*This volume is dedicated to our colleague and great friend Professor Anthony D. Hawkins. Professor Hawkins (Tony) has been a pioneer in the study of fish bioacoustics for over 60 years. He has conducted an immense body of research from basic science of hearing to very applied aspects of fisheries biology. But, from the perspective of Aquatic Noise, Tony is co-founder of the set of international conferences on Effects of Noise on Aquatic Life, from which this book is derived. Through these conferences, Tony has had immense impact on the field, and how it has moved forward. While not participating in future conferences, Tony's influence, both as grand scholar and founder of the conferences, will endure.*

# Preface

***The Effects of Noise on Aquatic Life***
**Berlin, Germany, 10-15 July 2022**

*Effects of Noise on Aquatic Life: Principles and Practical Considerations* is a compilation of chapters based on the papers presented at the sixth International Conference on "The Effects of Noise on Aquatic Life" that took place in Berlin, Germany, July 10–15, 2022 (https://aquaticnoise.org/2022/). This conference, generally referred to as AN2022, followed the very successful conferences on the same general topics held in Nyborg, Denmark (in 2007), Cork, Ireland (in 2010—see Popper and Hawkins, 2012), Budapest, Hungary (in 2013—see Popper and Hawkins, 2016), Dublin, Ireland (in 2016), and Den Haag, Netherlands (in 2019).

The primary goal of AN2022, like our past conferences, was to define the current state of knowledge on the impact of underwater noise on aquatic life and to explore the progress made in this field in the three years since the last conference. The continued need and value of these conferences, and the publications that come from them, are a result of ongoing human development that adds a wide range of noise to aquatic environments. These anthropogenic noise sources include (but are not limited to) exploration and extraction of oil and gas in offshore waters, increasing vessel traffic, various military activities, the prospect of industrial development of previously pristine waters (e.g., polar regions), ongoing and recent proposals to open

new areas for marine renewables around the world, as well as the development of other technologies, such as deep-sea mining. In all cases, there is increasing concern over potential impacts of these activities on aquatic species and their habitats

All this work has resulted in greater, and growing, interest in, and need to understand, the effects of underwater noise on aquatic life by investigators, regulators, industry, and the public. Moreover, the need for rigorous examination of the environmental impact of underwater noise has driven new research into the effects of anthropogenic noise on a variety of aquatic life including (but not limited to) aquatic invertebrates, fishes, and marine mammals, and on sound sources and on methods of mitigating their impact.

## Purpose of the Conference and This Book

Research on the impact of underwater noise on aquatic life is challenging. Major new technological developments are taking place within the offshore industry, and, quite often, the new technology produces sound. Those concerned with assessing the impact of sounds on aquatic organisms are investigating the biology, physiology, and ecology of animals not readily examined in the laboratory, and often must develop new methods that can be applied to free-living animals in the in underwater environments itself.

Thus, a very significant feature of the conference (as our past conferences) was to provide extensive opportunities for learning about current research and fostering interactions with colleagues who focus on different taxa, different noise sources, and different approaches to understand these issues and their mitigation. Indeed, there was a strong emphasis for communication of ideas between participants from different backgrounds and interests in the overall themes of the conference.

Consequently, a major feature of the conferences, and this book, is that they bring together individuals and the latest ideas from a great variety of disciplines, ranging from biologists interested in behavioral and physiological effects of exposure to sound, to acousticians and engineers with an interest in the physics of underwater sound generation, to regulators and conservation groups concerned with the protection of aquatic life. The fact is that surveys of participants in the Cork, Budapest, Dublin, Den Haag, and Berlin conferences showed that the overall opportunity for communication between people from different disciplines might have been the most important long-term outcome of the conference.

*Indeed, the fundamental goal for the Aquatic Noise conferences, and the books coming from the conferences, is effective communication and consultation between the breadth of people and groups with interest in the topic*.

While this book may not impart the personal interactions found in the conferences and which will certainly continue at our next conference in Prague in 2025 (www.an2025.org), the chapters do reflect the ideas and issues discussed. Moreover, the chapters bring together ideas, and "introduce" many of the current and future "players" who will be making future major contributions to this field today and in the future.

## Broader Impact of the Conference

The information and ideas presented at the conference, as reflected in the chapters in this book derived from that conference, will certainly help shape future research and understanding of effects of noise on aquatic life. In fact, the impact of our earlier Springer books based on earlier conferences (Popper and Hawkins 2012, 2016) is apparent from the more than 1 million (as of 1 December 2023) chapter views to date. Moreover, based on surveys and informal comments, it is apparent that the books and the interactions and networking that took place at the 2022 conference have already resulted in new collaborations between investigators, a broader understanding of the science used in their work by decision-makers, a better understanding of regulatory issues by scientists and industry, and substantial cross-fertilization of experimental design and approaches by investigators.

## This Book Is Like a Library of "Old"!

There are 142 chapters in this book, and it is very hard to classify them—indeed, as the editors compiled the book they realized that there were perhaps four or five ways to organize the chapters and that many of the chapters would fit into several of the categories. Thus, we encourage readers to "browse" the Table of Contents beyond the chapters in the section they think most fit their interests. We suggest this since readers are likely to find other chapters, in other sections, that are of considerable interest and value. Indeed, the editors like to think of the book as like going into a library of old where one did not just go to grab the book or journal that brought one to the library, but rather one looked around the shelves and often "bumped into" other books or journals that struck an interest and may have even helped answer the questions that brought the person to the library in the first place (or other questions that were not even the basis for the visit)!

# Acknowledgements

There are many people who helped make a giant difference for the success of the conference, and this book. But since they are acknowledged on our web site (www.AquaticNoise.Org), we limit ourselves here to just a few people.

First, every one of the organizers and attendees owe a giant debt to Ms. Terri Cullinane, principal in the conference organizing group VenuesWorld. Terri has worked with the Aquatic Noise organizers since the second conference in Cork, Ireland, and she and her colleagues are integral to the success of our conferences. We could go on for pages about what Terri and her colleagues do, but suffice it to say that we are extremely grateful for their great contribution.

The other two people we want to acknowledge (and particularly by Tony Hawkins and Art Popper) are Sue Hawkins and Helen Popper. Helen and Sue were our (Tony and Art) best colleagues and supporters and guides when we conceived of the conferences in 2005 at a dinner in Aberdeen, Scotland. Sue and Helen provided wisdom, guidance, and invaluable work for many of the conferences. Even though Helen and Sue were not involved in the last few conferences, their legacy is integral to the success of the conferences even today.

For this book, we would like to express our sincere gratitude to our colleagues and friends who served as section editors—Paul A. Lepper, Marta Picciulin, Denise Risch, Amy R. Scholik-Schlomer, and Kathleen J. Vigness Raposa. These colleagues each handled dozens of papers with timely reviews and re-reviews and were instrumental in ensuring the highest quality from every paper.

We also are grateful to colleagues at Springer Nature. We thank Susanne Friedrichsen and Sonal Nagpal from the Springer Reference Team, the publishing program in which the book appears, and William Lamsback, the Springer Nature editor in New York, who first provided suggestions to include the book in this key program and who was always willing to provide guidance and solve problems.

Finally, we are very grateful to the many agencies and funders who supported the conference (all listed on our web site). One of the hallmarks of the Aquatic Noise conferences is having participation from younger colleagues who are just entering the field of aquatic noise (and related topics) and participants from developing countries. Our goal is to expand interest in aquatic noise, ensure that it is an issue recognized to be of importance worldwide, and to bring new people into the field.

Thus, a very substantial portion of the funds we receive supports these participants, and we are proud that we can do this.

Arthur N. Popper, College Park, MD

Joseph A. Sisneros, Seattle, WA
Frank Thomsen, Copenhagen, Denmark

# Overview of the Book

Because a reasonable number of the chapters in this book represent updated material and may take slightly different approaches than the meeting presentations, the book organization is somewhat different than the meeting organization. At the same time, we recognize that the book could be organized in any number of ways, depending on the organizers and their interests. Thus, readers are welcome to "reorganize" the book for their own interests and needs. Indeed, with the chapters online, it very easy to set up a different organization in a computer file and then link that organization to the specific chapters.

The book starts in Section I with chapters covering works on the history and evolution of the aquatic life meetings and a summary of the Berlin meeting. Following the introduction, the sections have been arranged in the same order as one would commonly perform an assessment of noise impacts. Thus, Section II, "Sounds and Sources," includes works on anthropogenic and biological sound sources, encompassing the physical properties of these sources. These chapters also comprise research on numerical sound modelling and other acoustical topics. Section III is devoted to "Soundscapes," which encompasses studies dedicated to sound sources and the acoustic characteristics of the biotic and abiotic ambient sounds present in a large variety of locations around the globe.

