock chamber gates. Further, the temporal effects of acoustic deterrents are constrained, as they can be instantaneously turned on or off, depending on when dam gates are opened, for example.

Acoustic deterrents could be less effective if too intense or implemented for excessive durations. Long-term exposure to high-intensity broadband sound (24 h, 155 dB re 1 μPa) can induce temporary hearing loss in bigheaded carps (Nissen et al. 2019). This suggests that carp deterrents may render themselves less advantageous if designed to produce sound any longer than necessary or if fish remain trapped in the auditory range of the deterrent. However, Nissen et al. (2019) found that short-term exposure for 30 min at the same sound intensity resulted in fewer significant differences in hearing loss between control and treatment fish than the 24 h treatment. Tested immediately after 30 min sound exposure, bighead carp hearing thresholds were elevated above baseline by ~10 dB at 0.4, 0.6, 1, and 2 kHz. After 96 h of recovery, only the shift at 2 kHz remained. In contrast, a silver carp threshold shift was observed only at 0.6 kHz, which returned to baseline after 96 h of recovery. Thus, acoustic deterrent systems should be evaluated in the field to ensure target species do not undergo temporary threshold shifts that impair their ability to hear the deterrent. It will be necessary to assess whether motile fish in the field voluntarily remain in range of an acoustic deterrent long enough for hearing shifts to occur or if fish vacate an area too quickly for hearing shifts to pose any real risk.

Any behavioral deterrent will only be able to act on motile developmental stages that can chose whether to avoid or challenge the barrier. The movement of propagules like eggs by downstream water flow, or by transport from other species, will not be reduced by acoustic barriers. For example, invasive common carp may be able to colonize new waterbodies via the transport of eggs passing through the guts of waterfowl (Lovas-Kiss et al. 2020). Lovas-Kiss et al. (2020) found that only about 0.2% of common carp eggs survived intact through the mallard gut, as indicated by embryo movement in the intact egg after egression. However, given the large consumption of fish roe by birds, 0.2% survival might be sufficient for colonization. The majority of common carp eggs were egressed within 1 h of feeding, suggesting a maximum dispersal range of 60 km given the flight speed of mallards. Any underwater deterrent system will be limited to dispersal through water, and so airborne vectors are not specific limitations for acoustic deterrents.

Bigheaded carps may habituate to an acoustic deterrent as exposure time increases. Habituation to acoustic deterrents needs further and longer-term study. Few studies have examined habituation in fish at all, and many use different definitions or give no definition of “habituation” (Putland and Mensinger 2019). Some studies have found evidence of diminishing responses after repeated exposure to acoustic deterrents. Murchy et al. (2017) found that the percentage of successful repels away from an acoustic deterrent decreased slightly with consecutive sound presentation over a short time period. However, the methodology was unable to discriminate between habituation to sound and fatigue from repeated simulation. Notably, the repulsion rates remained above 80% after the fifth consecutive

application. This long-term limitation could potentially be mitigated by playing the sound only when deterrence is most critical instead of continually. For example, acoustic deterrents could be turned on as the lock gates are opening and then stopped when the vessel is in the lock with the gate shut. By using an acoustic deterrent only as often as necessary, or by varying the sounds used, the risk of habituation can be reduced.

### Pairing Acoustic Deterrents with Other Modalities

Selectively allowing fish passage requires differentiation based on biological traits such as physical capability, morphology, sensory ability, behavior, or movement phenology (Rahel and McLaughlin 2018). It may prove most advantageous to design deterrents that act on multiple species differences at once. For example, to overcome the limitations of acoustic deterrents such as insufficient efficacy and habituation, it will likely be necessary to pair sound with other stimuli that invasive carp can sense and avoid. For example, a bubble curtain paired with an acoustic deterrent was 95% effective at deterring the movement of bighead carp across a channel (Taylor et al. 2005).

Further, nonphysical barrier systems could simultaneously use a "push-pull" strategy to be even more effective (Cook et al. 2007). Deterring stimuli like acoustics or chemical irritants could be used to "push" individuals away, whereas attractive stimuli like food or pheromones "pull" select organisms toward an area for removal (Cook et al. 2007). Adding multiple modalities to any deterrent system builds redundancy and resiliency into the integrative solution.

## Carbon Dioxide as a Deterrent

A localized area of elevated dissolved $CO_2$ could serve as either a behavioral or physiological barrier to fish passage, in the former by reaching levels of avoidance or in the latter by exceeding homeostatic thresholds for dissolved $CO_2$ in the bloodstream, known as hypercapnia tolerance (Noatch and Suski 2012). Invasive carp becoming immobilized by loss of equilibrium (LOE) from hypercapnia will be pushed downstream by the flow of the river, effectively reducing upstream passage. Moreover, by adding dry ice to frozen-over ponds, the partial pressure of $CO_2$ ($pCO_2$) can be increased to lethal levels for controlled winter fish kills (Cupp et al. 2018a). Silver and bighead carps were more susceptible to this under-ice $CO_2$ application than a related native cyprinid, the fathead minnow (*Pimephales promelas*) (Cupp et al. 2018a). Unlike other chemical additives such as conventional piscicides, $CO_2$ does not pose similar toxicity threats (Noatch and Suski 2012). Further, $CO_2$ diffuses spontaneously out of water. For targeted $CO_2$ removal, water can be cheaply aerated to push dissolved gases out of solution.

Free-swimming bigheaded carps avoid regions of elevated $pCO_2$ (Borland et al. 2020; Cupp et al. 2017; Dennis et al. 2015; Donaldson et al. 2016). In a moving water column, schools of bighead carp decide to spend less time in a $CO_2$-injected flume in preference to a non-injected flume (Hasler et al. 2019). When implementing

a nonphysical gas bubble curtain in outdoor controlled ponds, $CO_2$ injection significantly reduced the number of attempted crossings over the barrier but was not 100% effective at reducing passages (Cupp et al. 2017). Spatial analysis of this dataset reveals carps prefer areas as far away from the $CO_2$ injection site as possible (Borland et al. 2020).

A $CO_2$ barrier will likely be best implemented as part of a multi-modal system utilizing multiple integrated deterrents. By acting on multiple sensory modalities, deterrents will be more easily detected than unimodal systems and elicit heightened behavioral responses (Deleau et al. 2020; Putland and Mensinger 2019). For example, light and sound stimuli could be coupled with the bubbling of $CO_2$ gas into the water column to produce an augmented bubble curtain barrier. It will be necessary to determine which of these modalities is most biologically relevant to target species' sensory systems. One study found invasive common carps primarily use sound and hydrodynamic flow cues when avoiding an air bubble curtain instead of visual signals (Zielinski et al. 2014). When light was added to a coarse-bubble curtain, deterrent efficacy decreased significantly from 87% to 75%, opposite to the expected direction if light were perceived as a visual deterrent. Instead, the common carp may have used the light to visually identify and exploit gaps in the curtain (Patrick et al. 1985). Again, however, caution must be used in extrapolating results from common carp to bigheaded carp.

### Limitations to Carbon Dioxide as a Nonphysical Barrier

A pattern of negative chemotaxis is widely observed across fish species and size classes; therefore, $CO_2$ barriers implemented alone will not afford species-level selective permeability (Dennis et al. 2015; Donaldson et al. 2016; Kates et al. 2012; Rahel and McLaughlin 2018). Juvenile bighead and silver carp, bluegill, and largemouth bass show similar aversion behaviors as well as RNA transcriptome stress responses to carbon dioxide exposure (Dennis et al. 2015). Irregular activities such as surface ventilations, twitching, and equilibrium loss also increase across these four species with $pCO_2$ (Kates et al. 2012).

There is high intra-species variation in $pCO_2$ avoidance thresholds (Kates et al. 2012), and deterrent systems will likely need to select for the upper end of these thresholds. Studies testing individuals repeatedly may explain some of this intra-species variation. Tolerance to $CO_2$ was found to be repeatable within individual largemouth bass (*Micropterus salmoides*), as evidenced by 60% of the variation in time to equilibrium loss being explained by inter-individual differences (Hasler et al. 2017). Therefore, $CO_2$ tolerance may be a heritable trait subject to natural selection, although further work will be necessary to determine if this is the case (Hasler et al. 2017). Notably, inter-individual differences are not the standard test for heritability; rather, changes across generations are, which was not captured in the methodology.

If anthropogenic $CO_2$ deterrents provide a positive selective force for hypercapnia tolerance, populations could potentially evolve increased tolerance (Hasler et al. 2017). This would render $CO_2$ deterrents less effective on generational timescales. However, it is reasonable to expect that the level of dissolved $CO_2$ could be quickly adjusted if any meaningful tolerance to $CO_2$ evolved in invasive populations. Future

research will be necessary to establish whether $CO_2$ tolerance is heritable and whether $CO_2$ deterrents pose meaningful selective pressure at relevant timescales. Future studies should be completed in both native species and target invasive species, as not all species would be expected to undergo equal selective pressure from a given deterrent. For example, if a native species evolves $CO_2$ tolerance as suggested is possible by Hasler et al. (2017), but an invasive species does not, $CO_2$ barriers might affect the deterrent's species selectivity in a beneficial direction.

Management actions are not without risk; a poorly implemented barrier of any type would allow the passage of undesirable species while blocking desirable species and may result in worse outcomes than an unaltered river channel (Rahel and McLaughlin 2018). If implemented alone, a $CO_2$ barrier would likely result in a similarly negative outcome due to the indiscriminate deterrence of all fish species. Increased fragmentation of native fish habitat is a potential cost to consider in tradeoff with reducing bigheaded carps' range expansion. For this reason, $CO_2$ may be best deployed as part of a multi-modal deterrent system only when other sensory modalities provide sufficient species-level selectivity and $CO_2$ is not continually deployed (Deleau et al. 2020; Putland and Mensinger 2019).

In contrast, an especially well-designed barrier will be able to alter upstream and downstream movement independently. The Illinois River flows downstream from Lake Michigan, requiring bigheaded carps to swim upstream to colonize the Laurentian Great Lakes. Modeling of bigheaded carp movement in the Illinois River reducing both upstream and downstream carp movement together suggests populations may increase near the invasion front if fish are not allowed to travel back downstream (Coulter et al. 2018). That is, downstream bigheaded carp movement in the Illinois River exceeds upstream movement, such that if barriers are deployed that reduce bidirectional travel equally, carp populations may increase upstream at the invasion front (Coulter et al. 2018). It will likely only be necessary to place deterrents at downstream lock gates instead of upstream ones. Finally, a $CO_2$ barrier will only be effective when mobile organisms can choose to avoid elevated zones, and it would not deter downstream movement of propagules (Kates et al. 2012). In the Illinois River, $CO_2$ barriers would primarily attempt to reduce upstream passage of mobile adult fish, as downstream propagule movement would be less critical to preventing colonization of Lake Michigan.

## Adverse Effects in Native Species

Fathead minnows, but not silver carp, were found to lose olfactory predator avoidance behaviors when exposed to prolonged $pCO_2$ over multiple hours (Tix et al. 2017). Therefore, the impairment of olfactory ability by $CO_2$ may be species specific. An unintended reduction in predator avoidance in native species, but not invasive species, would oppose the conservation goal to reduce invasive populations' interspecific competitive advantages. However, Tix et al. (2017) did not control for the concentration of skin extract alarm cue used across species; thus, there is not yet definitive evidence that $CO_2$ barriers are more harmful to a native species than these target invasive species. Notably, most fathead minnow predator avoidance behaviors returned to baseline after recovery in ambient water, and

free-swimming native fish will likely move away from $CO_2$ barriers before olfactory impairment occurs (Tix et al. 2017).

Since $CO_2$ is toxic to all fish, it may weaken undesirable individuals that challenge a nonphysical barrier. However, similar effects are also likely to occur in non-target species. Elevated $pCO_2$ induces internal hypercarbia and LOE in fish when blood concentrations exceed physiologically tolerable levels, potentially rendering them unable to swim through a gas bubble curtain (Cupp et al. 2020). Weakened fish may not be able to swim through the high-velocity water found in partially open gated dams if weakened by $CO_2$, for example. In contrast to this suggested toxicity effect on passage through a barrier, elevated $pCO_2$ did not impair largemouth bass burst swimming speed and is not expected to impair the movement of similarly sized fish such as bigheaded carps; however, 25–50% of largemouth bass experience LOE when exposed to $CO_2$ concentrations of approximately 100,000 μatm for 120–600 seconds (Schneider et al. 2019). If concentrations and exposure durations of this magnitude are achievable in the field, inducing LOE could reduce the passage of all fish species. Studies on burst speeds in target invasive species need to be conducted, since the assumption that similarly sized largemouth bass will be equally impaired may be inaccurate.

Except for Tix et al. (2017), no study has found serious adverse effects of $CO_2$ in native riverine fish species that were not shared with bigheaded carps (e.g., LOE at elevated concentrations). However, full characterization of species richness, abundance, and susceptibility to $CO_2$ will be necessary to ensure application is appropriate for management goals before field installments of chemical deterrents (Cupp et al. 2020).

### Effects of Water Temperature and Fluid Dynamics

Rivers are not static systems. Moreover, any potential barrier site will have idiosyncratic environmental properties, and nonphysical barriers must therefore be effective under a variety of field conditions. Temperature, barometric pressure, pH, $CO_2$ uptake via photosynthesis, and hydrodynamics will introduce temporal variation in local $pCO_2$, and field testing will be necessary to characterize these conditions at any potential application site (Cupp et al. 2018b). Aerating downstream from a deterrent to increase $CO_2$ off-gassing could reduce risk to non-target species if field testing suggests there may be residual downstream effects (Cupp et al. 2018b). That is, the zone of elevated $CO_2$ can be highly spatially controlled with simple technology like air bubble barriers to mitigate negative effects on native species or at a minimum reduce the impacted area of the river system.

The amount of $CO_2$ used to deter bigheaded carps will likely need to be higher in summertime than in winter due to temperature-dependent effects on voluntary avoidance behavior; bighead carp avoided $CO_2$ at 41% lower concentrations in cold water compared to warm water (Tix et al. 2018). This likely occurs because cold water can hold more dissolved gas than warm water; water and gas concentration are inversely related. Fish metabolism is slower in cold temperatures, and both intake and elimination of $CO_2$ may retard at low water temperatures (Cupp et al. 2020). Studies should use both seasonally appropriate and physiologically optimal

temperatures when designing selectively permeable barriers based on trait differences between species (Rahel and McLaughlin 2018).

## Other Deterrence Methods

In addition to acoustic and $CO_2$ deterrence, other methods have been investigated to reduce the spread of bigheaded carps. Electrifying lock chambers has been proposed as one method to stop fish movement, but concerns about juvenile fish being able to travel through voltage fluctuations in the electrical barrier remain (Davis et al. 2017). Bubbling air into a curtain underwater creates a nonphysical barrier that has been found to substantially reduce bigheaded carp movement (Zielinski and Sorensen 2016). The process of bubbling air underwater inherently creates sound that may partially explain fish deterrence. Further, bubble curtains have been ensonified and illuminated to increase the modalities of deterrents with varied effects (Zielinski et al. 2014). It almost certainly is necessary to combine multiple deterrent methods to reduce the risk of invasive fish passage down to acceptable levels.

## Discussion

Acoustic deterrents have been proposed to reduce the upstream range expansion of bigheaded carps. As ostariophysians, these invasive fishes have hearing sensitivity in higher-frequency ranges than most native fishes, and so acoustic deterrents may afford species-level selectivity (Murchy et al. 2022). Most nonphysical deterrents will only be able to reduce the upstream passage of motile life stages of invasive populations, and acoustic deterrents will not provide an exception to this limitation. Concerns about habituation to repeated playback of acoustic stimuli will need to be further examined. To reach deterrent efficiencies suitable to prevent invasive species range expansion across long-term timescales, it may be necessary to combine acoustic deterrents with other sensory modalities.

While the specific application of carbon dioxide as an under-ice piscicide has been established as plausible and highly effective (Cupp et al. 2018a), its infusion through bubble curtains has been additionally proposed as a nonphysical behavioral barrier to bigheaded carps by effectively controlling their movement. However, $CO_2$ will require integration with additional stimuli as a behavioral deterrent in the field. In flowing rather than still water, bighead carps demonstrate avoidance behaviors like lateral switching between flumes of high and low dissolved $CO_2$ (Hasler et al. 2019). When considering the application of $CO_2$ plumes in locks and dams as a nonphysical deterrent, inter-species differences will not be sufficiently selective. Native and invasive species respond to elevated $pCO_2$ plumes in similar ways, including behavioral avoidance responses and molecular stress biomarkers (Dennis et al. 2015; Kates et al. 2012). Used in a barrier alone, $CO_2$ will not provide species specificity to target invasive species over native species. Additionally, it is reasonable to expect adding $CO_2$ to a river system would physiologically stress native

species (Dennis et al. 2015). The decision to implement a $CO_2$ barrier in the field will rely on determining whether the possible risks to native species outweigh the potential benefits of reducing the probability of invasive carp range expansion.

As bigheaded carps are highly fecund, if even a few individuals can overcome a barrier due to their exceptional intraspecific abilities, they may be able to produce a strong second generation. Therefore, deterrents should be designed to exclude even the most exceptional individuals of a target species (Rahel and McLaughlin 2018). Due to high inter-individual variance in $pCO_2$ tolerance (Kates et al. 2012), it may be necessary to design deterrents at the upper levels of $CO_2$ tolerance. However, care should be taken to determine whether selective pressure exerted by the deterrent will undermine its efficacy in future generations (Hasler et al. 2017) and prevent this if so.

Simulations suggest that to prevent invasion and establishment of a breeding population of bigheaded carps in new waterbodies, individual nonphysical barrier efficacy must be very high ($> 90\%$), and further, a series of high-efficacy deterrents may be necessary (Putland and Mensinger 2019). Carbon dioxide yields consistent negative chemotaxis in target invasive species and thus has potential to increase the efficacy of nonphysical barriers (Borland et al. 2020; Cupp et al. 2017; Cupp et al. 2018b; Hasler et al. 2019; Tix et al. 2018). However, because most fish species and size classes avoid this dissolved gas, it will not afford inherent species-level selectivity (Dennis et al. 2015; Donaldson et al. 2016; Kates et al. 2012; Rahel and McLaughlin 2018).