Sections IV through VII deal with "Hearing and Auditory Assessment." Sections V through VII include studies on hearing sensitivity and frequency range of hearing, as well as hearing anatomy and physiology.

Section VIII then deals with general issues of noise effects, while Section IX focuses on noise effects on fishes, Section X on marine mammals, and Section XI on other vertebrates. Section XII focuses on noise effects on invertebrates and plants. Management of noise in the form of specific frameworks for impact studies, noise criteria, and noise mitigation is covered in Section XIII. Finally, Section XIV deals with Monitoring, including marine animals using biological sound as well as ambient noise.

# Contents

## Volume 1

**Section I Introduction** . . . . . 1

1 **Brief History of "The Effects of Noise on Aquatic Life" Meetings** . . . . . 3
Arthur N. Popper and Anthony D. Hawkins

2 **Evolution of "The Effects of Noise on Aquatic Life" Meetings: 2007 to 2022** . . . . . 23
Amy R. Scholik-Schlomer, Christine Erbe, Anthony D. Hawkins, Paul A. Lepper, Frank Thomsen, Arthur N. Popper, and Joseph A. Sisneros

3 **Effects of Noise on Aquatic Life: An Overview of the Berlin Conference** . . . . . 35
Joseph A. Sisneros, Frank Thomsen, Paul A. Lepper, Amy R. Scholik-Schlomer, Anthony D. Hawkins, and Arthur N. Popper

**Section II Sounds and Sources** . . . . . 49

4 **Effects of Array Design on Acoustic Propagation Modeling in Seismic Surveys** . . . . . 51
Alexander S. Douglass and Shima Abadi

5 **Sound Fields in Two Small Experimental Test Arenas: A Comparison** . . . . . 61
Amelia Holgate, Paul R. White, Timothy Leighton, and Paul S. Kemp

6 **Measuring Directional Underwater Sound with Particle Motion Eccentricity** . . . . . 75
James A. Campbell and Sophie L. Nedelec

7 **Shaking Up Aquatic Substrates: Taking Lessons from Biotremology and Defining Terminology** . . . . . 85
Louise Roberts and Andreas Wessel

8 **Modeling Underwater Noise in the North Adriatic Sea** . . . . . 101
Michol Ghezzo, Robert Chavanne, Dominique Clorennec, Roger Gallou, Fantina Madricardo, Antonio Petrizzo, Marta Picciulin, and Thomas Folegot

9 **Fish Sound Production Research: Historical Practices and Ongoing Challenges** . . . . . 109
Audrey Looby, Kieran D. Cox, Santiago Bravo, Rodney Rountree, Francis Juanes, Amalis Riera, Sarah Vela, Hailey L. Davies, Laura K. Reynolds, and Charles W. Martin

10 **Sounds of Walleye Pollock: A Quantitative Description** . . . . . 129
Amalis Riera, Rodney Rountree, and Francis Juanes

11 **FishSounds Version 1.1: Data Archive, User Experience, and Online Resources** . . . . . 145
Kieran D. Cox, Audrey Looby, Sarah Vela, Amalis Riera, Santiago Bravo, Hailey L. Davies, Rodney Rountree, Brittnie Spriel, Laura K. Reynolds, Charles W. Martin, Stan Matwin, and Francis Juanes

12 **Underwater Noise of Two Operational Tidal Stream Turbines: A Comparison** . . . . . 157
Denise Risch, Brett Marmo, Nienke C. F. van Geel, Douglas Gillespie, Gordon Hastie, Carol Sparling, Joe Onoufriou, and Ben Wilson

13 **Underwater Sound Emissions from the Moorings of Floating Wind Turbines: HYWIND Scotland Case Study** . . . . . 179
Federica Pace, Robin D. J. Burns, S. Bruce Martin, Michael A. Wood, Colleen C. Wilson, C. Eric Lumsden, Kari Mette Murvoll, and Jürgen Weissenberger

14 **Underwater Radiated Noise from Leisure Boats: Measurement Using an Interim Guide** . . . . . 203
Mathias H. Andersson, Emilia Lalander, Peter Sigray, Mikael Svedendahl, and Martin Östberg

15 **Operational Underwater Noise from Offshore Wind Farms** . . . . 225
Klaus Betke and Michael A. Bellmann

16 **Interface Wave Contribution to Acoustic Particle Motion During Offshore Wind Farm Construction** . . . . . 237
Gopu R. Potty, James H. Miller, Ying-Tsong Lin, and Kathleen J. Vigness-Raposa

17 **Relation Between Underwater Noise and Operating Offshore Wind Turbines** . . . . . 247
Christian Terkelsen Holme, Matej Simurda, Stephan Gerlach, and Michael A. Bellmann

18 **Sound Emissions from Ultrasonic Antifouling Equipment** . . . . . 261
S. Bruce Martin, Alexander O. MacGillivray, Jason D. Wood, Krista B. Trounce, Dominic J. Tollit, and Kanachi Angadi

19 **Modelling Pile-Driving Sound and Mitigation in Realistic Environments** . . . . . 277
Ozkan Sertlek, Yaxi Peng, and Apostolos Tsouvalas

**Section III Soundscapes . . . . . 289**

20 **Ocean Sound: More than Just Amplitude** . . . . . 291
Jennifer L. Miksis-Olds, Dylan C. Wilford, and S. Bruce Martin

21 **Analyzing Long-Term Changes in Soundscapes Using Power Spectral Band Sums** . . . . . 299
Joseph J. Luczkovich and Mark W. Sprague

22 **Underwater Acoustic Sound Propagations: Climatological Characteristics of Seasonal, Mesoscale, and Submesoscale** . . . . . 321
Sung Yong Kim

23 **Natural Ambient Sounds as Sources of Biologically Relevant Information and Noise for Fishes** . . . . . 325
Sujay Balebail and Joseph A. Sisneros

24 **Soundscape in a Northern Patagonian Fjord with Salmon Farms** . . . . . 351
Elba Avilés-Sanhueza and Iván A. Hinojosa

25 **Acoustic Profiles of Underwater Soundscapes Affected by Road Traffic** . . . . . 365
Kees te Velde and Hans Slabbekoorn

26 **Baseline Assessment of Underwater Ambient Sound in the Northern Adriatic Sea** . . . . . 379
Antonio Petrizzo, Michol Ghezzo, Hrvoje Mihanović, Marta Picciulin, Jarosław Tęgowski, Predrag Vukadin, Iole Leonori, and Fantina Madricardo

**90 Effects of Repeated and Continuous Sound Exposures on Mussels (*Mytilus* spp.) in the Lab** . . . . . 1317
Jeroen Hubert, Emily Booms, Rosalie Moens, A. Daniëlle van der Burg, Rob Witbaard, and Hans Slabbekoorn

**91 Marine Bivalve Sound Detection and Associated Noise Impacts** . . . . . 1331
Seth F. Cones, Youenn Jézéquel, and T. Aran Mooney

**92 Effect of Operational Wind-Turbine Vibration on Surface-Dwelling Invertebrates** . . . . . 1343
Jordan Burgess, Stephen Thomas, Krysia Mazik, Sophie Al-Mudallal, Shiu Keung Tang, and Thomas Breithaupt

**93 Anthropogenic Noise Impacts on Invertebrates: Case of Freshwater Red Cherry Shrimp (*Neocaridina davidi*)** . . . . . 1363
Sasan Azarm-Karnagh, Laura López Greco, and Saeed Shafiei Sabet

**94 Sound Effect on the Maternal Care Behavior of a Crab** . . . . . 1375
María Paz Sal Moyano, Maria Ceraulo, Tomás Luppi, María Andrea Gavio, and Giuseppa Buscaino

**95 Marine Plants and Sound** . . . . . 1385
Marta Solé and Michel André

**96 Effects of Anthropogenic Noise on Marine Zooplankton** . . . . . 1405
Emilie Hernes Vereide and Saskia Kühn

**97 No Evidence for an Effect of Chronic Boat Noise on the Fitness of Reared Water Fleas** . . . . . 1429
Loïc Prosnier, Emilie Rojas, and Vincent Médoc

98 **Response of Freshwater Zooplankton Communities to Chronic Anthropogenic Noise** . . . . . 1445
Emilie Rojas, Camille Desjonquères, Simon Agostini, Sarah Fiorini, Béatriz Decencière, Michael Danger, Vincent Felten, and Vincent Médoc

## Volume 3

**Section XIII Management of Noise . . . . . 1463**

99 **Near Real-Time Underwater Sound Modeling of Dredging Noise to Meet Regulatory Noise Thresholds** . . . . . 1465
Thomas Folegot, Erwan Hemon, Georg Nehls, Mara Schmiing, Stefan Bräger, Michael A. Bellmann, Stephan Gerlach, Rainer Matuschek, and Judith Flamme

100 **EU Marine Strategy Framework Directive-Compatible Approaches for Impulsive Noise Assessment** . . . . . 1485
C. Juretzek, A. Müller, Dominique Clorennec, Erwan Hemon, B. Niesterok, Peter Sigray, J. F. Borsani, Thomas Folegot, and M. Boethling

101 **Acoustic and Carbon Dioxide Deterrents for Invasive Bigheaded Carps (*Hypophthalmichthys molitrix* and *H. nobilis*)** . . . . . 1505
Jackie Culotta, Brooke J. Vetter, and Allen F. Mensinger

102 **Spatial Impact of Wind Farm Constructionon Harbor Porpoise Detectability** . . . . . 1523
Nienke C. F. van Geel, Steven Benjamins, Brett Marmo, Jacob Nabe-Nielsen, Anja Wittich, Denise Risch, Darren Jameson, Victoria L. G. Todd, Ian B. Todd, Sophie E. Cox, and Ben Wilson

103 **SanctSound: Building Data Systems for Sound Decisions** . . . . . 1547
Leila Hatch, Jack Barkowski, Simone Baumann-Pickering, Carrie Wall Bell, Benjamin Best, Jennifer Brown, Annamaria DeAngelis, John Joseph, Ella Kim, Danielle Kitchen, Annebelle C. M. Kok, Anke Kügler, Anurag Kumar, Marc O. Lammers, Tetyana Margolina, Megan McKenna, Karlina Merkens, Lindsey Peavey Reeves, Timothy J. Rowell, Mandy Shoemaker, Jenni A. Stanley, Alison Stimpert, Brandon Southall, Brian Stone, Mitchell Tartt, Sofie Van Parijs, and Eden J. Zang

104 **Characterization of Noise Abatement Systems for Protecting Aquatic Invertebrates and Fishes** . . . . . 1559
Tobias Bohne, Tanja Grießmann, and Raimund Rolfes

**105 Broadband Excess Noise Estimation via Sample Distribution Field Calibration** . . . . . 1565
Sérgio M. Jesus, Cristiano Soares, Miriam Romagosa, Irma Cascão, Ricardo Duarte, Friedrich Zabel, and Mónica A. Silva

**106 Revised Danish Guidelines for Underwater Noise from Installation of Impact or Vibratory Driven Piles** . . . . . 1585
René Smidt Lützen, Søren Keller, and Jakob Tougaard

**107 Threshold-Based Assessment of Underwater Noise Pollution in French Marine Waters** . . . . . 1601
Laura Ceyrac, David Dellong, and Florent Le Courtois

**108 Sound-Related Effects of Offshore Wind Energy on Fishes and Aquatic Invertebrates: Research Recommendations** . . . . . 1617
Kathryn A. Williams, Arthur N. Popper, Lyndie Hice-Dunton, Dennis M. Higgs, Edward Jenkins, Justin M. Krebs, T. Aran Mooney, Aaron N. Rice, Louise Roberts, Frank Thomsen, Kathleen J. Vigness-Raposa, and David G. Zeddies

**109 Effective Underwater Noise Management of Offshore Energy Activities: Use of Monitoring and Adaptive Management** . . . . . 1635
Raquel Carter, Melissa Capill, and Tim Carter

**110 Geophysical Industry Marine Mammal Conservation Under the Gulf of Mexico Proactive Regulatory and Observational Program (GOM-PROP)** . . . . . 1647
Alexandria Loureiro, Sarah Courbis, Miles Roden, Melissa Snover, Aude Pacini, and Heidi Etter

**111 Real-Time Monitoring of Underwater Radiated Noise Levels from Ships** . . . . . 1667
Mathias H. Andersson, Emma Alenius, Emilia Lalander, Marcus Linné, Ylva Ljungberg Rydin, Robin Nordström-Larsson, and Mikael Svedendahl

**112 Measurements of Underwater Radiated Noise from Mobile Offshore Drilling Units** . . . . . 1683
Melanie E. Austin, S. Bruce Martin, and Craig R. McPherson

**113 Management of Noise in a Busy Harbour Porpoise Protected Area** . . . . . 1697
Sónia Mendes, Abi Goulding, and Lisa Mogensen

**114 Balancing the Use of Acoustic Deterrent Devices (ADDs), Slow-Start, and Soft-Start for Offshore Impulsive Piling** . . . . . 1707
Simon J. Stephenson, Robert Lee, Charlotte Birch, Stephen P. Cook, and Daniel Jervis

**115 Evaluating the Benefits of Noise Reduction Mitigation: The ECHO Program** . . . . . 1715
Chloe E. Malinka, Dominic J. Tollit, Krista B. Trounce, and Jason D. Wood

**116 Acoustic Measurements During a Seismic Airgun Survey: The Case of the Cascadia Subduction Zone** . . . . . 1735
Kaustubha Raghukumar, Katherine Heal, Frank Spada, Grace Chang, Sarah K. Henkel, Taylor K. Chapple, and Scott A. Heppell

**117 Alignment and Incentivization of Underwater Noise Notations for Quiet Ships** . . . . . 1745
Krista B. Trounce, Michael A. Ainslie, David E. Hannay, and Justin M. Eickmeier

**118 Effect of Vessel Noise on Marine Mammals and Measures to Reduce Impact** . . . . . 1755
Laia Rojano-Doñate, Luca Lamoni, Jakob Tougaard, and Charlotte R. Findlay

**119 Mitigating Underwater Noise from Shipping, Seismic Airgun Surveys, and Pile Driving Using Best Available Technology and Environmental Practices** . . . . . 1773
Lindy Weilgart

**120 Influencing Parameters on Impact Pile-Driving and Noise Mitigation Measures** . . . . . 1809
Michael A. Bellmann, Adrian May, Stephan Gerlach, and Patrick Remmers

**121 Acoustic Disturbance Risk Estimates and Mitigation Strategies: An Animal-Centric Approach** . . . . . 1821
Rianna E. Burnham

**122 Environmental Risk Assessment Framework for Dredging Sounds** . . . . . 1853
Andrew D. McQueen, Burton C. Suedel, Matthew W. Ferguson, Christ A. F. de Jong, and Frank Thomsen

**123 Footprint of Sound Emissions from Fishing Vessels in the Adriatic Sea** . . . . . 1869
Federica Pace, Samuel J. Welch, Nicola Ferri, and Aurora Nastasi

**124 Offshore Wind Farms as an Anthropogenic Noise Source** . . . . . 1897
Michael Stocker

**125 Reporting Impulsive Noise from Underwater Explosions Using Seismic Data** . . . . . 1903
Mirko Mustonen and Aleksander Klauson

126 **Assessing Risk of Noise Pressure on Marine Life Using Bayes Estimator** . . . . . 1909
Sérgio M. Jesus, Ricardo Duarte, Giulia Spadoni, Cristiano Soares, and Marc Fernandez

127 **Seismic Survey Risk Assessment on Common Dolphins in the South-western Coast of Portugal** . . . . . 1923
Giulia Spadoni, Ricardo Duarte, Cristiano Soares, Marc Fernandez, and Sérgio M. Jesus

128 **Categorizing the Effects of Anthropogenic Noise on Aquatic Life** . . . . . 1939
Sophie L. Nedelec

129 **Deflagration: A Method for Lowering Noise from Underwater Unexploded Ordinance (UXO) Clearance Operations** . . . . . 1949
Paul A. Lepper, Stephen P. Robinson, Sei-Him Cheong, Lian Wang, Jakob Tougaard, Emily T. Griffiths, and John Hartley

130 **Joint Monitoring Program for Ambient Noise in the North Sea** . . . . . 1967
Niels Kinneging, Mathias H. Andersson, Christ A. F. De Jong, Karen De Jong, Jens Fischer, Monika Kosecka, Petter Kvadsheim, Nathan Merchant, Alain Norro, Stephen P. Robinson, and Jakob Tougaard

**Section XIV Monitoring . . . . . 1979**

131 **Automated Monitoring Technologies for Real-Time Marine Mammal Detection** . . . . . 1981
Carolyn M. Binder, Maj Dugald Thomson, and Craig Reesor

132 **Passive Acoustic Monitoring Power Analysis: A Tool for Designing an Acoustic Monitoring Program** . . . . . 1995
Megan Ryder, Cormac Booth, Cornelia Oedekoven, Tiago Marques, Ruth Joy, and Danielle Harris