Integrating multiple deterrents may reduce habituation to any one deterrent, provide redundancy, increase species selectivity, and improve overall efficacy (Noatch and Suski 2012). Carbon dioxide would likely best be implemented as one of the multiple tools used to prevent bigheaded carps' range expansion, where other modalities such as acoustics provide species selective permeability. Further research comparing the off-target effects on native species of individual and integrated deterrent systems will be necessary before deployment at field sites to optimize deterrent efficacy while minimizing costs to native ecologies. Fully characterizing the effects of elevated $CO_2$ at implementation sites will be required to mitigate potential adverse impacts on native species such as loss of equilibrium or reduced predator avoidance behaviors (Schneider et al. 2019; Tix et al. 2017). No nonphysical barrier technology can deter 100% of fish indefinitely; however, increasing the efficacy of nonphysical barriers will be necessary to prevent the spread of invasive fish species between connected waterbodies (Noatch and Suski 2012). Due to shared avoidance and toxicity with target bigheaded carps as well as non-target native species, $CO_2$ should be limited to multi-modal applications where other modalities allow for species selectivity.

**Abstract**

To combat impacts of climate change, offshore wind farm construction is accelerating globally. Accompanying increases in construction activity have raised concerns about associated noise impacts on acoustically sensitive species, including harbor porpoises (*Phocoena phocoena*). This study investigated spatial impacts from the construction of ScottishPower Renewables' East Anglia ONE (EA1) offshore wind farm (310 pin-piles), located off southeast England, on porpoises belonging to the North Sea Management Unit. Data on porpoise presence and received noise levels were collected from up to 12 monitoring stations around EA1 before, during, and after construction from March 2018 to June 2019, using automated click detectors (C-PODs) and full bandwidth acoustic recorders. Acoustic recordings were used to calibrate a sound propagation model to assess porpoise responses to received noise levels. Analysis of porpoise detection data in the presence and absence of pin-piling revealed negative effects of piling, with an overall decrease in porpoise detection probability out to 14.0 km from piling activity. The predicted frequency-weighted received level at this distance was 103.0 dB re 1 $\mu Pa^2s$ SEL. These observations inform our current knowledge of pin-piling-related impacts on harbor porpoises at the spatial scale of the individual wind farm, which is crucial to develop effective mitigation strategies.

## Introduction

Cetaceans, such as harbor porpoises (*Phocoena phocoena*), are known to be sensitive to anthropogenic noise pollution, including noise produced by offshore construction activities involving piling (e.g., Brandt et al. 2016; Carstensen et al. 2006; Teilmann and Carstensen 2012). Considerable amounts of piling related to the continued expansion of the offshore wind energy sector are either ongoing or forecast to occur over the next decade in many parts of the world. In Europe,

activities are continuing to ramp up throughout the North Sea, which has long been a global epicenter for offshore wind deployment (Cruciani 2018).

However, there are concerns about auditory injury, masking, and behavioral disturbance imposed upon animals from this activity, particularly when considering the cumulative impacts of overlapping construction projects and noise from other industries such as shipping and oil and gas exploration. Previous studies have shown temporary reductions in porpoise presence and vocalization rates (indicating behavioral disturbance and/or changes in distribution) around marine construction sites, with reduced impacts at increasing distances from the noise source (e.g., Brandt et al. 2011, 2018; Dähne et al. 2013; Tougaard et al. 2009). Impacts are particularly problematic when they occur inside a protected area such as a Special Area of Conservation (SAC), especially when site-specific conservation objectives must also ensure that disturbance of porpoises "*from a significant portion of the designated site, for a prescribed period of time*" (JNCC 2020) is avoided.

In the UK, several Statutory Nature Conservation Bodies responsible for SAC management (Joint Nature Conservation Committee (JNCC), Natural England, and the Department of Agriculture, Environment and Rural Affairs (DAERA) in Northern Ireland) have specified noise disturbance within a harbor porpoise SAC from noise-generating activities, individually or in combination, to be "significant" if it excludes porpoises from more than:

1. 20% of the relevant area of the site, or any given day.
2. An average of 10% of the relevant area of the site over a season (JNCC 2020; based on ASCOBANS 2000).

Under this approach, there is a need to estimate the extent of the area around a wind farm construction site from which harbor porpoises are temporarily excluded. Undertaking regular vessel-based and/or aerial surveys for porpoises during construction to record spatial displacement due to disturbance is expensive and logistically challenging, and is not demanded of developers by the UK regulator. There is also no current UK requirement for passive acoustic monitoring (PAM) during wind farm construction and operation, such as has been proposed for new wind farm developments in the United States (van Parijs et al. 2021), although some developers have undertaken acoustic monitoring studies on their own accord (present study; Benhemma-Le Gall et al. 2021; Graham et al. 2023). Such data allows valuable *post-hoc* assessments of impacts on sensitive species, such as harbor porpoises.

In the UK, assessing the range of temporary habitat loss within harbor porpoise SACs due to construction-associated noise outputs is achieved by applying fixed "Effective Deterrence Ranges" (EDRs) for different types of marine construction activities (Table 1; JNCC 2020). Here, EDRs are determined based on available empirical evidence of significant reductions in porpoise vocal activity or sightings as reported in the scientific literature, rather than estimated based on predictive noise modelling. The latter was deemed by JNCC (2020) to be insufficiently precise due to: (1) lack of agreed quantitative thresholds for disturbance, (2) predictive outcomes dependent on choice of sound propagation models, (3) a lack of understanding of

**Table 1** Recommended Effective Deterrence Ranges (EDRs; Adapted from JNCC 2020)

| Activity | EDR (km) | References on which EDRs were based |
|---|---|---|
| Monopiling | 26 | Dähne et al. 2013; Tougaard et al. 2013 |
| Monopiling with noise abatement | 15 | Dähne et al. 2017; Rose et al. 2019 |
| Pin-piling (with and without noise abatement) | 15 | Graham et al. 2019 |
| Conductor piling for oil and gas wells | 15 | Graham et al. 2019; Jiang et al. 2015; MacGillivray 2018 |
| Unexploded ordnance detonation | 26 | Based on monopile EDR |

| Other geophysical surveys | 5 | Crocker and Fratantonio 2016; Crocker et al. 2019 |

relevant acoustic properties causing disturbance, and (4) lack of behavioral context (JNCC 2020).

JNCC (2020) recognized that their specified EDRs are based on a very limited number of scientific studies, and that they are intended to provide generic advice to cover a range of different types of construction activities. Additionally, JNCC (2020) recommended periodic evaluation of EDRs to consider new available data.

## Current Study

Underpinned by PAM data and propagation modelling, this study aims to quantify the spatial scales over which porpoises were being displaced during construction of ScottishPower Renewables' (SPR) East Anglia ONE wind farm (hereafter referred to as EA1), involving a total of 310 pin-piles with a diameter of 2.5 m. The development-specific "pin-piling impact range" is defined here as the distance (in km) within which porpoise presence (inferred from acoustic detection of vocalizations) is affected negatively by pin-piling activity at EA1 throughout the duration of the construction phase. Additionally, the study aims to obtain the porpoise frequency-weighted received level, calculated as Sound Exposure Level (SEL; in dB re 1 $\mu Pa^2s$), associated with this "pin-piling impact range."

This work was part of a larger project that sought to clarify consequences of construction of the EA1 offshore wind farm on the porpoise population in the North Sea Management Unit (IAMMWG 2022). Specifically, this larger project involved modelling population-level impacts of EA1 pin-piling using the interim Population Consequences of Disturbance (iPCoD; King et al. 2015) and DEPONS (Nabe-Nielsen et al. 2018) population impact modelling frameworks. Full methodological details and outcomes of this project were reported by van Geel et al. (2023a, b, c).

## Methodology

Data analyzed in this study were gathered by a PAM array, which was deployed at the EA1 offshore wind farm, located in the southern North Sea (Fig. 1), within the Southern North Sea SAC designated for porpoises (JNCC and NE 2019).

Operational since summer 2020, the wind farm contains 102 Siemens Gamesa wind turbines with a combined rated capacity of 714 MW (SPR 2021). Construction started in April 2018 and continued until January 2019 (involving 310 pin-piles in total), with unexploded ordnance (UXO) clearing operations by high-order detonation continuing until June 2019. Full pin-piling and UXO detonation schedules were provided by SPR; no pin-piling occurred at multiple piles simultaneously.

## Data Collection

Spatiotemporal presence of porpoises within and around EA1 was monitored using a PAM array from the 11 March 2018 to 21 June 2019, involving eight consecutive deployments. The array of 12 monitoring stations, each containing a C-POD automated porpoise click detector (Chelonia Ltd.), was deployed in and around the EA1 site to monitor porpoise echolocation activity (Fig. 1). C-PODs were configured using default settings, except that devices were programmed to record at all angles relative to vertical. Up to six of these monitoring stations also contained RTSYS EA_SDA14 full bandwidth (FBW) acoustic recorders, connected to either a SPARTON PHOD-1 or a RESON TC4014 hydrophone, used to calibrate the transmission loss model. Lost FBW recorders were not replaced, resulting in a reduction in the numbers of monitoring locations equipped with these recorders during later

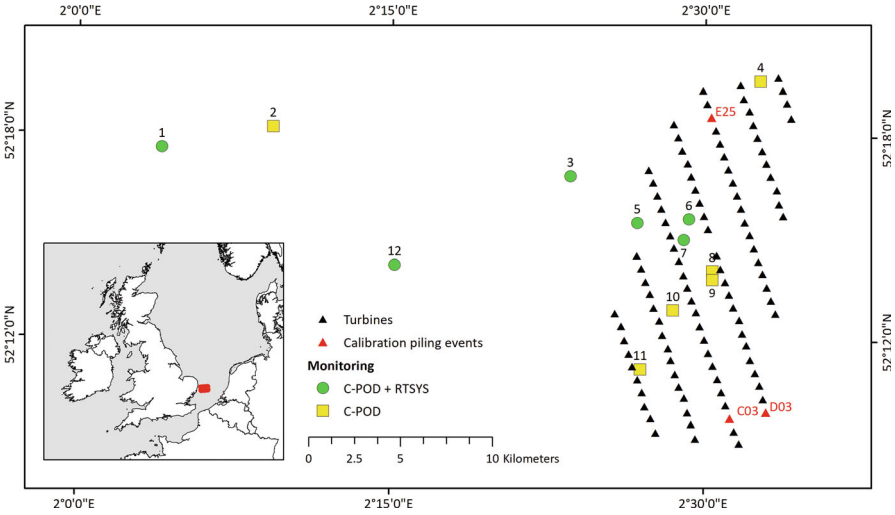

**Fig. 1** Location of the SPR East Anglia ONE wind farm, with positions of individual turbines (black triangles) and acoustic monitoring stations collecting C-POD data only (yellow squares), or both C-POD and full bandwidth data (green circles). Data for calibration of the propagation model were collected during the construction of turbines C03, D03, and E25 (red triangles). European country shapefile data were obtained from European Commission, Eurostat, GISCO @EuroGeographics and UN-FAO (https://ec.europa.eu/eurostat/web/gisco/geodata/reference-data/administrative-units-statistical-units/countries)

deployments. FBW recorders were programmed to collect data at a sampling rate of 156 kHz, adhering to a 10/14 h on/off duty cycle during the first deployment, followed by a 6-h on/off duty cycle in subsequent deployments.

## Data Processing

Following recorder recovery, C-POD and FBW data were checked for issues (e.g., corrupted files, data gaps, and clipping in FBW recordings) before proceeding with in-depth analysis. C-POD data were processed using the proprietary analytical software CPOD.exe (Version 2.044; Chelonia Ltd.), applying the KERNO Narrow-Band High Frequency (NBHF) species classifier and the "Hi" (high) and "Mod" (moderate) train filter detection settings. Data were exported as Porpoise-Positive Minutes per hour. Note that PAM only provides information on acoustic presence of animals. An absence of acoustic detections may indicate an absence of animals, animals not vocalizing, or both.

The C-POD preset recording limit of 4096 clicks per minute was regularly exceeded due to high levels of non-cetacean click-like noise (from movement of waterborne sediment, anthropogenic activities etc.), resulting in loss of monitoring time until the onset of the next minute. Sections of data where C-PODs had logged clicks $\leq$90% of each hour were excluded from further analysis. Processing of the FBW data is described in the next section.

## Propagation Modelling

FBW data, and consequently measured received levels, were not available for each C-POD location (as FWB data were collected at six of the 12 monitoring stations), nor did it they match the full C-POD monitoring period (as FBW recorders operated on a duty cycle, and due to their overall shorter monitoring capability during individual deployments compared to C-PODs). Consequently, a site-specific transmission loss model was developed to estimate received noise levels at the locations of all C-PODs for each pin-piling event, so that these could be related to porpoise presence. This model integrated two techniques for modelling the propagation of underwater noise, each of which was appropriate for specific frequency ranges. For each of these techniques, the transmission loss model incorporated local bathymetry, sediment type, sound attenuation in seawater, piling location, piling schedule, and hammer energetics.

At frequencies up to 3 kHz, the parabolic code RAMSGeo (from the open-source AcTUP suite of codes) was used, but this becomes numerically inefficient as frequency increases. Instead, a ray tracing code, using the commercially available software package COMSOL Multiphysics (COMSOL Inc.), was used at higher frequencies. A sensitivity analysis was conducted to ensure results were not dependent on the frequency at which the modelling approach changed, with transition frequencies between 2 and 5 kHz giving similar results. The RAMSGeo formulation

includes parameters relating to seabed characteristics reflecting the complex interaction between the water column and seabed at low frequency, while the seabed was modelled as an impedance boundary in the ray tracing model. Material properties of water and seabed used in the models are summarized in Table 2. The seabed was modelled as consisting of sandy sediment; its impedance condition was based on a sediment density of 2040 kg/m$^3$ and speed of sound of 1720 m/s (LeBlanc et al. 1992). In shallow water, the water and seabed can form a waveguide that prohibits propagation of low frequency noise (Urick 1983). For the given speed of sound in water and the seabed, frequencies below 40 Hz cannot propagate.

The propagation model was calibrated using acoustic measurements of selected FBW data (>10 min in duration) of three separate pin-piling events from July 2018 (Fig. 1; Table 3). Data selection for this calibration was based on the following criteria:

- Continuous simultaneous recordings from all six recorders.
- Closest sensor at sufficient distance from pin-piling events, such that the acoustic signal did not exceed hydrophone sensitivity (i.e., signal not clipped).
- Recordings not contaminated by noise events unrelated to piling, such as surface vessel noise or UXO detonations.
- Recordings included short piling breaks to allow synchronization of acoustic signals of individual hammer strikes recorded at different sensors to account for different arrival times.

**Table 2** Properties of water and the seabed used in the models. Temperature, salinity, and pH were used to determine the acoustic absorption of sea water, following the method of Ainslie and McColm (1998)

| | Speed of sound (m/s) | Density (kg/m$^3$) | Temperature (°C) | Salinity | pH |
|---|---|---|---|---|---|
| Sea water | 1500 | 1026 | 15 | 35 | 8 |
| Seabed sediment | 2040 | 1720 | – | – | – |

**Table 3** Details of pin-piling events used to calibrate the acoustic propagation model. See also Fig. 1 for corresponding wind turbine and monitoring station locations

| Wind turbine | Maximum hammer energy (kJ) | Start of recording (UTC) | End of recording (UTC) | Distance from monitoring station (km) | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| | | | | 01 | 03 | 05 | 06 | 07 | 12 |
| C03 | 737 | 2018/07/13 23:27 | 2018/07/13 23:37 | 34.24 | 15.81 | 11.77 | 11.08 | 10.05 | 20.08 |
| D03 | 643 | 2018/07/24 21:14 | 2018/07/24 21:25 | 35.90 | 16.71 | 12.47 | 11.33 | 10.42 | 21.77 |
| E25 | 617 | 2018/07/22 09:43 | 2018/07/22 09:55 | 29.91 | 8.22 | 7.02 | 5.67 | 6.84 | 19.09 |

For the selected data, peak sound pressure level (peak SPL; $L_{p,\mathrm{pk}}$; in dB re 1 µPa) was computed for 35 1/3-octave bands (base 10; also referred to as decidecade bands) with a nominal central frequency ranging from 25 Hz to 63 kHz over a 1-s window using a customized MATLAB script.

In these selected pin-piling events, piling noise was distinguishable from ambient sound at frequencies up 16 kHz, and as such, broadband noise levels were computed for the 40 Hz–16 kHz 1/3-octave band frequency range. The transmission loss model was applied to predict source level of pin-piling at each turbine location, expressed as SEL ($L_{E,p}$; in dB re 1 µPa$^2$s at 1 m; based on maximum hammer energy), as well as frequency-weighted (for porpoises) received levels based on Southall et al. (2019) and NMFS (2018) at the C-POD deployment locations during construction of each EA1 turbine. The overall frequency-weighted received level below which porpoises were negatively affected by EA1 pin-piling was subsequently derived by using the obtained relationship between distance from piling activity and modelled frequency-weighted received level.

## Harbor Porpoise Presence Modelling

Porpoise presence modelling was undertaken to assess differences in the probability of detecting porpoises in relation to distance from individual pin-piling events, when compared to their distribution in the absence of pin-piling activity. Predicted porpoise presence at increasing distances from pin-piles was modelled to quantify the "pin-piling impact range" for the entire construction phase. Two separate C-POD datasets, covering piling and non-piling periods, were created for this purpose. The piling dataset contained all hours during which pin-piling activity took place. The non-piling dataset consisted of all non-piling days, except for the exclusion of the two calendar days prior to or following a piling day. Both model datasets were analyzed at an hourly temporal resolution. As mentioned previously, only those hours that were effectively monitored >90% of the time were retained in either dataset. Statistical modelling was undertaken in R (Version 4.0.2; R Core Team 2020) based on the "*mgcv*" package (Wood 2017a) using a binomial Generalized Additive Model (GAM) with a logit link function. The binary response variable was defined as porpoise presence/absence (1/0; Table 4). The GAM models for both the piling and non-piling datasets were fitted via Restricted Maximum Likelihood (REML), with model selection based on Akaike's Information Criterion (AIC) values. During the statistical modelling process, the covariate "Distance" was always retained as this was required for the overarching project objectives (van Geel et al. 2023b, c – see also the "Introduction" section).

Numerous studies have provided evidence that porpoise spatiotemporal distribution is related to environmental factors varying in space and time (e.g., Benjamins et al. 2017; Booth et al. 2013; Embling et al. 2010; Marubini et al. 2009; Skov and Thomsen 2008; Williamson et al. 2017). Porpoise presence in the EA1 area, as in the wider southern North Sea, varies both seasonally and annually in response to environmental changes (Gilles et al. 2016; Heinänen and Skov 2015; Paxton et al. 2016).