133 **Acoustic Activity of Harbour Porpoise Around an Offshore Oil and Gas Platform** . . . . . 2011
Victoria L. G. Todd, Jane C. Warley, Laura D. Williamson, and Ian B. Todd

134 **Acoustic Detection of Franciscana Dolphins Near Artisanal Fishing Nets in Argentina** . . . . . 2029
Gisela V. Giardino, Mel Cosentino, Giuseppa Buscaino, Ricardo Bastida, and Diego Rodríguez

**135 Passive Sonar Equation-Based Marine Mammal Detection Probability Modeling** . . . . . 2041
Baptiste Menetrier, Morgane Pommier, and Joanne O'Brien

**136 Automatic Deep-Learning-Based Classification of Bottlenose Dolphin Signature Whistles** . . . . . 2059
Frants Havmand Jensen, Piper Wolters, Louisa van Zeeland, Evan Morrison, Gracie Ermi, Scott Smith, Peter L. Tyack, Randall S. Wells, Sam McKennoch, Vincent M. Janik, and Laela S. Sayigh

**137 Measuring Fin Whale Songs in a Noisy Environment** . . . . . 2071
Virginia Sciacca, Giuseppe Morello, and Francesco Filiciotto

**138 Acoustic Baseline Monitoring of Marine Mammals Offshore West Africa: Using an Autonomous Surface Vessel** . . . . . 2091
David Hedgeland and Chris Pierpoint

**139 Measuring Fluctuation in Humpback Whale Presence in Hawaii Based on Song Chorusing Levels** . . . . . 2111
Marc O. Lammers, Eden J. Zang, Anke Kügler, and T. Aran Mooney

**140 Background Noise Impacts Harbor Porpoise Detections in Passive Acoustic Monitoring** . . . . . 2121
Mel Cosentino, Jakob Tougaard, and Magnus Wahlberg

**141 Methods to Measure Underwater Sound Sources from Oil and Gas Activities** . . . . . 2131
Christ A. F. de Jong, Michele B. Halvorsen, David E. Hannay, and Michael A. Ainslie

**142 A Global Library of Underwater Biological Sounds (GLUBS): An Online Platform with Multiple Passive Acoustic Monitoring Applications** . . . . . 2149
Miles J. G. Parsons, Audrey Looby, Kranthikumar Chanda, Lucia Di Iorio, Christine Erbe, Fabio Frazao, Michelle Havlik, Francis Juanes, Marc O. Lammers, Songhai Li, Matthias Liffers, Tzu-Hao Lin, Simon Linke, T. Aran Mooney, Craig Radford, Aaron N. Rice, Rodney Rountree, Laela S. Sayigh, Renata S. Sousa-Lima, Jenni A. Stanley, Karolin Thomisch, Edward R. Urban, Louisa van Zeeland, Sarah Vela, Silvia Zuffi, and Sophie L. Nedelec

**Correction to: Anthropophony Effects on Acoustic Metrics in a Marine Soundscape** . . . . . C1
Lara C. Lopes, Eliziane G. Oliveira, Christopher W. Clark, and Renata S. Sousa-Lima

# About the Editors

**Arthur N. Popper** is Professor Emeritus and Research Professor in the Department of Biology, University of Maryland, College Park, MD (USA). His current research focuses on the effects of man-made (or anthropogenic) noise on aquatic life, and particularly on fishes. This interest follows Popper's decades of basic research on fish hearing capabilities and mechanisms. Recent studies have included effects of very intense man-made signals (pile driving, seismic air guns) as well as general increase in background noise levels (as from shipping and aquaculture). He also works with US and international institutions in evaluating overall effects of the increase in man-made noise on animals. This includes being organizer of six international conferences on effects of noise on aquatic life. Popper has edited 77 volumes of books on hearing and related topics in the *Springer Handbook of Auditory Research* series and edits the science and technology magazine *Acoustics Today.*

**Joseph A. Sisneros** is Professor and Chair of the Department of Psychology and an Adjunct Professor in the Department of Biology at the University of Washington (UW), Seattle, WA (USA). The primary focus of Dr. Sisneros' work is the investigation of seasonal reproductive-state and steroid-dependent changes in the adult auditory system of fishes. A secondary focus of his work is the investigation of sound source localization by fishes. Dr. Sisneros' work on sound source localization and reproductive-state-related changes in fishes has been primarily funded over the past 16 years by the National Science Foundation. He has published

over 90 scholarly papers and book chapters in top journals and book publications. Dr. Sisneros was editor of the Springer book *Fish Hearing and Bioacoustics* and he is senior editor of the *Springer Handbook of Auditory Research*.

**Anthony D. Hawkins** was Managing Director of Laughine Limited, Aberdeen, Scotland, a company dealing with fish biology. He was Director of Fisheries Research for Scotland (1987–2002) and an Honorary Professor at Aberdeen University. He was made a Commander of the British Empire (CBE) in 2000 for his services to fisheries science. His research interests have ranged from migrations of salmon to the effects of sound on fishes. In 1991, he set up the North Sea Commission Fisheries Partnership, bringing together fishermen and scientists, and he then set up and worked as Rapporteur for the North Sea Regional Advisory Council (NSRAC), providing advice from fishers and scientists to the European Commission on the management of North Sea fisheries. Together with Arthur Popper and others, Dr. Hawkins organized international conferences on the Effects of Noise on Aquatic Life bringing together scientists, engineers, regulators, and industry to discuss the latest scientific findings in this field.

**Frank Thomsen** is a Principal Scientist in Underwater Acoustics with DHI A/S, Denmark. His work focuses on the effects of anthropogenic underwater noise on aquatic life, especially looking at offshore wind farms and dredging. Dr. Thomsen's scientific work has also covered the acoustic communication in wild killer whales (*Orcinus orca*) and the distribution and abundance of marine mammals using aerial and acoustic monitoring. Dr. Thomsen has worked as chairman of working groups and advisor for a variety of national and international organizations such as the European Marine Board, the European Commission, OSPA, and the United Nations. He was chairman of the 6th International Conference of the Effects of Noise on Aquatic Life in Berlin (AN2022). Dr. Thomsen has published over 80 papers and reports, many in leading journals.

**William D. Halliday** Wildlife Conservation Society Canada, Whitehorse, YT, Canada

School of Earth and Ocean Sciences, University of Victoria, Victoria, BC, Canada

**Michele B. Halvorsen** Formerly University of New Hampshire, Jackson Estuarine Laboratory, Durham, NH, USA

**Quentin Hamard** Marine Observation Centre, Flanders Marine Institute (VLIZ), Ostend, Belgium

France Énergies Marines, Plouzané, France

**David E. Hannay** JASCO Applied Sciences Ltd., Victoria, BC, Canada

**Kirstin Anderson Hansen** Marine Biological Research Center, Department of Biology, University of Southern Denmark, Kerteminde, Denmark

**Craig A. Harms** Department of Clinical Sciences and Center for Marine Sciences and Technology, College of Veterinary Medicine, North Carolina State University, Morehead City, NC, USA

**Danielle Harris** Centre for Research into Ecological and Environmental Modelling, University of St Andrews, St Andrews, Scotland, UK

**John Hartley** Hartley Anderson Ltd, Aberdeen, UK

**Gordon Hastie** Sea Mammal Research Unit, St. Andrews, Scotland, UK

**Leila Hatch** NOAA Office of National Marine Sanctuaries, Silver Spring, MD, USA

**Michelle Havlik** King Abdullah University of Science and Technology, Red Sea Research Center, Thuwal, Saudi Arabia

**Anthony D. Hawkins** Loughine, Marine Research, Kincraig Blairs, Aberdeen, Scotland, UK

**Katherine Heal** Integral Consulting Inc., Santa Cruz, CA, USA

**David Hedgeland** bp, Sunbury on Thames, Middlesex, UK

**Erwan Hemon** Quiet-Oceans, Plouzane, France

**E. Elizabeth Henderson** NIWC Pacific, San Diego, CA, USA

**Sarah K. Henkel** Department of Integrative Biology, Oregon State University, Corvallis, OR, USA

Hatfield Marine Science Center, Oregon State University, Newport, OR, USA

**Scott A. Heppell** Department of Fisheries, Wildlife, and Conservation Sciences, Oregon State University, Corvallis, OR, USA

**Lyndie Hice-Dunton** National Offshore Wind Research and Development Consortium, Albany, NY, USA

**Dennis M. Higgs** Department of Integrative Biology, University of Windsor, Windsor, ON, Canada

**Iván A. Hinojosa** Departamento de Ecología, Facultad de Ciencias, Universidad Católica de la Santísima Concepción, Concepción, Chile

Centro de Investigación en Biodiversidad y Ambientes Sustentables (CIBAS), Universidad Católica de la Santísima Concepción, Concepción, Chile

Center for Ecology and Sustainable Management of Oceanic Islands (ESMOI), Departamento de Biología Marina, Facultad de Ciencias del Mar, Universidad Católica del Norte, Coquimbo, Chile

Centro de Investigación Oceanográfica COPAS COASTAL, Universidad de Concepción, Concepción, Chile

**Caroline Hoeschle** BioConsult SH, Husum, Germany

**Amelia Holgate** Faculty of Engineering and Physical Sciences, University of Southampton, International Centre for Ecohydraulics Research (ICER), Southampton, UK

**Christian Terkelsen Holme** Ørsted Wind Power A/S, Fredericia, Denmark

**Kelsey N. Hom** PhD Program in Biology, The Graduate Center, City University of New York (CUNY), New York, NY, USA

Biology Subprogram in Ecology, Evolution, and Behavior, The Graduate Center, CUNY, New York, NY, USA

Department of Biology, Brooklyn College, CUNY, Brooklyn, NY, USA

**Dorian Houser** National Marine Mammal Foundation, San Diego, CA, USA

**Jeroen Hubert** Institute of Biology Leiden, Leiden University, Leiden, The Netherlands

**Laura Valentina Huertas-Amaya** Departamento de Ecología y Territorio, Facultad de Estudios Ambientales y Rurales, Pontificia Universidad Javeriana, Bogotá, Colombia

**Darren Jameson** Ocean Winds, Edinburgh, Scotland, UK

**Vincent M. Janik** Sea Mammal Research Unit, Scottish Oceans Institute, School of Biology, University of St Andrews, St Andrews, UK

**A. Keith Jenkins** Naval Information Warfare Center Pacific, San Diego, CA, USA

**Edward Jenkins** Biodiversity Research Institute, Portland, ME, USA

**Nancy Jennings** Dotmoth, Bristol, UK

**Frants Havmand Jensen** Department of Biology, Syracuse University, Syracuse, NY, USA

Department of Ecoscience, Aarhus University, Aarhus C, Denmark

Biology Department, Woods Hole Oceanographic Institution, Woods Hole, MA, USA

**Daniel Jervis** Seiche Ltd, Bradworthy Industrial Estate, Bradworthy, UK

**Sérgio M. Jesus** LARSys, Universidade do Algarve, Faro, Portugal

**Youenn Jézéquel** Biology Department, Woods Hole Oceanographic Institution, Woods Hole, MA, USA

**Ian T. Jones** Center for Acoustics Research and Education, University of New Hampshire, Durham, NH, USA

**John Joseph** Naval Postgraduate School, Monterey, CA, USA

**Ruth Joy** School of Environmental Science, Simon Fraser University, Burnaby, BC, Canada

Centro de Estatística e Aplicações, Departamento de Biologia Animal, Faculdade de Ciências da Universidade de Lisboa, Lisbon, Portugal

**Francis Juanes** Department of Biology, University of Victoria, Victoria, BC, Canada

**C. Juretzek** Bundesamt für Seeschifffahrt und Hydrographie, Hamburg, Germany

**Mart Jüssi** ProMare MTÜ, Saula, Harjumaa, Estonia

**Ron A. Kastelein** SEAMARCO (Sea Mammal Research Company), Harderwijk, The Netherlands

**Hilary Kates Varghese** Center for Marine Acoustics, Bureau of Ocean Energy Management, Sterling, VA, USA

Center for Coastal and Ocean Mapping, University of New Hampshire, Durham, NH, USA

**Søren Keller** Danish Energy Agency, Copenhagen, Denmark

**Paul S. Kemp** Faculty of Engineering and Physical Sciences, University of Southampton, International Centre for Ecohydraulics Research (ICER), Southampton, UK

**Darlene R. Ketten** Woods Hole Oceanographic Institution, Woods Hole, MA, USA

The Hearing Research Center, Biomedical Engineering, Boston University, Boston, MA, USA

**Ella Kim** Scripps Institution of Oceanography, La Jolla, CA, USA

**Sung Yong Kim** Department of Mechanical Engineering, Korea Advanced Institute of Science and Technology, Daejeon, Republic of Korea

**Niels Kinneging** Rijkswaterstaat, Utrecht, The Netherlands

**Michelle Kissling** Wildlife Biology Program, Department of Ecosystem and Conservation Sciences, W.A. Franke College of Forestry and Conservation, University of Montana, Missoula, MT, USA

**Danielle Kitchen** Office of the Deputy Assistant Secretary of the Navy, Washington, DC, USA

**Aleksander Klauson** Tallinn University of Technology, Tallinn, Estonia

**Annebelle C. M. Kok** Groningen Institute of Evolutionary Life Sciences, Rijksuniversiteit Groningen, Groningen, The Netherlands

Scripps Institution of Oceanography, University of California San Diego, La Jolla, USA

**Yann Kolbeinsson** Northeast Iceland Nature Research Centre, Húsavík, Iceland

**Vladislav Kosarev** BioConsult SH GmbH & Co. KG, Husum, Germany

**Monika Kosecka** Marine Scotland Science, Aberdeen, UK

**Sarah E. Kotecki** Naval Information Warfare Center Pacific, San Diego, CA, USA

**Katie Kowarski** JASCO Applied Sciences, Dartmouth, NS, Canada

**Cassandra A. Kramer** Department of Biology, University of St. Thomas, St. Paul, MN, USA

**Justin M. Krebs** AKRF, Hanover, MD, USA

**Anke Kügler** University of Hawai'i at Mānoa, Kāne'ohe, HI, USA

**Saskia Kühn** Coastal Ecology, Research and Technology Centre West Coast, Kiel University, Kiel, Germany

**Anurag Kumar** U.S. Navy Living Marine Resources Program, Port Hueneme, CA, USA

**Mikhail Yu. Kuznetsov** Pacific Branch of Russian Federal Research Institute of Fisheries and Oceanography (FSBSI "VNIRO" ("TINRO")), Vladivostok, Russia

**Petter Kvadsheim** Norwegian Defence Research Establishment, Horten, Norway

**Dominic Lagrois** Département des sciences naturelles, Université du Québec en Outaouais (UQO), Gatineau, QC, Canada

**Emilia Lalander** FOI Swedish Defence Research Agency, Stockholm, Sweden

**Frans-Peter A. Lam** TNO, Acoustics and Sonar, The Hague, The Netherlands

**Marc O. Lammers** NOAA Hawaiian Islands Humpback Whale National Marine Sanctuary, Kīhei, HI, USA

Oceanwide Science Institute, Honolulu, HI, USA

**Luca Lamoni** International Council for the Exploration of the Sea (ICES), Copenhagen, Denmark

**Janet M. Lanyon** The University of Queensland, St. Lucia, QLD, Australia

**Benjamin C. Lawrence** Marshall Day Acoustics, Auckland, New Zealand

**W. T. LeBlond** Fisheries and Oceans Canada: Pacific Science Enterprise Centre, West Vancouver, BC, Canada

**Florent Le Courtois** French Naval Hydrographic and Oceanographic Services (Shom), Brest Cedex 2, France

DGA Techniques Navales, Toulon, France

**Robert Lee** Seiche Ltd, Bradworthy Industrial Estate, Bradworthy, UK

**Timothy Leighton** Faculty of Engineering and Physical Sciences, University of Southampton Institute of Sound and Vibration Research (ISVR), Southampton, UK

**Iole Leonori** CNR-National Research Council, IRBIM – Institute for Marine Biological Resources and Biotechnology, Ancona, Italy

**Paul A. Lepper** Wolfson School of Mechanical, Electrical and Manufacturing Engineering, Loughborough University, Loughborough, UK

**Aléxia A. Lessa** Programa de Pós-Graduação em Ecologia da Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil

**Steve Lewis** U.S. Fish and Wildlife Service, Division of Migratory Bird Management, Juneau, AK, USA

**Shihan Li** Fisheries and Oceans Canada, Dartmouth, Canada

**Songhai Li** Marine Mammal and Marine Bioacoustics Laboratory, Institute of Deep-sea Science and Engineering, Chinese Academy of Sciences, Sanya, China