**Table 4** Overview of candidate parameters considered in the statistical modelling

| Parameter | Description | Values[b] | Modelled |
|---|---|---|---|
| **Response variable** | | | |
| HP presence | Hourly presence/absence of porpoise detections of "Hi" or "Mod" quality | 0 = Absent<br>1 = Present | Response |
| **Covariates of main interest** | | | |
| Distance | Linear distance (in m) between each piling event and each C-POD deployment site | 1179–35,912 | Linear; smooth |
| Received level | Measured frequency-weighted received sound level (in dB re 1 $\mu Pa^2$s SEL; calculated over the 40 Hz – 16 kHz 1/3-octave band frequency range) at C-POD location | 94.1–194.5 | Linear; smooth |
| **Other covariates** | | | |
| Deployment | Identifier of successive deployments | 1–8 | Random effect |
| Location | Identifier of the deployment location | 1–12 | Random effect |
| Julian day | Julian day | 4–365 | Cyclic smooth |
| Month | Calendar month | 1–12 | Cyclic smooth |
| Year | Calendar year | 2018; 2019 | As factor |
| Hour | Hour of the day (in UTC) | 0–23 | Cyclic smooth |
| Diel cycle | Temporal position in the diel cycle; related to changes in daylight levels | 0 – <1<br>0 = 1 = Sunrise<br>0.5 = Sunset | Cyclic smooth |
| Tidal cycle | Temporal position in the tidal cycle; related to changes in the tidal cycle (water level and tidal flow speed) | 0 – <1<br>0 = 1 = High tide<br>0.5 = Low tide | Cyclic smooth |
| Lunar cycle | Temporal position in the tidal cycle; related to changes in changes in spring-neap tidal cycle (water level and tidal flow speed) | 0 – <1<br>0 = 1 = Spring tide<br>0.5 = Neap tide | Cyclic smooth |
| Project day | Numbered sequence of days from the beginning of the project | 1–468 | Linear; smooth |
| Cumulative piling day[a] | Numbered sequence of piling days throughout the project | 1–136 | Linear; smooth |
| Consecutive piling day[a] | Numbered sequence of consecutive piling days without a break (i.e., calendar day without piling) | 1–13 | Linear; smooth |
| Hammer energy[a] | Maximum hammer energy (in kJ) | 475–1169 | Linear; smooth |
| Source level[a] | Modelled frequency-weighted piling source level (in dB re 1 $\mu Pa^2$s SEL) | 178.3–182.2 | Linear; smooth |
| UXO day | Presence/absence of UXO detonation (or attempt) that day | 0 = Absent<br>1 = Present | As factor |

(continued)

**Table 4** (continued)

| Parameter | Description | Values[b] | Modelled |
|---|---|---|---|
| UXO hour | Presence/absence of UXO detonation (or attempt) that hour | 0 = Absent<br>1 = Present | As factor |
| C-POD number | Individual C-POD ID number | 825–3199 | Random effect |
| Angle | Angle (in °) describing C-POD deviation from vertical | 0–84.5 | Linear; smooth |
| Number of clicks | Average number of unfiltered clicks recorded per minute within an hour; index of noise levels | 0–4095 | Linear; smooth |

[a] Parameter only used in development of piling model
[b] Values across the piling and non-piling datasets prior to data exclusions

For both GAM models, a range of covariates were considered describing parameters known or suspected to influence porpoise spatiotemporal distribution, such as diel cycle, tidal cycle, and lunar cycle (Table 4). Sunset and sunrise times were obtained using the sun-methods function of the R "*maptools*" package (Bivand and Lewin-Koh 2020) for monitoring location 08 centered in the EA1 offshore wind farm. Tidal information was extracted from POLTIPS tidal prediction software (Version 3.9.0/16; National Oceanography Centre). In addition, for the non-piling dataset, distances for each monitoring location (the "Distance" covariate; Table 4) were randomly subsampled from the distribution of "wind turbine – monitoring station" distance combinations in the piling dataset. Finally, the piling GAM model also contained various other covariates related specifically to pin-piling activity, namely modelled frequency-weighted source level (see "Propagation Modelling" section), maximum hammer energy, and consecutive number of pin-piling days, which were not relevant to the non-piling model. Information underpinning the various piling-related covariates was provided by SPR.

Initial data exploration included testing for concurvity; covariates were excluded from further modelling when the worst-case concurvity estimates exceeded 0.8. The model fitting approach broadly followed the method outlined in Pirotta et al. (2011). Numeric covariates were optimized in terms of how to best incorporate them into the model (in linear form or as a smooth term), based on AIC values. A full model, including all potential covariates in their optimal form, was then created and stepwise backward model selection was applied to identify the best subset of covariates. Remaining covariates were subsequently included in the model in declining order of importance (i.e., the first covariate caused the greatest increase in AIC if excluded from the model). Significance of each covariate was tested using the Wald's test (using a significance threshold of $\alpha = 0.05$), and nonsignificant covariates were excluded from the model. Finally, the parameter $k$-values (related to the degrees of freedom allocated to a smooth) were optimized in a stepwise process, at each stage excluding those covariates that had become nonsignificant as a result of alteration of the $k$-value.

Following final model selection, posterior simulation was undertaken (cf. Wood 2017b). This allowed for quantification of trends in the probability of porpoise

presence as a function of distance from piling activity (or frequency-weighted received level; see the "Discussion" section), while taking the values of other model covariates, and their uncertainties, into account. Additionally, this approach allowed predictions to be made over covariate value combinations not present in the original dataset.

The prediction matrix was generated over a prediction grid representing ~740,000 (piling) and 1.5 million (non-piling) possible combinations of values for the covariates that were included in the fitted models. This matrix mapped model parameters to the predictions of the linear predictor for any supplied covariate values. Next, 500 replicate parameter vectors were sampled randomly from the posterior distribution of the parameters by taking 500 multivariate normal samples from the posterior distribution of the model coefficients. These parameter vectors, containing coefficients for the model intercept and each model term, were multiplied with the prediction matrix, and the inverse link function was applied to generate predictor values on the response scale (i.e., probability of acoustic porpoise presence) for the given set of covariate values specified in the prediction grid. The median predicted smooth and associated 95% confidence intervals for the relationship between distance and the probability of porpoise presence for the piling and non-piling datasets were visualized using the R package "*ggplot2*" (Wickham 2016). Model outcomes were compared to determine at what distance from piling the median probability of porpoise detection in the piling model achieved parity with the median porpoise detection probability in the non-piling model. This made it possible to establish the perimeter of the piling impact range around the pin-piling activity at EA1.

## Results

### Data Availability

Usable C-POD data were collected during 86 out of 96 individual deployments across the entire monitoring period (11/03/2018–21/06/2019), with gaps in monitoring effort related to a combination of technical problems, loss of devices, and logistical issues. The amount of C-POD data varied between monitoring locations and through time, with fewer data collected during the 2018/2019 winter period, and the amount of pre-piling data available was limited (Fig. 2). Significant amounts of data (up to 38%) were discarded from some stations due to tidally driven noise, leading to hours monitored for $\leq$90% of their duration. This resulted in usable data for these stations being concentrated mainly at periods of reduced tidal flow. Various stations also experienced longer-term periods (i.e., continuously up to several days) of reduced monitoring effort, primarily caused by vessel noise.

FBW data from 24 out of 40 deployments were, on a deployment level, suitable for further analysis, with data excluded or absent mainly due to technical issues, equipment loss, and reduced FBW recording capabilities compared to C-PODs. No

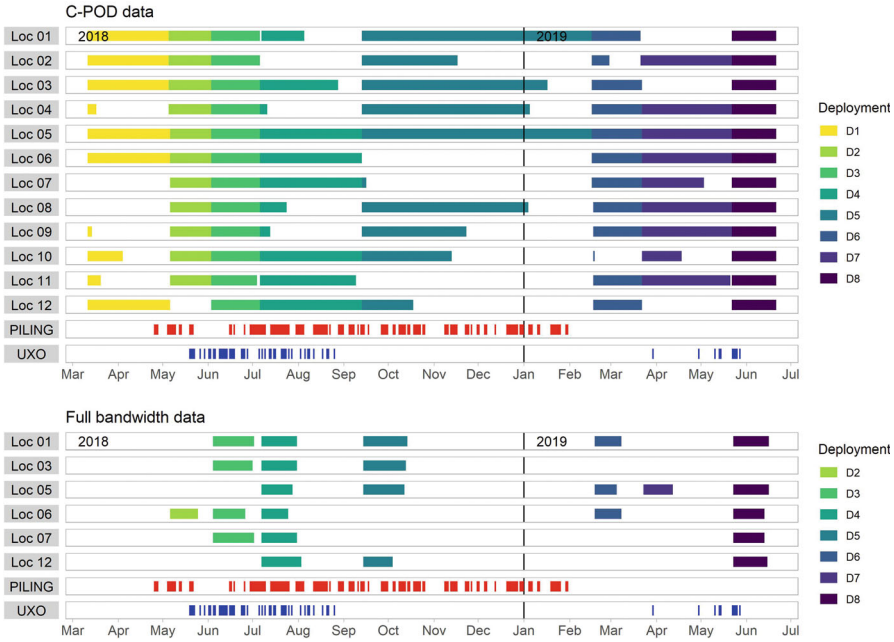

**Fig. 2** Summary of C-POD data (top panel) and FWB data (bottom panel) suitable for subsequent analysis (at deployment level; i.e., not taking into consideration exclusion of hours monitored for ≤90% of their duration, or sporadic corrupted acoustic files), in relation to realized EA1 pin-piling (in red) and unexploded ordnance (UXO) detonation activity (in blue)

pre-piling FBW data were available, and only limited data were available for the 2018/2019 winter months and during the post-construction period.

## Overall Porpoise Presence

Across the entire project duration (11,203 h between 11/03/2018 and 21/06/2019), C-POD monitoring effort (monitoring >90% of each hour) ranged from 3638 to 9668 h, depending on the monitoring station. Pre-construction porpoise detection rates were relatively high but declined considerably during the period of pin-piling activity. Especially for locations within the wind farm, detections remained low post-piling (Fig. 3). While monitoring coverage across both summer and winter was limited, porpoise detections appeared to increase during winter compared to summer.

## Harbor Porpoise Presence Modelling

Following the exclusion of hours that were ≤ 90% monitored, the piling and non-piling datasets contained a total of 6102 and 37,607 h available for modelling of porpoise presence, respectively.

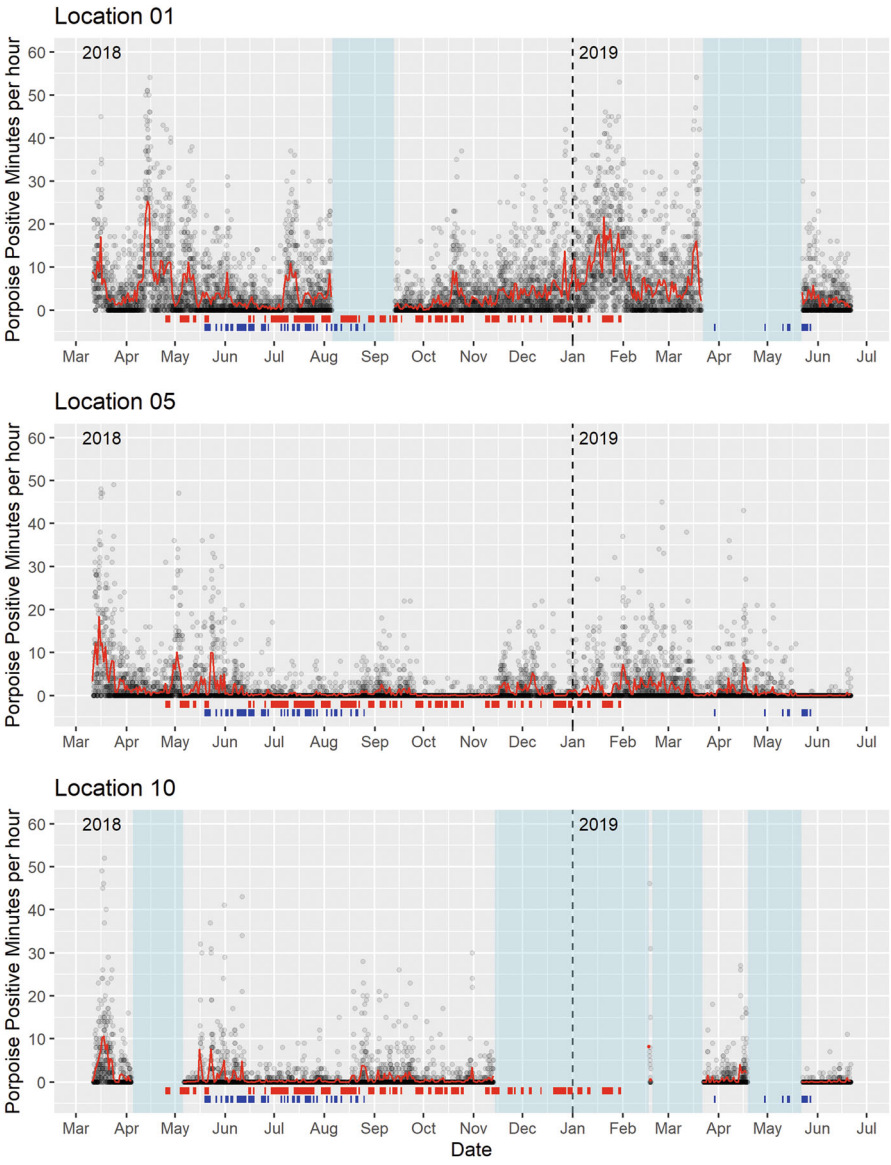

**Fig. 3** Examples of variability in hourly (gray circles) and daily averaged (red line) rates of Porpoise-Positive Minutes per hour throughout the monitoring period, as observed at 3 of the 12 monitoring stations: Station 1 (~20 km outside EA1), Station 5 (on the edge of EA1), and Station 10 (within EA1; see Fig. 1). Light blue areas indicate an absence of data; days with pin-piling and UXO detonation activities are indicated with red and blue markers, respectively

"Distance" was revealed to be the most important (piling model) or second-most important (non-piling model) explanatory variable in predicting porpoise presence. The fitted piling model contained fewer covariates but explained a higher percentage of

**Table 5** Harbor porpoise statistical modelling results. Note that the amount of insufficiently monitored data excluded differed among monitoring stations, and that remaining data represented periods with reduced tidal influences

| Dataset | Fitted model | Deviance explained |
|---|---|---|
| Non-piling | HP presence ~ s(Julian day) + s(Distance) + as.factor(Year) + s(Number of clicks) + s(Tidal cycle) + s(Diel cycle) + s(Lunar cycle) + s(Angle) | 25.1% |
| Piling | HP presence ~ s(Distance) + s(Julian day) + s(Number of clicks) + s(Angle) + s(Lunar cycle) | 38.4% |

s() represents a smooth term

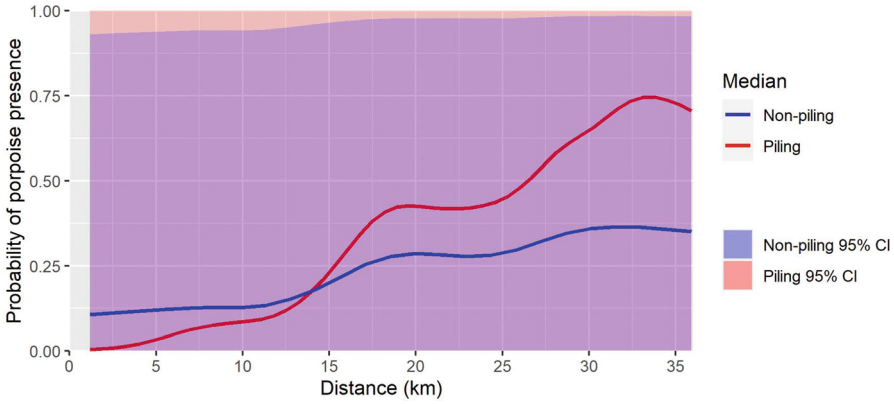

**Fig. 4** Effect of "Distance" on harbor porpoise presence at the EA1 site during non-piling periods, as well as during pin-piling activity. The probability of porpoise presence during pin-piling remains below the probability estimated in the absence of pin-piling out to 14.0 km from the piling activity

deviance in the dataset (38.4% vs. 25.1%; Table 5). The posterior simulation indicated that, despite large 95% confidence intervals (CI), when uncertainty around all model coefficients were incorporated, the median probability of detecting porpoises across the 500 simulations was lower during pin-piling than in the non-piling period up to 14.0 km from pin-piling activity (Fig. 4). The 14.0 km overall "pin-piling impact range" corresponded to a 615.75 $km^2$ impact zone around EA1 piling activity.

## Propagation Modelling and Predicted Received Noise Levels

Using the calibrated transmission loss model, porpoise frequency-weighted source levels were computed for each of the 310 pin-piles. These broadband source levels, calculated over the 40 Hz–16 kHz 1/3-octave band frequency range, fluctuated between 178.3 and 182.2 dB re 1 $\mu Pa^2s$ SEL at 1 m (unweighted source levels ranged between 211.9 and 215.2 dB re 1 $\mu Pa^2s$ SEL at 1 m). The relationship between distance and frequency-weighted received level, as derived from the

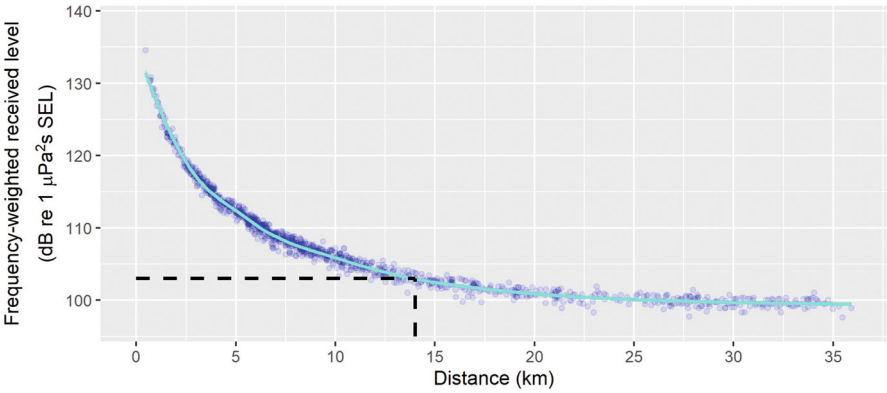

**Fig. 5** Predicted frequency-weighted received levels (dB re 1 µPa$^2$s SEL) in relation to distance from pin-piling activity, for the 40 Hz–16 kHz 1/3-octave band frequency range

propagation model (Fig. 5), indicated that the frequency-weighted received level associated with the pin-piling impact range at 14.0 km is 103.0 dB re 1 µPa$^2$s SEL.

## Discussion

Construction of the EA1 wind farm resulted in a reduced probability of porpoise detection out to 14.0 km from pin-piling activity. At this distance, the frequency-weighted received level from piling was 103.0 dB re 1 µPa$^2$s SEL.

### General Porpoise Presence

Analyses of C-POD data collected prior to, during, and post-construction of SPR's EA1 wind farm revealed that porpoises were present at the site throughout the monitoring period (March 2018–June 2019). Presence varied throughout the year and across the acoustic array, with detection rates generally lower within the wind farm compared to more distant stations. Especially for monitoring locations within, and close to, the wind farm, porpoise detection rates were higher during non-piling periods compared to when pin-piling activities occurred (April 2018–January 2019), and post-piling detection rates remained low compared to the pre-construction period.

Despite some data gaps during autumn and winter, porpoise detection rates appeared to be higher in winter compared to summer. This observation supports previous results showing higher local porpoise densities in the southern North Sea during the winter period (e.g., Gilles et al. 2016; Heinänen and Skov 2015; Paxton et al. 2016; Waggitt et al. 2020), likely reflecting seasonal variability in habitat use. The EA1 offshore wind farm is located within an area of the Southern North Sea SAC known as the "winter area" (October–March), which was designated based on

seasonally persistent, above-average porpoise densities (Heinänen and Skov 2015; JNCC and NE 2019). A general decrease in porpoise detections during the construction period (most of which occurred during the summer months) could thus be anticipated based on natural seasonal variation at the site.

The current study was underpinned by modelling porpoise presence derived from acoustic monitoring and is therefore subject to the same caveats associated with other PAM studies of porpoises, in that it relies on animals vocalizing to become detectable (e.g., Verfuss et al. 2018). Porpoise vocalization detectability is also influenced by multiple factors including ambient noise, source level, and orientation of porpoises' directional echolocation clicks (e.g., Au et al. 1999; Claussen et al. 2019; Macaulay et al. 2020; Nuuttila et al. 2018; Villadsgaard et al. 2007). Reduced detection rates may therefore reflect a decrease in animal presence, altered vocalization behavior, or both. Few studies have investigated the vocal behavior of porpoises in relation to (pin-)piling noise, as well as individual variation in movement patterns in response to noise impacts (but see Graham et al. 2023; Koschinski et al. 2003; van Beest et al. 2018). PAM has been used in a similar way extensively in the past, accepting above caveats (e.g., Brandt et al. 2018; Dähne et al. 2013). Various studies have provided additional support for the application of acoustic detections as a proxy for relative porpoise presence, by comparing acoustic detections to aerial visual line-transect and digital video-strip-transect survey data (Williamson et al. 2016), to vessel-based and aerial visual line-transect survey data (Brookes et al. 2013), to satellite telemetry data (Mikkelsen et al. 2016), and to theodolite tracking data (Kyhn et al. 2012). To further increase confidence that observed occurrence patterns reflected porpoise behavior (rather than changes in detectability due to environmental conditions), data with compromised monitoring efforts were excluded (up to 38.7% for individual C-POD monitoring stations; predominantly comprising of hours with increased tidal flow or persistent vessel noise). Data included in the current study therefore represented only those periods coinciding with reduced tidal flow and vessel noise, the effects of which varied across the array.

## Pin-Piling Impact Range

Statistical modelling of PAM data revealed clear negative effects of pin-piling, with an overall decrease in the probability of porpoise detections out to 14.0 km from the piling locations (associated impact zone of 615.75 $km^2$). At this distance, the overall predicted porpoise frequency-weighted received level was 103.0 dB re 1 $\mu Pa^2s$ SEL as modelled over the 40 Hz–16 kHz 1/3-octave frequency band range over which EA1 pin-piling signals were distinguishable from background noise. Reduced detection probability within the obtained pin-piling impact range, however, does not necessarily equal complete displacement. Likewise, displacement or other behavioral responses to noise by individual porpoises at distances beyond the overall impact range identified here may also have occurred. Individual sensitivity and

motivation, behavioral context, and previous exposure, may all contribute to individual responses (e.g., Ellison et al. 2012).

The GAM modelling revealed the partial contribution of pin-piling activity on the probability to detect porpoises. However, it is likely that porpoises also responded to other EA1 construction-related activities (e.g., increased vessel traffic, acoustic deterrent use, UXO clearance), as well as activities in neighboring wind farm development sites (e.g., geophysical/geotechnical surveys and construction) and other ongoing unrelated activities (e.g., passage of recreational and cargo vessels) in the surrounding area. For example, responses to non-piling activities have been demonstrated for wind farm construction in Scotland, where porpoise occurrence and detection rates of "buzzes" (suggesting foraging activity) were influenced negatively by jacket and turbine installation works and presence of support vessels (Benhemma-Le Gall et al. 2021). Similarly, observed pre-construction declines in porpoise presence in German waters could have occurred in response to construction-related activities like vessel movements and preparations for impact mitigation, i.e., bubble curtain deployment (Brandt et al. 2016). It is reasonable to assume that porpoise distribution and/or vocalization behavior are affected by this wide range of activities occurring alongside pin-piling. Moreover, as demonstrated in the current study and described in the scientific literature (e.g., Brandt et al. 2011, 2016, 2018; Dähne et al. 2013, 2017; Graham et al. 2019; Teilmann and Carstensen 2012; van Geel et al. 2023b), porpoise detection rates are reduced around piling locations, with impacts continuing for some time after construction activities have ceased, indicating that piling activity not only influences porpoise distribution during piling but also during subsequent non-piling periods. Considering the above, the pin-piling impact range revealed in the current study therefore not only reflects porpoises' vocalization and/or distributional responses in relation to pin-piling noise but may also be influenced by porpoises' past experiences, the presence of other anthropogenic pressures, and ecological characteristics of the habitat (e.g., abundance of prey), none of which were evaluated during the present study.

The 103 dB re 1 $\mu Pa^2s$ SEL broadband frequency-weighted received level above which the probability of detecting porpoises was negatively affected during hours of pin-piling, was derived from the relationship between distance from pin-piling activity and frequency-weighted received noise level. These received levels were inferred from propagated source levels (which in turn were based on provided maximal hammer energy applied per pin-pile) and were calculated using an acoustic propagation model that represents a simplification of the actual situation. For instance, a single source level was derived for the installation of an individual pin-pile based on the maximum hammer energy. In reality, however, noise levels vary throughout a piling event due to variation in applied hammer energy (resulting from ramping up protocols or penetration depth-related energy requirements) and changes in the amounts of energy being transferred into the sediment as piles are driven further into the seafloor (Banda and Cook 2018; Martin and Barclay 2019; Thompson et al. 2020). Similar generalizations are often applied to parameters affecting sound propagation, such as seasonally fluctuating water temperatures, stratification of the water column, and differences in weather conditions

(Malme et al. 1995). The transmission loss model developed for this study combined two propagation modelling techniques, incorporated project-specific information on pin-piling and environmental conditions, and was calibrated using acoustic measurements of field data. For these reasons, despite the uncertainties and the simplification, model validation with actual measurements increased confidence that the model predictions are realistic.

The current study did not explicitly incorporate non-piling construction activities and noise from other industries adjacent to the EA1 site into the propagation modelling. Modelling received levels based solely on the propagation of piling noise, while ignoring these other sound sources, may result in predicted sound levels that differ substantially from actual levels experienced by porpoises. To try to account for other noise-generating activities, as well as compare to the frequency-weighted received level of 103 dB re 1 $\mu Pa^2s$ SEL broadband above which the probability of detecting porpoises was negatively affected during hours of pin-piling (as indirectly obtained from the GAM model applying the "Distance" covariate), attempts were made to statistically model porpoise presence/absence using the directly measured frequency-weighted received levels (in dB re 1 $\mu Pa^2s$ SEL calculated over the 40 Hz–16 kHz 1/3-ocatve band frequency range) from the FBW data recorded at the six C-POD monitoring stations where these were collected simultaneously. Despite minimal coincidence between pin-piling activity and FBW monitoring resulting in a limited piling dataset available for the GAM modelling (444 h), the frequency-weighted received level was the most important explanatory variable. The final fitted non-piling model included received level as the 6th term, and it explained a very limited amount of the variation present in the data. As such, comparison with the probability of porpoise presence under piling conditions was impeded and the approach did not work. For this reason, measured (rather than modelled) frequency-weighted received levels were not used to derive the noise level at which the probability of porpoise detection was lower during pin-piling activity than in the absence of piling. Instead, this was obtained indirectly via the relationship between "Distance" and "modelled received level" as described in the "Propagation Modelling" section.

## Pin-Piling Impacts within UK Harbor Porpoise SACs

The results of the current study contribute new information on porpoise disturbance by pin-piling in addition to those presented by Brandt et al. (2016) and Graham et al. (2019). At present, the recommended impact range that should be applied when assessing the impacts of pin-piling on porpoises within English, Welsh, and Northern Irish SAC boundaries, as stated in JNCC (2020), is based on a single study by Graham et al. (2019) involving porpoises in the vicinity of a wind farm in the Moray Firth (Scotland). Construction in that study involved the piling of four 2.2 m pin-piles per turbine, and a deterrence response was defined as a >50% reduction in the number of Porpoise-Positive Hours (PPH) in the post-piling response period compared to those in the pre-piling baseline period. These authors reported a ≥50%

probability of such a behavioral response to piling at distances up to 7.4 km (95% CI 5.7–9.4 km) in the 24 h following cessation of piling, with a ≥0.25 probability of such a response to distances approximately 18 km from the piling location. Graham et al. (2019) also reported that porpoises appeared to habituate to ongoing piling activities, with response distances decreasing over the course of wind farm construction. Based on these results, JNCC (2020) recommended an EDR for pin-piling of 15 km (Table 1) on the premise that most of the effect would occur within this range, acknowledging that a 100% deterrence/disturbance was not expected to occur within the associated area and that this EDR also did not represent the maximum range at which effects may be detected.

JNCC (2020) has recommended periodic evaluation of EDRs as new data become available. The current lack of UK requirements for monitoring and assessing the impacts of offshore wind farm construction based on empirical data means that, unless developers themselves decide to undertake such a campaign (e.g., current study; Benhemma-Le Gall et al. 2021; Graham et al. 2023), the UK will rely on new insights originating from elsewhere in Europe or further afield. For example, data collection under US license requirements (e.g., van Parijs et al. 2021) may contribute to this process.

The pin-piling impact range obtained in the current study for the EA1 offshore wind farm provides useful insights from another UK development area compared to the Graham et al. (2019) study, and can be considered when evaluating the "Guidance for assessing the significance of noise disturbance against Conservation Objectives of porpoise SACs in England, Wales and Northern Ireland" (JNCC 2020), and in broader noise management within the UK and elsewhere. The 14.0 km impact range identified in the current study does not deviate widely from the recommended EDR of 15 km; however, the 1 km difference translates into a smaller overall impact area (615.75 $km^2$ vs. 706 $km^2$), which could have implications for future management of piling schedules in relation to SAC noise management.

**Acknowledgments** This project was funded by ScottishPower Renewables, and we wish to express our gratitude to SPR's Offshore Environment Team for their support. We would like to thank Dr. Carol Sparling (SMRU, University of St. Andrews) and Dr. Cormac Booth (SMRU Consulting) for their assistance and advice during this project. Additionally, we would like to thank the representatives of the following organization for their contributions to the stakeholder workshops: JNCC, Natural England, Marine Scotland Science, NatureScot, DEFRA, the Crown Estate, the MMO, and the Wildlife Trust. We thank the additional Ocean Science Consulting (OSC) Ltd. team members involved in data collection (Vilislav Velikov) and data downloading (Dr. Laura Williamson). Megan Ryder (SMRU Consulting) and Dr. Eiren Jacobson (Centre for Research into Ecological and Environmental Modelling – CREEM, University of St. Andrews) provided helpful analytical advice in the GAM modelling process.

**Abstract**

In April 2022, the US National Oceanic and Atmospheric Administration, the US Navy and partners launched a Sanctuary Soundscape Monitoring Project (SanctSound) web portal (https://sanctsound.ioos.us/). The portal allows the public to learn about the importance of ocean sound and explore the findings from this collaborative effort by over 50 scientists spanning 3 years. Here, we aim to increase awareness of this new platform and discuss lessons learned and next steps for development of such assets in the future among international colleagues. The portal provides a tangible reference for discussing community-level progress in addressing the priorities that have guided the SanctSound project: (1) enhanced

standardization through data collection and analysis steps; (2) development of new metrics, indicators, and visualization techniques to inform local to system-wide management needs; (3) centralization and public access for both raw recordings and data products; (4) data-driven communication and education products for a wide array of audiences; and (5) creation of sustainable data pipelines that can be leveraged broadly across projects. The portal also showcases how underwater sound monitoring helps resource managers design methods to better protect national marine sanctuaries. Examples ranging from informing large whale protections to coral reef restoration to fishery management will be provided to highlight both the achievements of the project and emerging opportunities through large-scale data collections to answer questions of interest to managers.

## Introduction

The Sanctuary Soundscape Monitoring Project (SanctSound) was a 3-year underwater sound monitoring effort in the waters of the USA that began in the fall of 2018 and ended in spring 2022. It was co-led by two federal government agencies, the US National Oceanic and Atmospheric Administration (NOAA) and the US Navy, and engaged experts from 24 institutions from all over the country. The project collected underwater recordings from 30 locations in seven US National Marine Sanctuaries and one National Marine Monument distributed off the US East and West Coasts and off the Pacific Islands.

Recordings aimed for continuous sampling up to 24 kilohertz and moorings were maintained by divers and using acoustic releases. The project resulted in several hundred terabytes of data. This chapter outlines the web interfaces that were built to access, explore, and interpret these data in order to support their applications to managing protected areas.

The SanctSound project is accessed on the web through NOAA's main launch site for ocean observation datasets, known as the Integrated Ocean Observing System. Selecting the project's tile provides a single access point (https://sanctsound.ioos.us/) for three main web services: the project's landing page (which serves a general user audience), the project's data portal (which serves a scientific and managerial user audience), and the project's archive (which provides metadata and download access for the project's data).

## Touring the Portal

The project's landing page provides six tutorials, accessed through a panel of six tiles, with educational graphics and videos explaining the project's specifics and underwater sound recording in sanctuaries generally (Fig. 1). It provides a sound

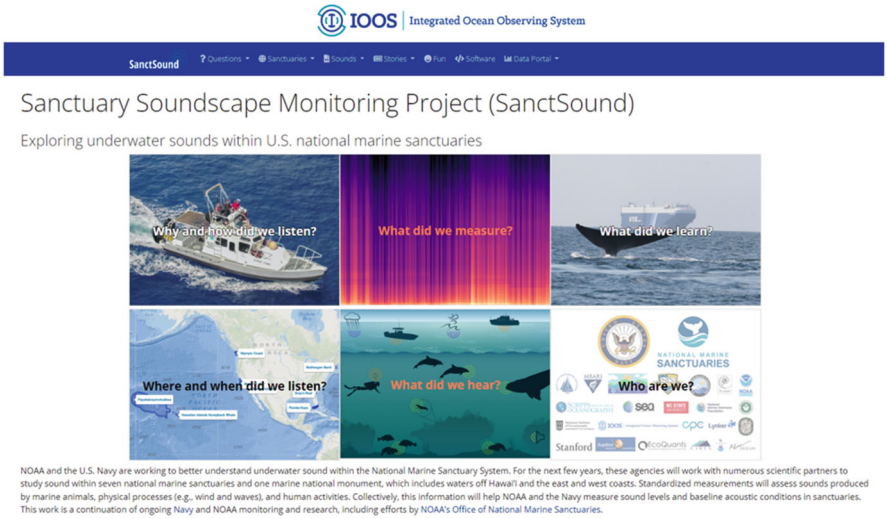

**Fig. 1** SanctSound project landing page (https://sanctsound.ioos.us/)

library for a subset of the specific sources that were heard and identified in sanctuaries, including human made, marine animals, and environmental. A larger library of almost 200 sound clips is available through the project's data portal.

The main menu at the top of the landing page allows users to tour the project's results by sanctuary. This menu also provides access to web stories highlighting project results around the country, a list of software and tools that were used or generated for the project and direct links to the data portal.

In the data portal, green download and citations buttons allow users to access results by recorder deployment. Each dataset has a DOI and is archived at NOAA's National Centers for Environmental Information (NCEI). Download access for raw recordings and results is provided through NCEI's Google Cloud services following selection using a map viewer (https://www.ncei.noaa.gov/maps/passive-acoustic-data/). Download access for results is also provided via another NOAA service called ERDDAP (https://coastwatch.pfeg.noaa.gov/erddap/griddap/).

## Tour 1: Sound Sources in Sanctuaries

The sanctuaries menu item provides users with a clickable map of the sanctuaries where monitoring occurred. For each sanctuary, under the "what did we hear" tab, users are provided with an interactive acoustic scene that shows all of the sources of sound that were identified during the project in this sanctuary (Fig. 2). Selecting an element of the acoustic scene provides a picture and video spectrogram of that source recorded in that sanctuary. For those that were detected over time, users can look at examples of their temporal patterns using tabs that show results both as histograms

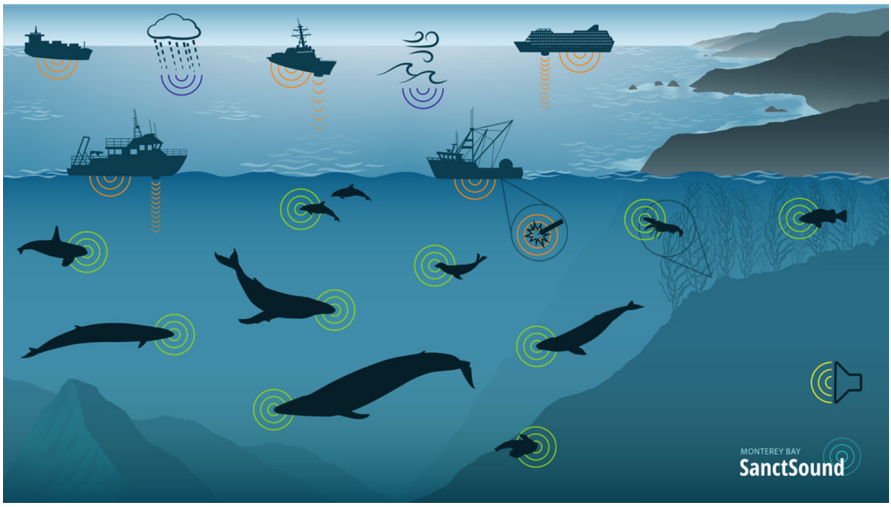

**Fig. 2** Clickable soundscape for Monterey Bay National Marine Sanctuary on the US West Coast (https://sanctsound.ioos.us/s_mbnms.html)

and as seasonal clock or rose plots. In these project page graphics, the plots are annotated to make the results easy to understand and results showcase examples from individual monitoring locations per sanctuary.