**Matthias Liffers** Australian Research Data Commons, Curtin University, Bentley, Western Australia

**Ashlee Lillis** Biology Department, Woods Hole Oceanographic Institution, Woods Hole, MA, USA

Sound Ocean Science, Calgary, AB, Canada

**Tzu-Hao Lin** Biodiversity Research Center, Academia Sinica, Nankang, Taipei, Taiwan

**Ying-Tsong Lin** Woods Hole Oceanographic Institution, Woods Hole, MA, USA

**Simon Linke** Commonwealth Scientific and Industrial Research Organisation, Dutton Park, QLD, Australia

**Marcus Linné** FOI Swedish Defence Research Agency, Stockholm, Sweden

**Audrey Looby** Fisheries and Aquatic Sciences, Institute of Food and Agricultural Sciences, University of Florida, Gainesville, FL, USA

Nature Coast Biological Station, Institute of Food and Agricultural Sciences, University of Florida, Cedar Key, FL, USA

**Lara C. Lopes** EAR Hub – Laboratory of Bioacoustics and EcoAcoustic Research Hub, Biosciences Center, Federal University of Rio Grande do Norte, Natal, Brazil

**Laura López Greco** Laboratorio de Biología de la Reproducción, Crecimiento y Nutrición de Crustáceos Decápodos, Departamento de Biodiversidad y Biología Experimental, Facultad de Ciencias Exactas y Naturales, Instituto de Biodiversidad y Biología Experimental y Aplicada (IBBEA), Universidad de Buenos Aires, CONICET, Ciudad Autónoma de Buenos Aires, Argentina

**Alexandria Loureiro** EnerGeo Alliance, Houston, TX, USA

**Klaus Lucke** JASCO Applied Sciences (Australia) Pty Ltd, Capalaba, QLD, Australia

**Joseph J. Luczkovich** Department of Biology, East Carolina University, Greenville, NC, USA

**C. Eric Lumsden** JASCO Applied Sciences, Halifax, Canada

**Andrea Luna-Acosta** Departamento de Ecología y Territorio, Facultad de Estudios Ambientales y Rurales, Pontificia Universidad Javeriana, Bogotá, Colombia

Javeriana Institute of Water, Bogotá, Cundinamarca, Colombia

**Tomás Luppi** Instituto de Investigaciones Marinas y Costeras (IIMyC), FCEyN, Universidad Nacional de Mar del Plata-CONICET, Mar del Plata, Argentina

**Xavier Lurton** Center for Coastal and Ocean Mapping, University of New Hampshire, Durham, NH, USA

**René Smidt Lützen** Vysus Denmark, Copenhagen, Denmark

**Alexander O. MacGillivray** JASCO Applied Sciences (Canada) Ltd., Victoria, BC, Canada

**Fantina Madricardo** CNR-National Research Council, ISMAR – Institute of Marine Sciences in Venice, Venice, Italy

**Peter T. Madsen** Aarhus University, Department of Biology, Aarhus, Denmark

**Chloe E. Malinka** SMRU Consulting, Scottish Oceans Institute, University of St Andrews, St Andrews, UK

**Lena Marie Mannes** Department of Biology, University of Southern Denmark, Odense, Denmark

**Tetyana Margolina** Naval Postgraduate School, Monterey, CA, USA

**Brett Marmo** Xi Engineering Consultants, Edinburgh, Scotland, UK

**Emmaline C. Marotte** Fisheries and Oceans Canada, Dartmouth, Canada

**Tiago Marques** Centre for Research into Ecological and Environmental Modelling, University of St Andrews, St Andrews, Scotland, UK

School of Environmental Science, Simon Fraser University, Burnaby, BC, Canada

Centro de Estatística e Aplicações, Departamento de Biologia Animal, Faculdade de Ciências da Universidade de Lisboa, Lisbon, Portugal

**Abstract**

The idea for holding The Effects of Noise on Aquatic Life meetings arose in 2005 when the two of us and our wives got together in Aberdeen, Scotland. We discovered a shared interest in the effects of noise on aquatic animals and also realized that others with interests in the topic often focused on a single animal group, a single sound source, or specific technical issues. Even though these people could learn from one another and likely have very useful and productive collaborations, they almost never came together to share ideas and knowledge. Thus, we agreed that having a meeting that encouraged participation by a wide range of individuals with diverse interests could have a major impact on the field. This led to our first meeting in Nyborg, Denmark, in 2007, which we co-organized with Magnus Wahlberg, and then to very successful subsequent meetings.

This chapter shares the history of the meetings from our perspective. We discuss the fundamental goals we set out for the meetings in 2007 and insights into how we planned several of the meetings. Finally, because we no longer anticipate being very involved in future meetings, we discuss how we would like to see the meetings evolve further.

Sound · Noise · Regulation

## Introduction and Chapter Purpose

This chapter tells the history of The Effects of Noise on Aquatic Life, often referred to as Aquatic Noise, meetings from our perspective. We share our remembrances starting from the origin and early days of the meetings to the present. We discuss the fundamental goals we set out for the meetings in 2007 and insights into how we planned them. At this point in our lives, we anticipate that our participation in future meetings will be far be less active, but we still would like to provide some input into how the meetings might evolve, using this chapter.

Moreover, because the overall issue that the meetings consider is only getting larger, as the use of the oceans increases from shipping, and the quest for alternative energy sources increases, we suspect that there will continue to be the need for these meetings. Thus, we want to put on record how and why we came up with the idea for holding the meetings (Fig. 1).

**Fig. 1** The authors, Tony Hawkins (left) and Art Popper (right), checking out the tasting room at the Jameson Brewery in Cork to decide if this could be the site of the banquet for AN2010

## The Origins

The origin of Aquatic Noise can be easily traced to Helen and Arthur Popper taking a vacation in Scotland in 2005 and visiting Susan and Tony Hawkins. Art and Tony first met in 1980 at a meeting on hearing and sound communication in fishes in Sarasota, Florida (published in Tavolga et al. 1981). However, it was at the Scottish visit in 2005 that we discovered shared interests, leading to now almost 20 years of collaboration and close friendship.

Over a long dinner at the Tolbooth Seafood Restaurant in Stonehaven, Scotland, we realized that we shared deep interests in the potential effects of anthropogenic sounds on aquatic animals. Both of us had started to engage in research and writing about the subject, and many of our views were quite parallel.

In subsequent discussions during that visit, we also realized that we shared the view that one of the real problems in studies of aquatic noise was that there was very little communication between investigators asking similar questions but who were concerned with different animal groups, sources, or regulatory issues. For example, it was rare, other than perhaps at meetings of the Acoustical Society of America (ASA), that investigators interested in fishes and marine mammals got together to share ideas about anthropogenic sound or that those interested in seismic sources and pile driving would get a chance to hear about other work. And it was even rarer for those interested in issues such as sound mitigation would learn about work on the effects of sound on the animals they were trying to protect (Popper et al. 2020).

At the same time, we realized that these different groups really had a lot they could share with one another, ranging from the potential effects or acoustics of pile driving versus seismic sources versus sonar to how fishes and marine mammals responded to such sources. Our view was that by sharing knowledge, ideas, and experimental approaches, each field could move forward more than if they stayed isolated.

## Thinking About a Meeting

From our discussions and over a few months, mostly by email, we came up with the idea that there might be considerable interest in a meeting that would bring together individuals from the research, regulatory, conservation, and industrial communities to meet one another, share ideas, and form networks. Indeed, we saw a very important goal would be to meet at a location that would foster networking and conversation across species and sources.

As we continued to develop the idea for an Aquatic Noise meeting, we came up with several goals for the meeting. Indeed, although these were our guiding principles for the first meeting in 2007, they remain guiding principles in 2022 and for the future! They include:

- Focusing on sharing ideas and knowledge across taxa, disciplines, techniques, sound sources, regulatory issues, and conservation issues.
- Single plenary sessions so that every participant would be able to hear every oral presentation to broaden what they learn and to increase awareness of all issues.
- Promoting networking by holding the meeting in a very comfortable environments with lots of spaces to meet and mingle.
- Having meetings in places where the whole meeting, including talks, posters, and sleeping accommodations, would be in the same building so that people would constantly be "bumping into" one another. This would include providing breakfasts and lunches so participants would, again, be together as much as possible.
- Providing support for younger participants and for participants who come from countries where travel support may be particularly limited. Achieving these goals would be the focus of our fundraising for the meetings so that we could bring new people into our field.
- Producing an impactful publication so that the presentations would have the most impact well beyond the meetings.
- Holding the meetings in interesting places so that people would find additional things to do before and after the meetings and be able to bring families who would find lots to do while the participants were in sessions.