For the user who is interested in further exploring time series results, there are links provided into the portal. The data portal also organizes all results around sanctuary locations, which are also accessed via a map browser (Fig. 3). However, in the data portal, the user can explore results from each monitoring location within each sanctuary in more depth. For results that were collected at finer granularity the user can explore sound detection by hour and by month.

## Tour 2: Sound Levels in Sanctuaries

For each sanctuary selected on the project's landing page, the user can also explore the second tab to understand "where we listened" in this sanctuary. This provides information on the recording locations in the sanctuary, including why each was chosen and an example of the sound propagation modeling results that were completed for each monitoring station. Charts show the time periods for which data are available.

The "what did we measure" tab provides a visual overview of the sound level results for this sanctuary with annotations for each visualization to help the general user understand first the long-term spectrogram for the 3 years of recording data, a stacked histogram showing hours above each octave's median over time, and then a power spectrum and anomaly plots. The project landing pages explain what each of these visualization types are showing, using captions to help the user interpret what

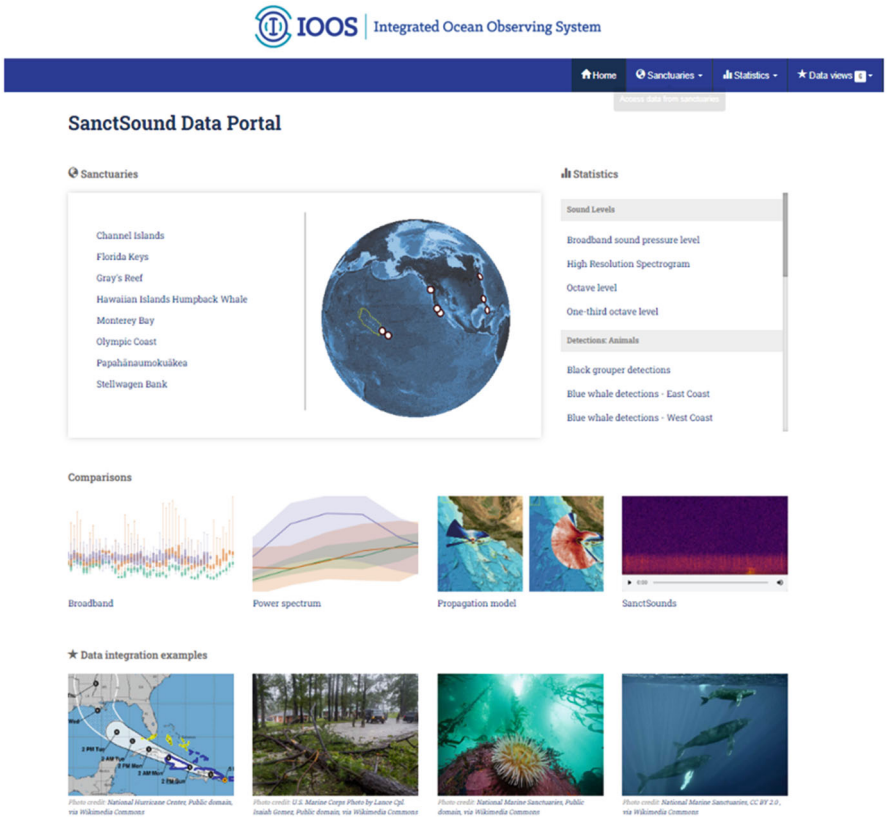

**Fig. 3** Landing page for SanctSound Data Portal. (https://sanctsound.portal.axds.co/)

each tells us about a soundscape (Fig. 4). Selecting this same location in the data portal, under "sound levels overview," provides the same plots but here they are fully explorable. The user can select time and frequency bounds of interest and hover to get summary statistics. Sound levels data summaries are also provided for third octave and octave band levels. Each plot can be expanded and exported.

## Tour 3: Comparing Sound Attributes Across the Sanctuary System

The data portal also supports comparison of sound level statistics across all monitoring locations. The user can hand select which locations and frequencies they are interested in visualizing on the same axes (Fig. 5), or they can review a panel of plots. Histograms and rose plot patterns for sounds that were detected across sanctuary locations (selected through a drop-down menu) can be compared as a panel of plots.

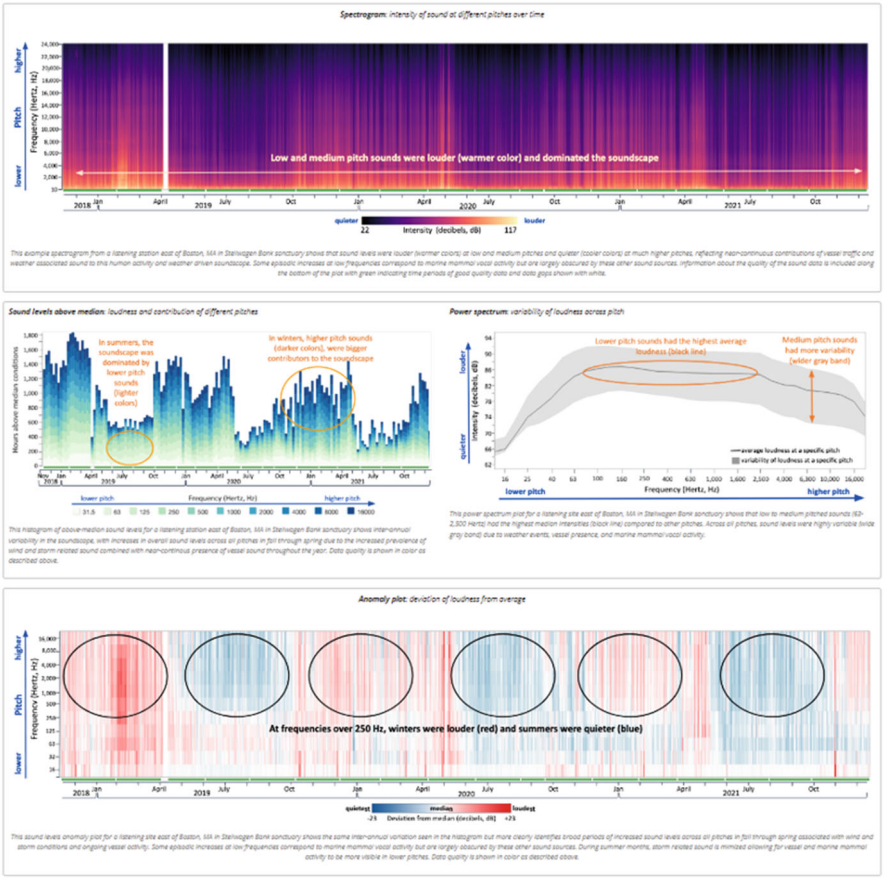

**Fig. 4** "What did we measure" results for Stellwagen Bank National Marine Sanctuary. (https://sanctsound.ioos.us/s_sbnms.html)

Comparisons are also supported for sound propagation modeling results. Estimates of signal to noise and received levels can be selected for standardized sound sources, selecting frequencies and months of interest. Map and histogram results can be reviewed (Fig. 6).

## Tour 4: Integrating Sound Results

The project worked to interpret its data relative to questions of interest in each sanctuary and across the sanctuary system. The "stories" tab on the project's landing page provides access to 17 visually compelling web presentations, accessed through a panel of tiles (Fig. 7). Most of these stories include maps of sound propagation for

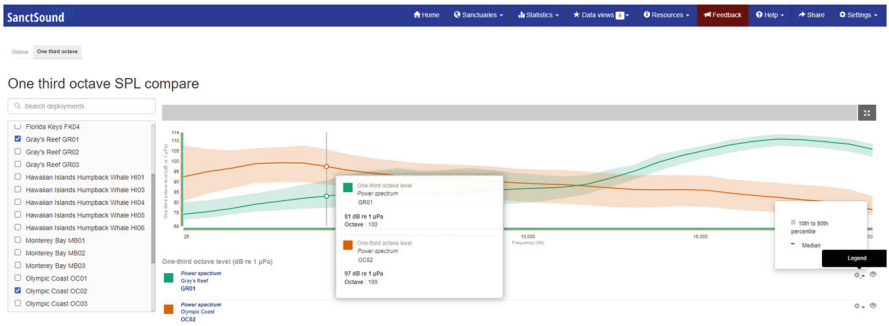

**Fig. 5** Power spectrum data for a shallow water temperate reef site (Gray's Reef National Marine Sanctuary site GR01) and a deeper water site near a busy traffic lane (Olympic Coast National Marine Sanctuary site OC02) showing near-mirror image results, with snapping shrimp dominated higher frequencies versus large commercial shipping traffic lower frequencies. (https://sanctsound.portal.axds.co/#sanctsound/compare/powerspec)

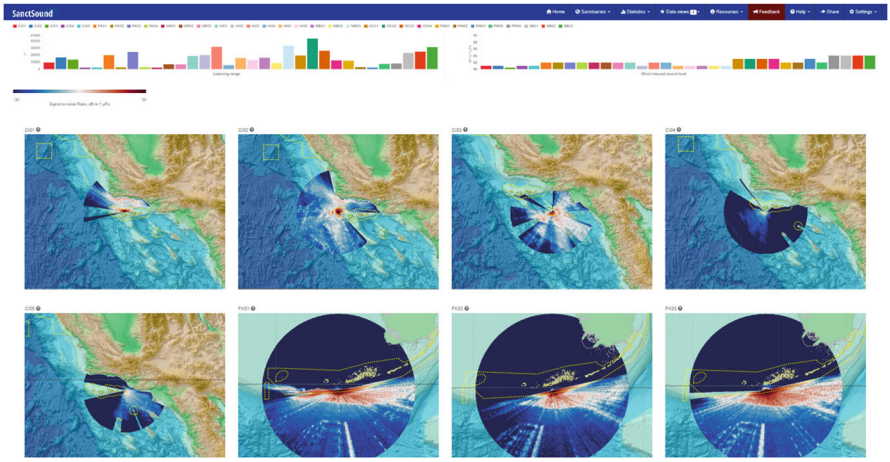

**Fig. 6** Signal-to-noise ratio modeling results across multiple recording locations. (https://sanctsound.portal.axds.co/#sanctsound/compare/prop-model)

the sources that they are examining to help readers understand the relevance of sound measurements to areas within and beyond the sanctuary.

The data portal provides the user with the ability to build their own "story" through curated data views. Selecting datasets of interest to co-visualize presents coincident time series with multiple axes. This visual can be saved, exported, and modified. The data portal also highlights the ability to integrate sound information with other ocean observation variables collected in the same areas and time periods from different mooring systems. The curated data views provided at the bottom of the home page provide examples of some integrations of interest.

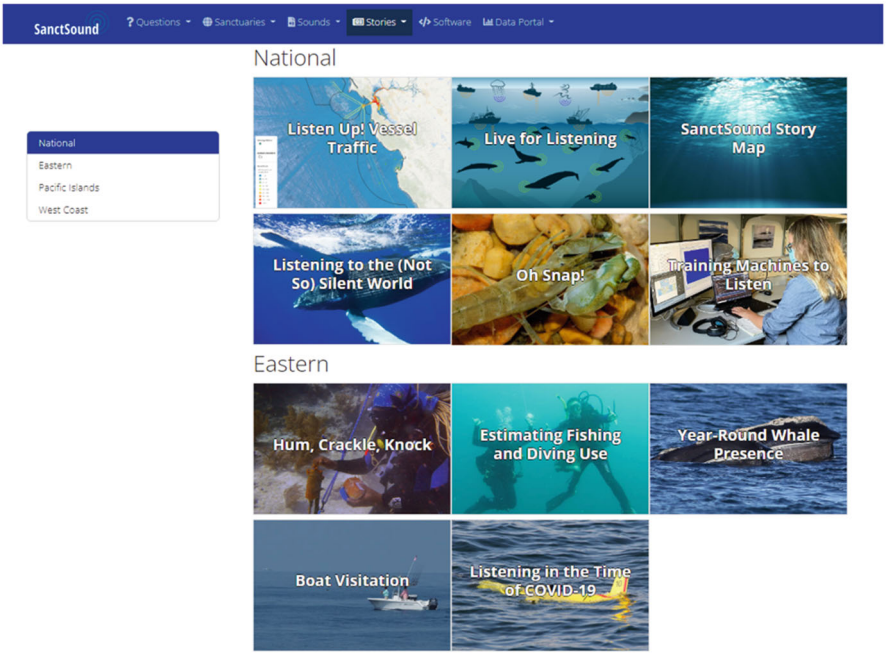

**Fig. 7** Panel of tiles that provide access to web stories published by NOAA's Office of National Marine Sanctuaries highlighting applications of SanctSound results to site- and system-level management questions (https://sanctsound.ioos.us/stories.html)

## Applications

SanctSound focused on the accessibility and interpretability of its data results as critical to ensuring their utility for conservation decision-making. The project applied its data to a diversity of management contexts of marine protected areas, ranging from supporting restoration efforts in reef systems, enforcement of zones within sanctuaries (including detection of illicit activities and compliance monitoring), tracking the status of resources in changing climatic conditions, evaluating use of sanctuaries and their valuation by people, and human use risk evaluation and impact reduction (strike, disturbance, lost communication, and stress). Across all applications, common attributes that determined utility were: longevity, comparability, and accessibility.

Several applications highlighted in the "stories" made available through the portal continue to see development and investment by NOAA and partners. For example, the SanctSound data supported comparison of the influence of vessels on diverse and nationally distributed soundscapes, and showed variance from very little or rare vessel noise dominance to higher vessel noise exceedance and

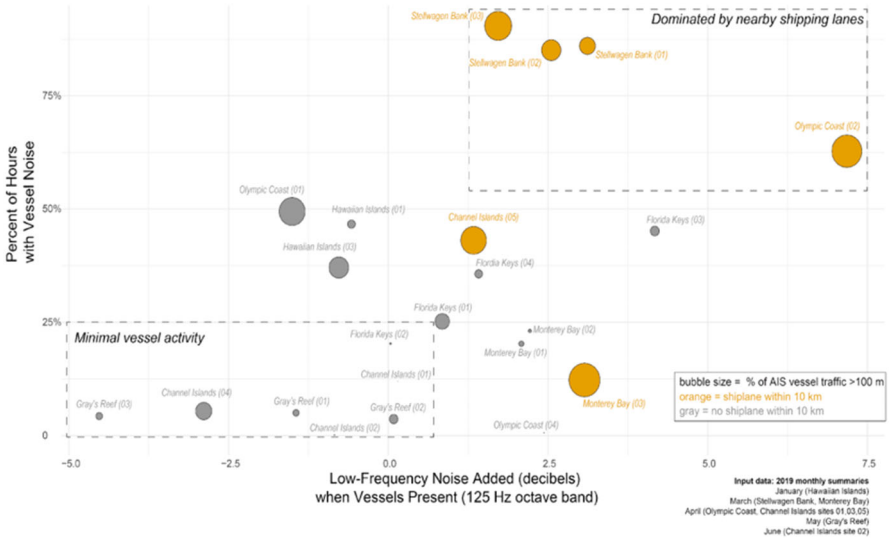

**Fig. 8** The national story on vessels in sanctuaries explored the presence of vessels across sanctuary soundscapes through acoustic detection of vessels, levels of sound in vessel-dominated bands, and comparison with other tracking methods like Automatic Identification System data. (https://sanctuaries.noaa.gov/science/monitoring/sound/listen-up.html)

prevalence (Fig. 8). These results continue to be evaluated relative to the conservation priorities in each sanctuary and to assess the effectiveness of different mitigations, including mandatory and voluntary vessel speed reduction zones that overlap monitored areas.

These data are also continuing to support our understanding of the effectiveness of existing zones within sanctuaries, including those designated to protect spawning fishery stocks and support research. Monitoring for fish spawning sounds in and around these zones as well as detecting illicit fishing activity helps sanctuary managers evaluate their efficacy.

As a final example, these data have provided important baselines for coral reef restoration efforts. Indicators range from snapping shrimp activity levels for sites off Hawaii and off the US Southeast Coast to detections of keystone fishes in and around the iconic reefs of the Florida Keys National Marine Sanctuary that are undergoing active restoration. This is also a research area where training datasets available through SanctSound are supporting the extraction of more holistic metrics of change in soundscapes that capture the multidimensional features of soundscapes (acoustic diversity and ecosystem indicators). Ground-truthing these methods are critical to our ability to continue to integrate sound within restoration monitoring frameworks.

## Next Steps

Although SanctSound ended in spring 2022, NOAA has continued efforts to monitor underwater sound throughout the sanctuary system. Monitoring in 2022–2024 includes 11 sanctuaries and 1 proposed sanctuary with a total of 26 recording locations. NOAA continues to work across diverse communities to build methods for people with a range of interests to access sound information services.

**Acknowledgments** This work depended on the collective efforts of many determined people from the coauthoring institutions who were dedicated to this project during extraordinary times.

# Characterization of Noise Abatement Systems for Protecting Aquatic Invertebrates and Fishes

**Abstract**

Offshore wind energy plays an important role in the future energy supply. But its expansion poses a risk to the marine environment. Especially, during the construction of the foundations high sound pressure levels occur in the water column due to impact pile driving. Noise abatement systems are used to reduce sound pressure levels, primarily to protect marine mammals. However, there is little information on how effective these systems are for protecting aquatic invertebrates and fishes that are sensitive to particle motion. In order to quantify the reduction of sound particle motion due to a noise abatement system a metric is proposed according to the one for sound pressure. For the simple case of a plane wave, the metrics for describing the sound particle motion and sound pressure are compared.