## Facts and Figures

The rest of this chapter deals with the individual meetings, focusing on vignettes and broad information. Because many readers will be curious about data such as attendance, Tables 1 and 2 summarize some information about all the meetings. Table 1 also provides links to the programs for each meeting where interested readers can find lists of the organizers, co-organizers, funders, and other information. Past programs are available and contain more data.

## The Aquatic Noise Trust

After the second Aquatic Noise meeting (Cork, referred to as AN2010) and as we started to work on AN2013 (Budapest), we realized that we needed a way to manage funds for the meeting and particularly to take in and distribute the funds we received from many international funding agencies and companies. Therefore, after getting legal advice, we set up the Aquatic Noise Trust as a charitable organization in the

United Kingdom. Some of the goals of the Trust were to: (1) organize lectures and conferences on the effects of noise on aquatic life, (2) facilitate the international exchange of information to enhance collaboration and research, (3) support the education of students and others by providing grants to facilitate attendance at lectures and conferences on aquatic noise and its effects, and (4) distribute funding for research into the effects of noise on aquatic organisms.

The original trustees of the Trust were Anthony Hawkins, Susan Hawkins, Arthur Popper, and Helen Popper. Paul Lepper is now the head of the Trust, and it continues in the United Kingdom and supports the meetings. The Trust is the owner of the meetings and associated websites.

## Aquatic Noise 2007: The First Meeting, Nyborg, Denmark

A critical question for the first meeting (Fig. 2) was location. We quickly realized that this is not a simple question because selecting a site requires getting a hotel, arranging meeting facilities, organizing space, and reserving hotel rooms. We also realized that dealing with all the details was way beyond our expertise or available time; indeed, this could have been a major barrier to organizing a meeting.

Fortunately, Art recalled attending a meeting of the International Society for Neuroethology in Nyborg, Denmark, organized by colleagues from the University of Southern Denmark, Odense. That meeting took place in a conference hotel, the Nyborg Strand. The appeal of this site was that the hotel was set up for conferences, and we would not have to deal with details such as reservations and food service.

We contacted Magnus Wahlberg, a colleague at Odense, about the meeting, and he agreed to co-organize with us (see Table 2 for a list of co-organizers). Indeed, Magnus graciously took over all work with the hotel and was a great collaborator in all aspects of the meeting planning. In fact, it turns out that Magnus had to sign the contract with the Nyborg Strand personally, putting him potentially in debt to over $150,000 (US) if the meeting did not go forward.

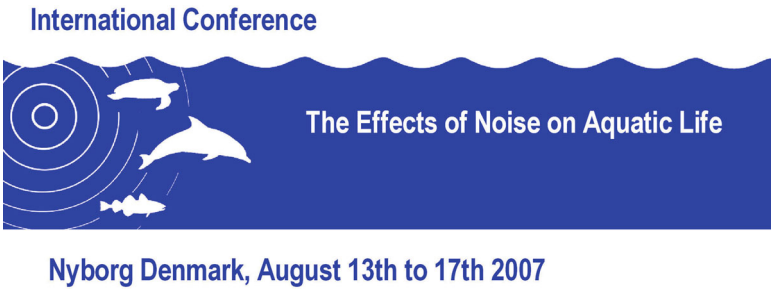

**Fig. 2** Logo for Nyborg meeting. Drawn by Tony Hawkins

In terms of the program, the three of us worked together along with major input from Peter Tyack (then at the Woods Hole Oceanographic Institution) and assistance in organization by Lydia Wysocki (then at the University of Vienna). Planning for the meeting took place not only via email but also at several other preceding meetings that various organizers attended in the United States.

Once we had figured out where to hold the meeting, we had to come up with a plan to let people know about it and how best to get funding. As we recall, publicizing the meeting was not too hard in that between us we knew many people in the field, and so we sent out announcements to hundreds of friends and colleagues and encouraged them to spread the word, and we used various mailing lists to further increase visibility.

The response was quite substantial; although others may not have thought about doing a meeting, there was clearly a sense among our colleagues that this kind of meeting was needed and would be a major step forward for the field.

## Funding

Getting funds was a bit of a challenge, but in our proposals, we focused on supporting students and participants from countries in which funds were not readily available. We were fortunate that we were able to get substantial funding from several US agencies including the US National Science Foundation, the US Navy (the Office of Naval Research and ONR Global), and the US Minerals Management Service (now BOEM). We also received substantial funding from the International Association of Oil and Gas Producers and from the Danish Carlsberg Foundation. We had several other smaller funders (see Supplemental Material in the program books for names of funders of this and other meetings).

Because we did not want parallel sessions, we could only have a limited number of talks over the 5 days of the meeting. In selecting talks from all the papers submitted, we tried to emphasize diversity in topic, and we focused on six major areas: (1) how animals use sound, (2) detection of sound by aquatic organisms, (3) underwater acoustics and ambient noise, (4) anthropogenic sources, (5) effects of anthropogenic sound on aquatic animals, and (6) regulation. We also had 84 posters.

## Lightening Sessions

We also created what we later called Lightening Sessions where many poster presenters would get a few minutes, and a few slides, to give an overview of their work. This proved to be very popular and was a major feature of all future meetings. At the first meeting, Lightening Session presenters tried to cram a 15-min talk into 5 min. We learned from these first presentations and subsequently changed things to give specific guidance on how to do a very short talk, including emphasizing that talks

should only include the research questions and the results, with minimal mention of background and methods.

## Keynote Speakers

An additional feature of the first, and all subsequent, Aquatic Noise meetings was to invite keynote speakers who could introduce new ideas and questions to our participants. Part of this was to share ideas and data from work with terrestrial animals (including humans) that is directly applicable to work on aquatic animals. Thus, for example, in Berlin, we invited Louise Roberts to talk about substrate vibration because this an area of growing interest to the aquatic community; and we asked Wei Qiu to talk about the applicability of kurtosis in assessing impacts of sound on animals. At earlier meetings, we had William Yost give a general overview of psychoacoustics and Colleen Le Prell discuss the latest findings on the effects of noise on human hearing and health. Many other colleagues have joined us in keynotes. These presentations and messages have resonated with attendees and have influenced the work and thinking of many.

By all accounts, AN2007 was a total success (Fig. 3). The "reviews" were excellent, and there was a clear interest in having another meeting. So, we started to think about another meeting.

**Fig. 3** Participants at the Nyborg, Denmark, meeting. This is the only meeting for which we have a photo of most participants

## Aquatic Noise 2010 (AN2010): The Second Meeting, Cork, Ireland

When we decided to have a second meeting (Fig. 4), we, of course, asked Magnus to work with us. But other obligations kept him from participating. So, we started out on our own, with the intent of developing an organizing group once we figured out where the meeting would take place.

In considering locations, the cost for participants and for holding the meeting was paramount to our thinking. But we also wanted to keep our goals in mind about meeting in a place that included conference rooms, hotel rooms, and a locale that was interesting. To help in our planning, we devised a set of additional specific criteria for site selection. These included:

- Easy access for international travelers, especially from the United States and Europe. Our preference was no more than one change in conveyance to get to the meeting city.
- Conference space and facilities for 200+ delegates, with poster display space. (In fact, due to an increase in size of the meetings, we now require space for at least 300.)
- Two meeting hotels for delegates, if possible. Most delegates would stay at the main meeting hotel, but we would also try to have a second hotel at a lower price for delegates for whom cost is a major issue.
- Accommodations to be at the meeting hotel and within easy walking distance of the town center to allow delegates to access areas of interest.
- Dates in July or August. Based on our survey from Cork, these seemed to be the most preferred times for the meeting for most delegates.

### Finding a Conference Organizer

We initially thought it would be good to hold the meeting in Scotland, and Susan Hawkins thus contacted Visit Scotland. They were very keen to be helpful, but the

**Fig. 4** Cork logo

only facilities that met our criteria, including time in the summer, were in Edinburgh and surrounding regions. Because our dates corresponded with the Edinburgh Festival, no facilities were available. The other places offered to us were golf resorts in the beautiful countryside but miles from any town, making transportation difficult, especially for accompanying families who might like to sightsee and travel around.

Visit Scotland then suggested that we consider the Republic of Ireland and gave Susan the contact details of the Irish Tourist Board. This group advised that we consider working with the conference organizing group Venues Ireland, a part of Venues World and, in particular, with Terri Cullinane.

Venues Ireland was incredibly welcoming and helpful and suggested that either Dublin or Cork should be able to meet our requirements. After considering our dates and needs, Terri specifically suggested we consider meeting in the city of Cork, in County Cork. Because Susan was more familiar with Cork, she decided that we should focus on it.