## Introduction

Offshore wind energy represents an important pillar of the future energy supply. Due to the construction and the pile driving in particular, high sound pressure levels occur in the water column. These are potentially dangerous for the marine environment. In the last decade, different noise abatement systems have been developed. Following Popper et al. (2022), the use of these systems focus on the protection of marine mammals and thus on sound pressure reduction. In various measurement-based studies, c.f. Bellmann (2014) and Bellmann et al. (2017), and model-based studies, c.f. von Pein et al. (2021), Peng et al. (2021), and Bohne et al. (2019), the influence of noise abatement systems on the sound pressure level have been investigated. But there is much less information about how effective noise abatement systems are for protecting fishes and aquatic invertebrates, which often live close to the ground and can be sensitive to sound particle motions and substrate vibration, c.f. Hawkins et al. (2021). With the aim to investigate the influence of different noise abatement systems and piling energies on the particle motion, Sigray et al. (2022) performed, as one of the first groups, measurements during the pile driving of an offshore wind turbine foundation. They observed a clear reduction of the acceleration exposure level when using noise abatement systems.

The question arises if there is a correlation between the reduction of sound pressure and particle motion and thus a possibility to transfer the comprehensive results. This work will first give an overview of the functioning of the bubble curtain as a frequently used noise abatement system (c.f. section "Working Principles of the Bubble Curtain as a Noise Abatement System"). In order to prepare ongoing studies concerning the given research question, a metric is proposed to quantify the reduction of particle motion (c.f. section "Introducing a Metric to Describe the Reduction of Sound Particle Motion"). Three field quantities, i.e., displacement, velocity, and acceleration, exist to describe the particle motion. For the simple case of a plane wave, the metrics describing the sound particle motion and sound pressure are compared (c.f. section "Investigating the Simple Case of a Plane Wave"). Finally, the results are summarized and conclusions are drawn (c.f. section "Conclusion").

## Working Principles of the Bubble Curtain as a Noise Abatement System

To create a bubble curtain, a nozzle hose is laid on the seabed around the pile. In the next step, air is pumped through the hose. Bubbles form at the nozzles and rise, enveloping the pile. The sound waves emitted during the pile driving process strike the bubble curtain and interact locally with the bubbles. These act as oscillators depending on their size and the surrounding static pressure field. The local interaction of the bubbles with the sound wave represents the local acoustic properties of the bubble curtain. These strongly depend on the local air fraction and bubble size distribution. These in turn are determined by the fluid dynamics in the bubble curtain. Within a great part of the water column, the bubble curtain behaves like a

plane buoyant flow. The bubbles induce a buoyancy force in the surrounding water. The water-bubble mixture rises and expands continuously (Bohne et al. 2019). The bubble formation process occurs within a short distance to the nozzle. In this process, large bubbles form at the nozzles and break up into smaller bubbles with increasing distance. This process is driven by the local bubble-induced turbulence. With greater distance, the turbulence decreases significantly, the process stops, resulting in a bubble size distribution which no longer varies over the water depth (Bohne et al. 2020).

The acoustic properties within a certain water depth determine the local sound transmission of the bubble curtain. In the lower frequency range (100–300 Hz), the impedance difference between the water and water-bubble mixture is the decisive factor for the sound transmission and reflection. The width of the bubble curtain, which varies with water depth, produces locally increased sound transmission due to $\lambda/2$ conduction. In the higher frequency range (300–1000 Hz), the frequency of the incident sound wave is closer to the natural frequencies of the bubbles, and the effect of sound absorption increases. Due to the dependence of the natural frequencies on the static pressure, the sound absorption is higher in the upper water layers than at greater water depths. With increasing frequency, absorption also increases in greater water depths. Thus, the bubble curtain closes from the top to bottom.

## Introducing a Metric to Describe the Reduction of Sound Particle Motion

To the author's knowledge, no metric exists describing the reduction of sound particle motion due to a noise abatement system. For sound pressure, the noise reduction is typically described by the differences between the sound exposure levels, writing

$$\Delta L_{E,p} = L_{E,p,\mathrm{ref}} - L_{E,p,\mathrm{BC}} \tag{1}$$

with the sound exposure level of the reference case $L_{E,p,\mathrm{ref}}$ and the sound exposure level of the case with bubble curtain $L_{E,p,\mathrm{BC}}$. The definition of the sound exposure level $L_{E,p}$ follows ISO (2017). It should be noted that the $\Delta L_{E,p}$ corresponds to the insertion loss. A useful form of Eq. 1 can be derived using Parseval's theorem (ISO (2017)), writing

$$\Delta L_{E,p} = 10 \log_{10} \left( \frac{\int_{-\infty}^{\infty} |P_{\mathrm{ref}}|^2 df}{\int_{-\infty}^{\infty} |P_{\mathrm{BC}}|^2 df} \right) \tag{2}$$

with the double-sided sound pressure spectrum $P_{\mathrm{ref}}$ of the reference case and the double sided sound pressure spectrum $P_{\mathrm{BC}}$ of the case with bubble curtain.

According to $\Delta L_{E,p}$, we propose to describe the reduction of the sound particle motion by means of the difference of the time-integrated squared sound particle velocity levels, writing

$$\Delta L_{E,u} = L_{E,u,\mathrm{ref}} - L_{E,u,\mathrm{BC}} \tag{3}$$

with the time-integrated squared sound particle velocity level of the reference case $L_{E,u,\mathrm{ref}}$ and the time-integrated squared sound particle velocity level of the case with bubble curtain $L_{E,u,\mathrm{BC}}$. Contrary to the recommendation of Nedelec et al. (2021), the sound particle velocity has been chosen as the field quantity to describe the particle motion. With the aim to compare the metric for sound pressure reduction with that of sound particle motion, this seems reasonable as shown in the next section.

## Investigating the Simple Case of a Plane Wave

For the case of a plane undamped forward traveling wave, the sound pressure spectrum writes

$$P(x,\omega) = p^{+} e^{-ikx} \tag{4}$$

and the velocity spectrum writes

$$U(x,\omega) = \frac{k}{\omega\rho} p^{+} e^{-ikx} \tag{5}$$

with the amplitude of the pressure wave $p^{+}$ and the real valued wavenumber $k = \frac{\omega}{c}$. Inserting Eq. 4 into Eq. 5 leads to

$$P(x,\omega) = c\rho\, U(x,\omega) \tag{6}$$

Inserting Eq. 6 into Eq.2 shows that for the simple case of a plane undamped wave the reduction of sound pressure is identical to the reduction of sound particle motion in terms of sound particle velocity $\Delta L_{E,p} = \Delta L_{E,u}$.

## Conclusion

With the aim to describe the reduction of sound particle motion by noise abatement systems, a metric has been proposed similar to the one for sound pressure. For a plane wave, it has been shown that the reduction potential of a noise abatement system for sound particle velocity is equal to the one of sound pressure. This chapter proposes to use the sound particle velocity as field quantity in following studies, which refer to the reduction of particle motion by noise abatement systems, to allow for comparability with the reduction of sound pressure.

**Abstract**

The Marine Strategy Framework Directive (MSFD) of the European Union currently requires meaningful noise level-based indicators to be obtained either through field data observations or computer modeling. Acoustic recordings in the 20–1000 Hz frequency band were performed 6 h a day during June 2018 in three

moorings to the southwest of the Islands of Faial and Pico (Azores). Anthropogenic noise was modeled due to ship traffic drawn from AIS data, and environmental sound was attributed to wind. Comparing field and model data at these three locations allowed to introduce a field calibration procedure based on the linear transformation of sample distribution probability density functions in the sound pressure-level domain. The broadband version of the excess noise level (ENL) appears as the sum of the 1/3-octave bands transformed power over the data recording frequency band. The results show that field-calibrated broadband ENL sound maps are in line with the main shipping routes, fishing activity, and leisure paths in the area revealing; however a significant noise spread due to sound propagation conditions to the east and the southwest of the Faial-Pico Islands. Field-calibrated broadband ENL may be seen as a reliable quantity for establishing continuous anthropogenic noise pollution MSFD indicators.

## Introduction

Ocean noise level worldwide was found to be increasing at an estimated rate of 3 dB/decade between 1950 and 2010, in line with the increase in shipping and GDP growth (Frisk 2012). The full impact of this ocean noise increase is still unknown, but evidence is piling up toward a deterioration of the marine habitat, the disruption of the life cycle of a number of endangered species, and biodiversity loss (Hildebrand 2009; Hawkins and Popper 2014; Williams et al. 2015; Erbe et al. 2019; Duarte et al. 2021).

Until recently, the focus of ambient noise studies was on its spatial correlation, coherence, and directivity, with the scope of reduction or elimination. The rising concern of impacts of ocean noise on marine species shifted the focus of ambient noise studies to the ocean sound level, classically defined as the sound pressure level (SPL) mapped into geographical coordinates, time, and frequency – the so-called sound maps. In practice, sound maps are obtained through computer modeling, in order to cope with the required time-space resolution for a meaningful representation, impossible to obtain otherwise by direct observation. Sound maps are, therefore, a fundamental tool for marine policies development/enforcement, identifying areas impacted with high sound levels when compared to others relatively protected, and to follow sound stress dynamical changes along time. Ocean sound was recently declared as an essential ocean variable by the Global Ocean Observation System (GOOS). In the recently published United Nations World Ocean Assessment report, a new full chapter was dedicated to trends on anthropogenic noise inputs into the marine environment (Sirovic et al. 2021).

Conceptually, there are at least two approaches for estimating ocean noise: one is by summing all the individual anthropogenic source contributions in any given point

in space, and the other is by measuring ocean sound and "subtracting" the natural background sound level. As we will see, both approaches have their own difficulties, flaws, advantages, and drawbacks.

The Marine Strategy Framework Directive (MSFD) is the European Union's main policy for marine life protection and conservation, aiming at achieving the good environmental status and its monitoring, along with protection policies which require identifiable and meaningful indicators (European Commission 2010). Descriptor 11 of the MSFD defines two indicators: one for impulsive noise and another for continuous noise. Depending on the context, these two components are often difficult to separate, which is a requirement for building suitable MSFD indicators. A recent proposal defines the excess noise level (ENL) which is the anthropogenic noise in excess of the natural background ambient sound as a possible basis for continuous noise indicator (Farcas et al. 2020). The idea behind ENL is that of determining the anthropogenic noise on top of the natural ocean sound normally present in the ocean. This, of course, requires a measurement (or an estimate) of the reference or baseline sound level without noise contamination which, nowadays, is practically impossible. This is particularly difficult in north Atlantic, which is the basin size region with the most intense and constant ship traffic in the world (Sirovic et al. 2021).

It is commonly assumed that the two main contributions to ocean sound in the band 20–1000 Hz are shipping noise and the sound generated by wind on the ocean surface. Therefore, sound maps use computer models to generate realistic approximations of these two sound fields taking as input environmental information such as bathymetry, water column temperature and salinity profiles, bottom characterization and wind speed estimates, as well as ship traffic information drawn from the Automatic Identification System (AIS). Acoustic propagation models have been used for obtaining three-dimensional (actually better described as N $\times$ 2D) deterministic representations of the shipping noise field (Colin et al. 2015; Soares et al. 2015; Skarsoulis et al. 2016). This is a very computation-demanding task, in particular for large areas with intense traffic, so an alternative was devised to represent ship location through a statistical distribution and thus reduce the computational burden (Kinda et al. 2017).

Sound maps obtained through numerical modeling are error prone due to inherent parameter uncertainties, model mismatch, and environmental/AIS data dropouts. Any direct acoustic observation should be a valuable resource, first for sound map validation and then for an eventual model adjustment. The process of integrating model and field data for sound maps' correction is known as "field calibration." The most common approach for field calibration assumes that environmental data used in acoustic propagation models is erroneous or incomplete and its adjustment allows for matching data and model (Farcas et al. 2020). Another alternative is to consider that the mismatch comes from the source level assumed for the ships cruising in the area and its estimation from the data itself would allow for a better match, as proposed in a simulation exercise in Jesus et al. (2017). Recently, the third approach directly calibrates the statistical distributions of the modeled field as proposed in Jesus et al. (2022). The validation of the gain provided by each field calibration

approach, and how this gain extends for time periods and locations where there are no ground truth observations is a challenging task.

The objectives of this study are as follows: one is to provide evidence for broadband ENL estimation methodology and explore the possibility of its usage to support building a continuous noise indicator, and the other to propose a sample field calibration method to integrate measurements and modeled data, for extending a localized observation into a wider area, where there were no observations.

This work is supported on acoustic recordings performed in the 20–1000 Hz frequency band, 6 h a day during June 2018 at three locations close to the Faial-Pico Islands, in the Azores archipelago, a well-known habitat for over 20 cetacean species (Silva et al. 2014). This data set was evaluated and found to be biased in some frequency bands, so its usage for model calibration is questionable and only made possible after filtering and conditioning. Ocean sound modeling was performed for ship traffic and surface wind action. The linear probability density functions' sample field calibration procedure presented in Jesus et al. (2022) was used and applied to this data set, extending the results with complimentary material in the following aspects: time and spatial evolution of water column; field calibration procedure is detailed; statistics for the worst-case recorder (MG) are shown; non-calibrated and calibrated model data detailed for all bands; and distribution means and variance before and after calibration.

## Methods

### Environmental Data

The Azores archipelago is formed by a total of nine islands in three groups: the western group of two islands, the eastern group of also two islands, and the central group composed of five islands, four of which are shown in Fig. 1 with the island of Graciosa to the north (not shown). The bathymetry data was obtained from the GEBCO (General Bathymetric Chart of the Oceans, www.gebco.net) database

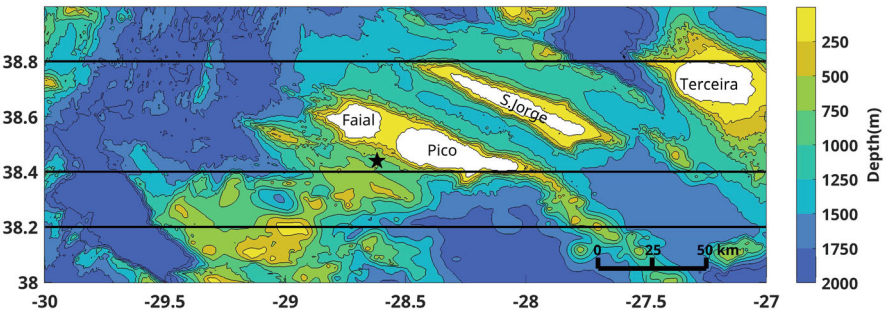

**Fig. 1** Central group of islands of the Azores archipelago. The horizontal lines and black star indicate positions for extracting water column information as shown in Fig. 2 (Adapted from Jesus et al. 2022). Bathymetry data credits: GEBCO database (Group, G.B.C 2020)

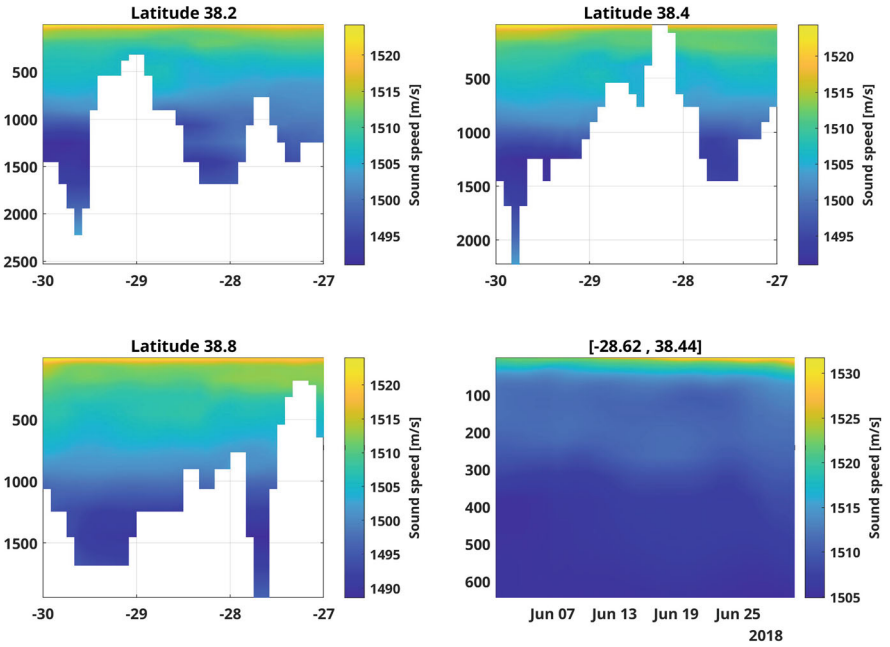

**Fig. 2** Depth-longitude sound speed for latitudes of 38.2°, 38.4°, and 38.8° North calculated from temperature and salinity profiles, upper left, right, and bottom left plots, respectively, and sound speed time evolution through the month of June 2018 at location [−28.62 W – 38.44 N] (bottom right). (Source: CMEMS-Copernicus Marine Service)

(Group, G.B.C 2020). The horizontal lines and the star symbol denote the locus for water column temperature and salinity information as shown in Fig. 2. The star symbol is in the vicinity of the acoustic recorders' location (see Fig. 5 for a close-up). The area under study is characterized by deep water with two main features: the shallow channel between Faial and Pico islands, with an average depth of approximately 80 m, and the shallow banks (<200 m depth) to the southwest of Faial Island, known as an important fishing area. Figure 2 shows computed sound speed using the temperature and salinity profiles extracted from the CMEMS (Copernicus Marine Environment Monitoring Service) (www.copernicus.eu) database, along constant latitude lines 38.2, 38.4, and 38.8, upper left, right, and bottom left plots, respectively, and for the sound speed evolution through time (bottom right plot) at the position indicated with the star symbol. Water column sound velocity variation with range is mild, as well as throughout the month of the study.

Figure 3 shows the wind speed over the month of June 2018 as predicted by the ECMWF (European Centre for Medium-Range Weather Forecasts, www.ecmwf.int) (Hersbach et al. 2018) for the mean (a) and the standard deviation (b). There is a significant deviation of more than 2 km/h from south to north of the considered area, while the standard deviation slightly decreases from west to east.

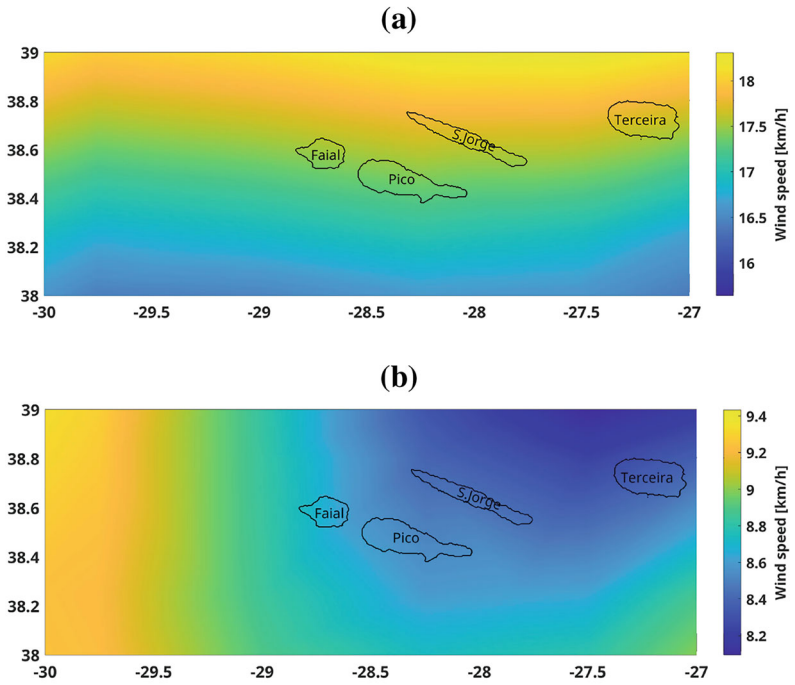

**Fig. 3** Azores wind speed for June 2018: mean (**a**) and standard deviation (**b**) (Source: ECMFW (Hersbach et al. 2018). Plot (**a**) reprinted from (Jesus et al. 2022))

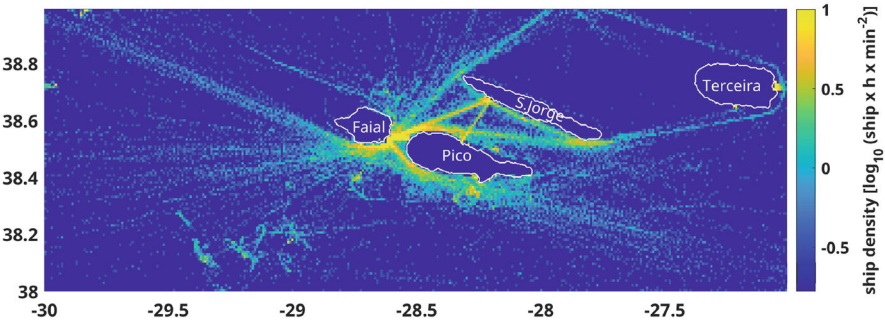

**Fig. 4** Cumulative ship density for the month of June 2018 (Source: AISHub. Figure reprinted from Jesus et al. (2022))

## Ship Traffic

Figure 4 shows the cumulative ship distribution as recorded on the community-shared platform AISHub (ship Automatic Identification System data exchange, www.aishub.net) for the study area during the whole month of June 2018. The

month of June was chosen since it approximately coincides with a period of high probability of the presence of cetaceans in the area. Data is shown as logarithm base 10 of ship density evaluated in ship x hour per square arc minute. That is, two ships for half an hour each on a square of approximately 1 nautical mile side will give rise to a ship density of 1 and will therefore appear as 0 in this figure.

## Acoustic Recordings

Three ecological acoustic recorders (EARs) (Lammers et al. 2008) were positioned at the locations CA, IN, and MG shown in Fig. 5. The EARs are deep water-rated recorders for long-term deployment with a sensitivity between −193 and −194 dB re 1 V/$\mu$Pa over the band 20–1000 Hz. During this experiment the data was sampled at 2000 Hz, with a 16-bit resolution and a 47.5 dB total chain gain. Antialiasing was achieved thanks to the usual low-pass filter to avoid out-of-band energy contamination. A high-pass filter was set at 20 Hz to attenuate static pressure low-frequency oscillations. SPL was estimated from 1 s duration Hann-windowed intervals with 50% overlap using the PAMGuide tool (Merchant et al. 2015) running under MATLAB® which is commonly used in the soundscape community. (See (Merchant et al. 2015) supplementary information with MATLAB® and R codes.) The three recorders at locations CA, IN, and MG were moored at depths of 484, 200, and 200 m, respectively. The received data was averaged in 10-min intervals and integrated over 1/3-octave (base 10) sub-bands in the 40–1000 Hz frequency band.

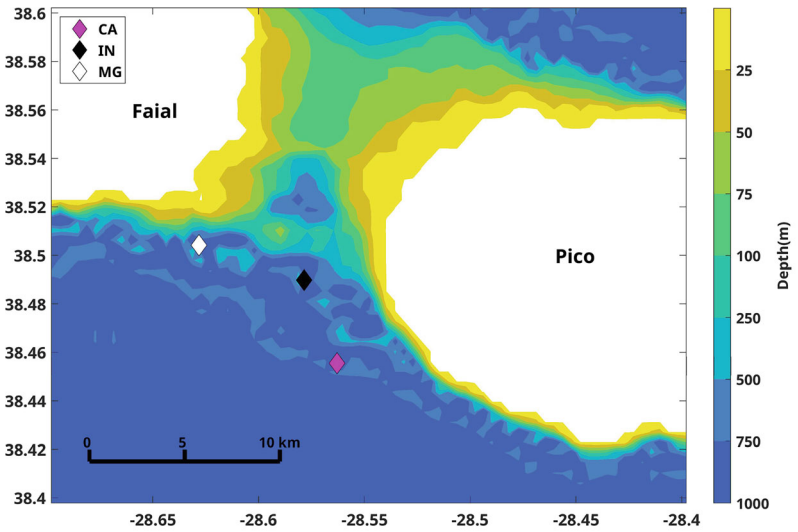

**Fig. 5** Detailed bathymetry with recorders' location on the Pico side (CA), in the channel (IN), and on the Faial side (MG). Recorder's depths are 484 m for CA and 200 m for IN and MG

## Ocean Sound Modeling

Ocean sound modeling was performed for the shipping noise and wind sound components in the frequency band 40–1000 Hz. Thus, model sound-level output $L_m$ may be written as

$$L_m(t,f,\mathbf{r}) = 10 \ \log_{10}\left[\sum_{q=1}^{Q_t} 10^{\left[L_{Hq}\left(t,f,\mathbf{r};\mathbf{r}_q\right)+L_{Sq}(f)\right]/10} + 10^{L_w(t,f,\mathbf{r})/10}\right], \qquad (1)$$

where the first term represents the noise level due to a distribution of $Q_t$ contributing ship sources of the individual level $L_{Sq}(f)$ (in dB) propagated from the $q$th source with a propagation loss $L_{Hq}(t, f, \mathbf{r}; \mathbf{r}_q)$ (also in dB) between source location $\mathbf{r}_q$ and receiver location $\mathbf{r}$ and $L_w$ is the surface wind-generated sound level also in dB, all for time $t$, frequency $f$, and location $\mathbf{r}$ (latitude, longitude, and depth). Note that in this formulation $L_{Hq}$ is taken as negative, since it represents the sound loss along the propagation path. Even acknowledging that the RANDI model is now widely used for source-level modeling (Breeding et al. 1996; MacGillivray and de Jong 2021) for a matter of simplification a lookup table-style source-level model for coefficient $L_{Sq}$ was used, deduced from historical measurements according to ship type from (McKenna et al. 2012). A high number of contacts of sailing vessels was found in the AIS data, and the adopted procedure was that of assigning them to a source level of 1% of that of cargos ≈ 20 dB (see Soares et al. (2020) for details). Source depth for the various ship types was set according to Scrimger and Heitmeyer (1991). Transmission loss is estimated with the Kraken normal mode model (Porter 1991) using the environmental information described in section "Environmental Data." Due to the typical deep water propagation conditions of the area, bottom properties are expected to play a minor role. Therefore, a generic bottom composed of a 10-m-thick sediment layer over a semi-finite hard rock half space was used (see Soares et al. (2015) for detailed properties).

The wind sound model was deduced from the ECMWF database (Hersbach et al. 2018) using the data set shown in the previous section, and the method proposed by Kewley et al. (1990) assumes that the sound generated at the sea surface results from a two regime mechanism: below 8–10 km of wind speed at low sea state and one above that speed involving the formation of white caps. The laborious step of estimating the wind source level is described in detail in the companion paper (Jesus et al. 2022).

## Sample Field Calibration

According to the sound model constraints and simplifications set above, the standard procedure for field calibration follows by estimating sound maps in 1/3-octave (base 10) frequency bands, represented by their center frequencies. At each

center frequency, the SPL time samples over the whole month are sorted into 1 dB bins to form histograms for both data observations and model predictions.

The sample field calibration procedure proposed in Jesus et al. (2022) is based on a linear variable transformation from the model to the data distribution, as described in more detail as follows. Let us assume that $p(L_m)$ and $p(L_d)$ are the model and the data distributions, with means and variances, respectively, given by $\left(\mu_m, \sigma_m^2\right)$ and $\left(\mu_d, \sigma_d^2\right)$. We seek to determine a model-calibrated distribution $p(L_{mc})$ drawn from the model samples, but with the same mean and variance than $p(L_d)$, by the linear scale transformation

$$L_{mc} = AL_m + B. \tag{2}$$

It can be easily found, from the identification between means and variances of $p(L_{mc})$ and $p(L_d)$, that $A^2 = \sigma_d^2/\sigma_m^2$ and that $B = \mu_d - A\mu_d$ which when inserted in (2) allow to determine the change scale of $L_{mc}$ and therefore the calibrated distribution $p(L_{mc})$. Calibration coefficients will be determined for each 1/3-octave band, so that the full calibration map will be obtained through the coefficient set $\{A(f_k), B(f_k); k = 1, \ldots, K\}$, where $K$ is the number of frequency bands. However, as we will see below, it is not sufficient to have the calibrated distributions, since in order to obtain a broadband estimate, the actual sample pressure power field needs to be summed across band. Replacing the levels in (2) by their respective pressure power definitions $L_* = 10\ \log_{10} P_*$ and solving for the calibrated power $P_{mc}$ give

$$P_{mc} = P_m^A 10^{B/10}, \tag{3}$$

which allows to transform power samples according to the calibration mapping.

When the acquired data is hardware calibrated, validated, and free of interferences and self-noise, the proposed sample field calibration may be useful for correcting model systematic biases through the adjustment of the model data distribution mean and variance. This applies to the time intervals and recording locations where the data is gathered, which gives no guarantees for the validity of the correction coefficients for other areas or time frames. The domain of validity of the calibration set depends on a number of factors and, in particular, on the origin of the data-model mismatch.

## Broadband Excess Noise Level

ENL is defined as the difference (in dB) between the measured and the baseline SPL for a given time, frequency, and space coordinates, expressed as

$$L_E(t,f,\mathbf{r}) = L_T(t,f,\mathbf{r}) - L_b(t,f,\mathbf{r}), \tag{4}$$

$$= 10 \ \log_{10} \frac{P_T(t,f,\mathbf{r})}{P_b(t,f,\mathbf{r})}, \tag{5}$$

where in (4), $L_E$ is the ENL, $L_T$ is the total sound level, and $L_b$ is the baseline ocean sound level without anthropogenic pressures. Relation (5) is readily obtained by replacing sound levels $L_T$ and $L_b$ by its respective pressure power counterparts $P_T$ and $P_b$, using $L_* = 10 \ \log_{10} P_*$. The total sound level $L_T$ is drawn either directly from observation or as the modeled sound level $L_m$ given in (1). The baseline (or background) ocean sound level is normally obtained from the modeled wind sound level $L_w$ (or the $P_w$ pressure power). Thus, replacing $P_T = P_S + P_w$, where $P_S$ is the shipping term power, and $P_b = P_w$ in (5) allows to rewrite ENL as

$$L_E(t,f,\mathbf{r}) = 10 \ \log_{10} \left[ 1 + \frac{P_s(t,f,\mathbf{r})}{P_w(t,f,\mathbf{r})} \right]. \tag{6}$$

Under these assumptions, the instantaneous ENL given by (6) will be always $\geq 0$, as expected, and takes into account noise and baseline estimates modeled at a given time and location. Alternatively, the baseline level could be defined as a mean over time, in which case $P_w(t,f,\mathbf{r})$ in (6) would be replaced by the mean $\overline{P}_w(f,\mathbf{r})$. Even in that case $L_E$ remains always $\geq 0$.

The expression above denotes ENL for a single frequency or for a narrow 1/3-octave band around a center frequency $f_k$. Extending this to the broadband case implies power summing (and not power averaging as was proposed in Farcas et al. (2020)) over the required bands so, in that case, the definition for broadband ENL would be given by Jesus et al. (2022)

$$L_E(t,\mathbf{r}) = 10 \ \log_{10} \left[ \frac{\sum_{k=1}^{K} P_T(t,f_k,\mathbf{r})}{\sum_{k=1}^{K} P_b(t,f_k,\mathbf{r})} \right], \tag{7}$$

where $K$ was already defined as the number of frequencies or bands. This definition allows to take into account a ratio of energies which are the preferred quantities for determining indicators of harm to marine life.

## Results and Discussion

### The Acoustic Data Set

Figure 6 shows the spectral probability densities for the received data at the three locations CA, IN, and MG in plots (a) to (c), respectively. Each vertical line is a normalized sample count color-coded image of a data histogram in 1 dB slots, for 1 Hz bin. Each frequency bin is obtained as the sample power spectrum (without averaging) of 1 s duration intervals with 50% overlap throughout the whole month. With this setting, clear colors denote most probable levels and dark colors the least

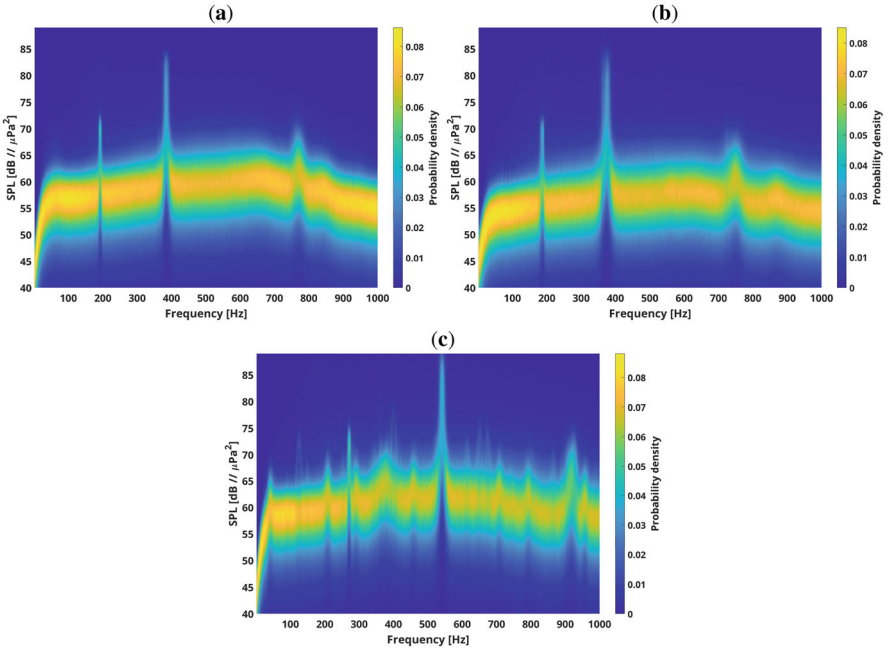

**Fig. 6** Spectral power distribution with 1 s, 50% overlap time slots between 14:00 and 20:00 UTC in June 2018 for recorders at sites CA (**a**), IN (**b**), and MG (**c**) (Figure reprinted from Jesus et al. 2022)

probable, across the frequency band. This figure shows a clear cut-off frequency at 20 Hz for the three recorders, followed by a slight and progressive SPL increase with frequency until approximately 300 Hz. This is the most relevant frequency band for shipping noise. The few spurious high-level peaks present in recorders CA (a) and IN (b) and in large number in recorder MG (c) are believed to be associated to recorders' self-noise. The origin of these peaks is actually unknown but believed to be related to some defecting amplifier or other components in the signal chain. This is clearly an issue on the quality of this particular data set and suggests precautions before its usage for field calibration. Therefore, the focus of this paper is not so much on the final calibrated field result but on showing and detailing the methodology employed for obtaining the result. Nevertheless, the impact of these peaks may be mitigated by filtering the frequency bands clearly off the mean level. The following procedures were adopted: (1) first detect the two highest peaks and (2) filter out the bins of the surrounding frequency band for each recorder of Fig. 6, leading to the result in Table 1. The proposed filtering is not a definitive response to the self-noise impairments found in the data and just attempts to mitigate its effects without compromising the field calibration broadband ENL estimation technique.

**Table 1** Recorder's self-noise filtered bands

| Recorder sites | Bands [Hz] |
|---|---|
| CA | [188–197], [374–393] |
| IN | [184–192], [357–387] |
| MG | [267–274], [528–553] |

## Experimental Data and Model Statistics

Figure 7 shows histograms of the observed data (red), shipping and surface wind sound-modeled data (blue), and field-calibrated data (green) for the MG recording location at the 1/3-octave (base 10) frequency bands between 40 and 1000 Hz. The corresponding broadband field histograms (bottom right plot) are also shown. The MG recorder corresponds to the worst-case self-noise according to the spectral power distributions of Fig. 6. Similar results were obtained for locations CA and IN (not shown). The field-calibrated distributions (in green) were obtained with the proposed method (see section "Sample Field Calibration") with a modification explained as follows. For this case, the data adjustment coefficients $\{A, B\}$ were calculated not independently for the data sets gathered at each location but, instead, from the data samples merged from all three data sets at locations CA, IN, and MG pulled together. This allows for the inclusion of all the observed data in the calibration method, thus providing a higher spatial and temporal robustness than by using sensors individually. This procedure also solves the problem of deciding which area or time interval to calibrate with each sensor. The data merging is also justified by the fact that the three sensor's location may be seen as a single point in the full study area (Fig. 1). The direct result of this merging is that the calibrated distributions are not exactly matched (mean and variance) to any of the data sets. This is illustrated in Fig. 7, for the case of MG, as a slight mismatch between green and red curves. That mismatch is also clear in the broadband case (bottom right plot). Note that in that case, the calibrated broadband distribution is obtained as the sample's sum over frequency and not from a direct calibration between the (broadband) model and data histograms.

The observed data statistical SPL distributions for the 1/3-octave (base 10) bands (Fig. 7 red curves) show a relatively narrow probability density function with a variable mean in frequency and self-noise limited low levels, either due to insufficient gain or poor resolution. As mentioned above, these histograms were obtained after filtering the frequency bands of the two main peaks of the spectral probability densities for each recorder of Fig. 6. Empirical probability density functions for the modeled ocean sound field were obtained for the same setup parameters as the data, i.e., for the recorder coordinates (latitude, longitude, and depth) and for the same time frames (Fig. 7 blue curves). In general, the model SPL distributions tend to overestimate the data in the low-frequency band until roughly 150 Hz, while a better model data fit is obtained above that frequency. In some cases, the model data distribution is bimodal or multimodal, which is also found in the observed data, but with a much larger variance in the model than in the data. Whether that multimodality comes from ship traffic at different times, distances, or ship types is

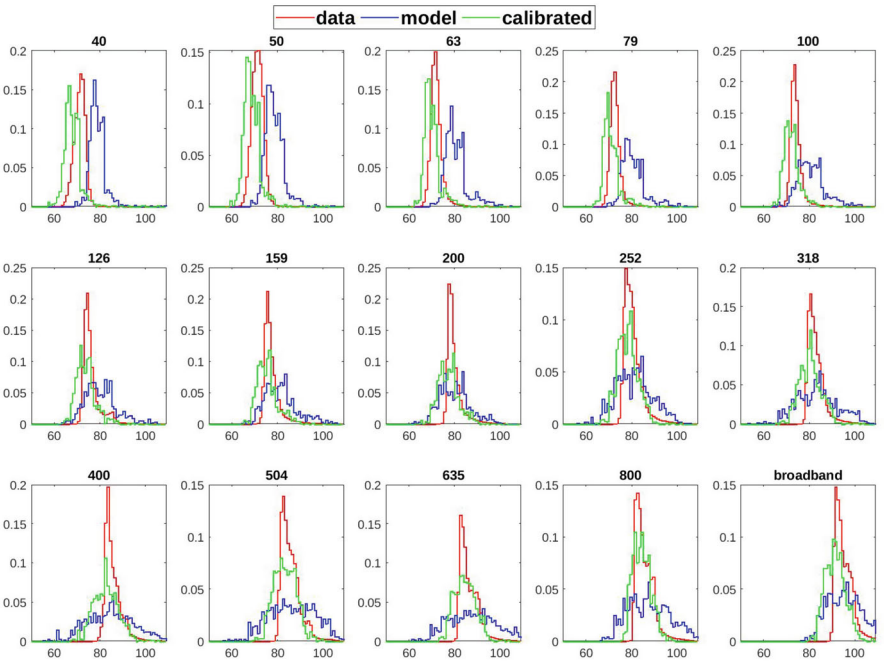

**Fig. 7** SPL histograms for 1/3-octave bands (base 10) and broadband (bottom right), using 1 s time slots with 50% overlap, between 14:00 and 20:00 UTC in June 2018 for recorder location MG positioned at 200 m depth: recorded data (red), shipping and wind model-generated data (blue), and field-calibrated model (green) [axes: probability density (y) in 1 dB re 1 μPa, SPL bins (x)]

unclear. No apparent low-level threshold is found in the modeled data. The high probability peaks larger in the data than in the model are simply due to probability density surface normalization. The differences between data and model were used as the basis for the proposed field calibration method for the wider area even if the real data recording conditions were not ideal.

The next step is to enlarge the modeling area to the four Islands shown in Fig. 1. A sampling interval of 10 min and a spatial grid of square size of 500 m were chosen for computing the wide area sound map. There is no consensus regarding receiver depth for sound models, so 10 m was chosen to represent a depth near the surface at which large whales spend a significant amount of time, and it was also noticed that, for this data set, this depth generally corresponded to the worst-case depth (highest level in general) among the various tests performed. Figure 8 shows the model's estimated mean SPL field for each 1/3-octave band (base 10) in 40–1000 Hz and the broadband case (bottom right plot) for the whole area. The same color scale is used for all frequency bands, including the broadband plot (bottom right). As expected, levels are lower for the lower bands and tend to increase with frequency. Noise peaks up to over 120 dB can be noticed in the channel between Faial and Pico and out of the port of Terceira. Shipping routes are apparent between Faial or Pico to S. Jorge

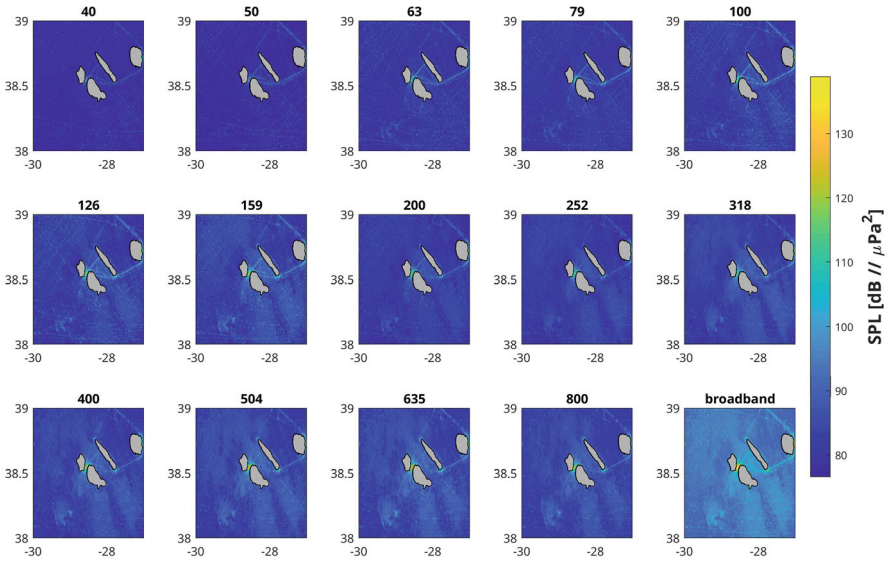

**Fig. 8** Mean SPL for the 1/3-octave band's (base 10) center frequencies in 40–1000 Hz and broadband field (bottom right plot), at 10 m depth for June 2018 [axes: latitude (y), longitude (x) both in decimal arc degrees] (Figure reprinted from Jesus et al. 2022)

and Terceira Islands, as well as other paths to other islands (out of the area). High SPL areas spreading out from these routes can be seen to the southeast of Faial-Pico-S. Jorge and in the shallow banks to the southwest, which is possibly due to the already mentioned fishing activity in the area.

## Field Calibration

The sample calibration method outlined in section "Sample Field Calibration" with the data-dependent modifications set forth in the previous section, illustrated for the MG location in the distributions of Fig. 7, was applied to the modeled data at the recorder locations for verification and then extended to the wide area and for the complete month. Figure 9 shows the frequency evolution of the mean (a) and standard deviation (b) of the sample distributions averaged over the three recorders for data (continuous blue), model prediction (continuous brown), and calibrated separately for CA, IN, and MG (dashed). As expected, there is a clear adjustment in mean and standard deviation from model to data procured by the calibration method. This adjustment is slightly better for IN than for MG and CA recorders. Model predictions overestimate the data over the whole band but more at low frequency (below 200 Hz). The mean absolute error between model and data is in the order of 6.8 dB for the whole data reduced, after calibration, to 3.9 dB.

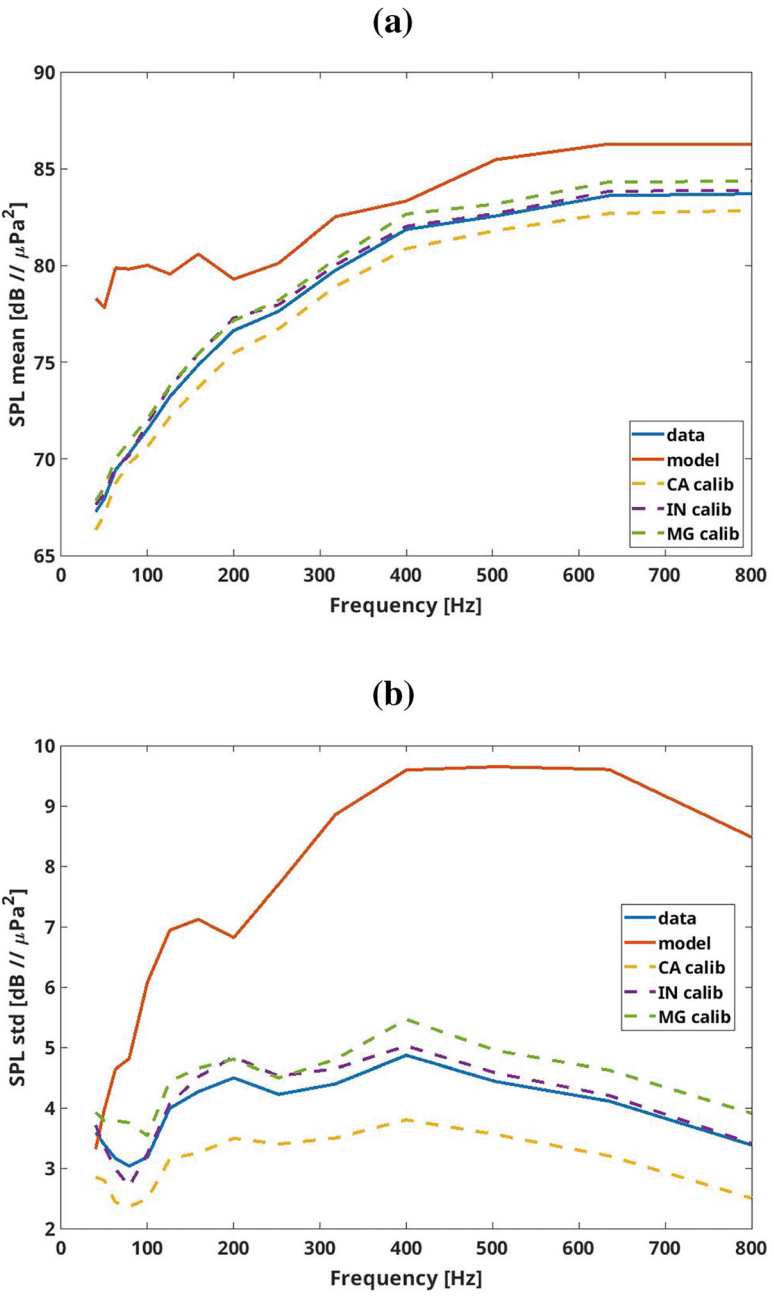

**Fig. 9** Sample distribution's SPL mean (**a**) and standard deviation (**b**) averaged over the three recorders for data (continuous blue), model prediction (continuous brown), and calibration separately shown for CA, IN, and MG (dashed) versus 1/3-octave band (base 10) center frequencies

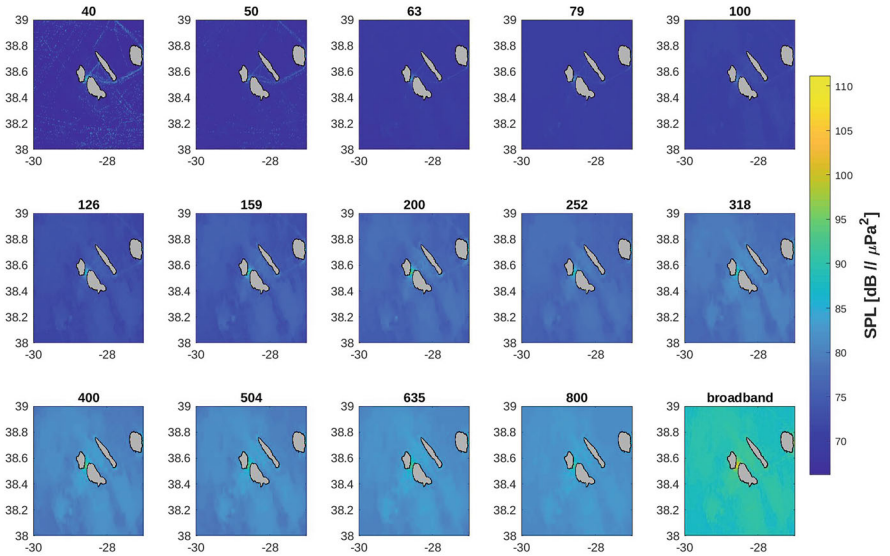

**Fig. 10** Field-calibrated mean SPL for the 1/3-octave band (base 10) center frequencies in 40–1000 Hz using (6) and broadband using (7) (bottom right plot), at 10 m depth for June 2018 [axes: latitude (y), longitude (x) both in decimal arc degrees]

Applying the calibration to the wider area allows to obtain the mean SPL results shown in Fig. 10 for the 1/3-octave band center frequencies and the whole month of June 2018. As expected, levels are overall lower than before calibration, and surfaces are flatter, because variance has, in general, been reduced.

## ENL Estimation

The wind model is used as baseline for estimating the instantaneous ENL using definition (6) and in its broadband form using (7). Figure 11 shows the 95, 75, and 50 percentiles of the broadband instantaneous ENL field at 10 m depth before calibration. ENL values up to 35 dB re 1 $\mu$Pa$^2$ were estimated in the channel between Faial and Pico Islands and from 15 to 25 dB in extensive regions away from the islands but only for 5% of the time.

Figure 12 shows the predicted ENL statistics for the same parameters as in Fig. 11 but using the $\{A, B\}$ field calibration coefficients deduced from the observed data merged for the three recorders, as explained above. The calibration process tends to approach the model to the data, imposing lower mean levels in the lower-frequency bands and narrower distributions (smaller variances), which is consistent with the differences between Figs. 11 and 12. There are a few ENL high peaks reaching over 15 dB at the usual locations (channel between Faial and Pico) and only for small time periods (5% and 25% of the month). Comparison of

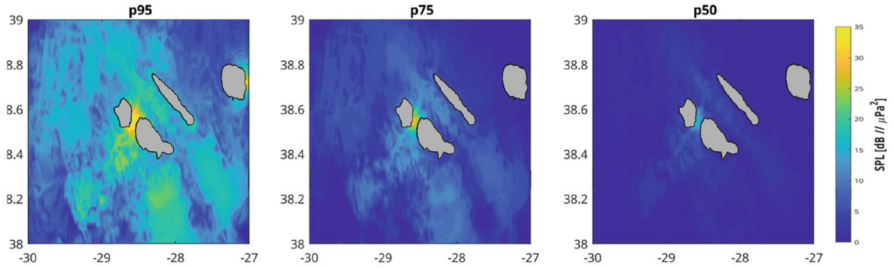

**Fig. 11** Model predicted instantaneous broadband excess noise level (ENL) 95, 75, and 50 percentiles in the 40–1000 Hz band at 10 m depth for the whole area, in June 2018 with a spatial and time resolution of 500 m and 10 min, respectively [axes: latitude (y), longitude (x) both in decimal arc degrees] (Figure partially reprinted from Jesus et al. 2022)

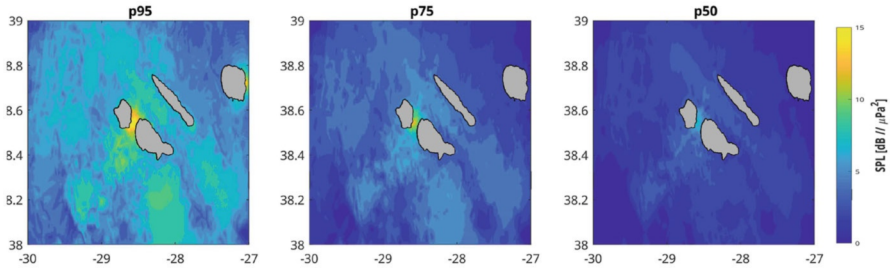

**Fig. 12** Field-calibrated predicted instantaneous broadband excess noise level (ENL) 95, 75, and 50 percentiles in the 40–1000 Hz band at 10 m depth for the whole area, in June 2018 with a spatial and time resolution of 500 m and 10 min, respectively [axes: latitude (y), longitude (x) both in decimal arc degrees] (Figure partially reprinted from Jesus et al. 2022)

figures before and after calibration shows an ENL mean decrease of approximately 8 dB re 1 $\mu$Pa. The validation of the calibration process is not an easy task due to the lack of observations both in time and space. For example, the area that extends from the channel between Pico and S. Jorge to the south and northeast shows prevailing noise levels that are difficult to objectively validate. We may speculate that these levels, which occur in a small portion of the time, might be associated with the shipping lane to Terceira that encounters favorable propagation. Thus, it can be put forward that the proposed calibration methodology provides a balanced adjustment for systematic modeling errors coherent with patterns of the study area. One of the features of the proposed calibration method is that it is based on a statistical behavior of the data in user-defined time lapses of the available data sets and thus perfectly adaptable to other areas and periods of the year.

## Conclusions

The Azores is an important habitat for cetaceans, but it is also a crossroad of several long-haul shipping routes, and a significant part of its economy is based on marine traffic around and between islands (ferries, leisure boats, small cargo and fishing). The ship traffic density around the islands shows some long well-identified routes between islands and from the islands to other destinations outside of the study area. There is also some traffic scattered well away of the islands, probably due to intercontinental traffic. Local ships connect close by ports for small leisure trips, ferries, or fishing. Noise propagates away from intense shipping lanes if and when acoustic propagation conditions are favorable. Marine traffic produces ocean noise that impacts on marine species. The Azores is also challenging for acoustic monitoring because it is a vast deep ocean area with a few islands for supporting permanent monitoring buoys or platforms.

Acoustic data recordings at the three locations to the southwest of the islands of Faial and Pico are in general coherent with AIS ship traffic density in the area. Assuming that model data may be systematically biased, field calibration is extended to a larger area covering four islands of the Azores archipelago for the full month of June 2018. The results show that field-calibrated broadband ENL sound maps are coherent with the ship traffic in the study area, revealing a number of potentially threatening hotspots due to sound propagation conditions off shipping routes and vessel traffic patterns between islands.

The validation of the results is an impossible task without the help of additional direct observations in space and time. However, the proposed broadband ENL formulation seems to give a good superposition with the estimated marine traffic activity in and around the central Islands of the Azores archipelago. More surprising were the vast areas of high ENL to the southeast of the central islands that can be asserted to sound spreading from the shipping routes from these islands to/from Terceira. However, intense spreading in this area only occurs for a small portion of the time, at least during the considered month. The attempt for using localized data for calibrating model predictions in the wide area produced two effects: one was the overall ENL reduction and the other a decrease in the dispersion for most of the time. However, the areas with higher ENL are consistent with direct observation of shipping. Although there is no other comparable study for this area, excess levels seem to be relatively low ($<$10 dB, 50% of the time) during the study period. It is possible that the wide area might be too large for an effective calibration with only three recorders relatively close to each other.