Thus, we concluded that we should look for locales in Cork because we anticipated reasonable costs. To make a final decision on meeting location, Tony and Sue Hawkins and Art and Helen Popper visited various hotels in Cork with Terri. Terri also took us around the County Cork region to show us places attendees could visit and how she could arrange tours and places for our banquet (Figs. 1 and 5). We even

**Fig. 5** Cork Banquet at the Jameson Brewery (also see Fig. 1)

got to meet Terri's parents and had a lovely several hours with them. We selected the Clarion Hotel Cork as our main meeting hotel.

Besides helping us pick and have Aquatic Noise 2010 (AN2010) in Cork, the decision to work with Terri may have been the most important single thing we did to ensure the quality of the Cork meeting and also the quality of future meetings. Indeed, Venues World took (and still takes) responsibility for everything from organizing our website to registering participants to collecting meeting registration to keeping our budget. Thus, the organizers can focus on meeting content, while Terri and her group ensure that everything works and that every attendee's needs are met.

## The Meeting

By the time we started to organize Aquatic Noise 2010, soliciting participants was far easier than in 2007. First, we had our participant list from 2007. But, equally importantly, the earlier meeting had been enough of a "hit" that when we announced Cork, people immediately made plans to attend and present.

We did decide to be a bit more formal, with an organizing group for the Cork meeting. Although the two of us did much of the overall organization, the organizing group was instrumental in helping design the program, soliciting speakers, and helping in a myriad of other ways. A list of organizers is in Table 2, while Table 1 has the links to the meeting programs that list all the people who helped with all the meetings.

Of course, we needed funding to hold the meeting, and we returned to the same groups that funded us in 2007. We received funds from most of those agencies but also funding from several other US agencies.

We also started to solicit support for specific parts of the conference from smaller organizations and companies, and this has turned out to be a substantial help in support of students and filling "niches" for things for which we could not get funds, such as paying for name badges, conference bags, and nicer coffee breaks. (These companies are listed in the program books; see Table 1 for the links.)

The organizing committee decided to require that all presenters do a chapter for the conference proceedings. We talked with several publishers and chose to work with Springer (now Springer Nature) because Art had a long history of working with them on other books and they were the most willing to produce the kind of volume we wanted. Most every presenter submitted a chapter. The chapters were meticulously edited by Helen Popper, a professional scientific editor, and the book was published as Popper and Hawkins (2012).

Every contributor received a copy of the book, as did our funders. Indeed, our insistence on a substantial publication from the meetings has been of major importance to many of our funders and has helped us get substantial support because there is a clear outcome from the meeting.

## Aquatic Noise 2013: The Third Meeting, Budapest, Hungary (Fig. 6)

### Finding the Location

With the success of the first two meetings, we started to think of Aquatic Noise as a triennial conference. Our thinking was that doing a meeting every year or every other year was just too much work for us and the meetings might be too close together to generate new material.

For this meeting, we again turned to Terri to get her thoughts on potential sites. She came up with several cities in Europe and found hotels in each that had the potential to hold the meeting. In addition to having our general criteria for meeting sites, one main hotel with conference and bedroom facilities in an interesting place, we added a request that most attendees should be able to get to the meeting with no more than one change in major transportation (e.g., one airport transfer).

After considering each of the locales, we eliminated some due to high costs, high summer temperatures, and other factors. We then decided that we would look at hotels in Prague and Budapest. Helen and Art Popper, Sue and Tony Hawkins, and Terri Cullinane visited both sites. One hotel in Prague was too far from the center of town and had no warmth; the second hotel was too expensive. Helen then remembered a hotel that the Poppers had stayed in that was in the old part of the city. Terri quickly arranged for us to see the hotel, and it was an instant hit. It had great meeting space and a meeting area that had spectacular views of the Old City. Indeed, this could easily have been our choice for the meeting, but the hotel refused to lower rates enough to make a meeting viable.

We then went to Budapest and looked at two spectacular hotels, one on the Buda side of the Danube and the other on the Pest side. We decided to go with the Corinthia in Pest because it was downtown and closer to restaurants and other venues. It also gave us rates that we felt were fair both for sleeping rooms and for the meeting. Importantly, the conference facilities were unsurpassed, providing a venue with style and gravitas yet with state-of-the-art facilities.

The hotel was a major "hit" with participants. Indeed, it has become the "benchmark" for all meeting sites since. The hotel was truly lovely, the sleeping rooms were

**Fig. 6** Budapest logo

**Fig. 7** Budapest plenary room. This was, by far, the most magnificent meeting room that we have ever had for an Aquatic Noise meeting

outstanding, and the main meeting room was perhaps the most magnificent that many participants had ever seen (Fig. 7). Delegates, thanks to participant Darlene Ketten, "discovered" the attached restaurant, the Bock Bistro, and made it a favorite during the meeting for its great Hungarian food and spectacular wine list.

## The Meeting

For this meeting, we decided to try to formalize the organizing group to provide more continuity and "corporate memory" to the planning process (Table 2). Funding for the meeting, which covered much of the support provided, again included the US National Science Foundation, several branches of the US Navy, and a myriad of smaller agencies and companies. Of the delegates, 49 students and postdocs received full or close to full support for travel, hotel, and registration. An additional 39 delegates received partial support.

Once again, all delegates were asked to contribute chapters to a volume published by Springer (Popper and Hawkins 2016). The volume was again edited by Helen Popper. It is worth noting that, as of this writing, chapters from the volumes from Cork and Budapest have been viewed over one million times, suggesting that the meetings, through the books, have likely had an extraordinary impact on the field.

## Aquatic Noise 2016: The Fourth Meeting, Dublin, Ireland

The organizing group for the 2016 (Fig. 8) meeting included the Art and Tony along with Christine Erbe, Joe Sisneros, and Frank Thomsen. Christine served as the nominal chair of the organizing committee, and she did a superlative job in moving us forward. We also started to formalize our approach to membership on the organizing committee by trying to diversify the disciplines and home countries of the participants.

We started to search for a venue for the 2016 meeting in 2014. Again, Terri came up with a list of suggested places that we winnowed down to Amsterdam, Den Haag, and Dublin. Art, Tony, Christine, and Terri visited the three sites. Our first visit was in Den Haag, and we fell instantly "in love" with the Grand Hotel Amrâth Kurhaus, and it wound up being the site of the 2019 meeting. However, the prices at this hotel for the 2016 meeting were somewhat higher than we wanted to pay. We visited several other venues in Den Haag, none of which offered the ambience we wanted. One of the sites was a conference hall that would have been good for the meeting, but delegates would have been spread over many hotels. In considering this site, we focused on our interest in keeping most delegates together as much as possible, and this site only reinforced that view.

We then went on to Amsterdam and visited several hotels. We were quite tempted by one hotel that told us that we could have use of the room where John Lennon and Yoko Ono stayed on their honeymoon and that it still had a Lennon guitar made it very tempting (and exciting). The hotel would have been great in many ways, but the management was not very accomodate.

We then went off to Dublin where Terri showed us the O'Callaghan Alexander Hotel, and we quickly decided that it was a great place to meet. We did look at several other places, but none had the same appeal in either facilities or location. During that visit, we also had the pleasure of meeting and getting to know Terri's husband John Burke, the co-owner of Venues World.

## The Meeting

A description of the meeting (Fig. 8) was published (Erbe et al. 2016) in Volume 27 of the *Proceedings on Meeting in Acoustics* (*POMA*), along with a large number

**Fig. 8** Dublin logo

of other papers. All the papers are open access. However, unlike the previous three meetings where we made submitting a paper to the meeting proceedings a requirement for all delegates, we only required this of people we funded to attend, although we did encourage others to submit as well. In fact, in hindsight, this approach did not achieve our goal of having meeting proceedings published. We tried a somewhat different approach in 2019 (see section "The Meeting"), but for the Berlin meeting, we again required papers be submitted for publication.

### Rodney Coates Student Award

We added a new piece to this meeting. One of the delegates at our first meetings was Rodney Coates. Rodney was particularly interested in seeing the success of younger attendees. However, he passed away in 2016 before the Dublin meeting. His family wanted to support Rodney's interests, and so they provided generous support, in his honor, for an award to the best student presentation. The Rodney Coates Student Award, still supported by his family, is now a strong tradition of the Aquatic Noise meetings.

In thinking about this award, we decided (with input from the Coates family) that every student or recent graduate could, if they wished, compete for the cash prize. However, we did not want judging solely based on posters, and we could not accommodate every student for a 15-min oral presentation. So we decided that candidates for the award would give a 4-min lightening (speed) talk and do a poster. We developed a rubric for judging so that every candidate would be evaluated in the same way, and we invited several senior delegates to judge the candidates and decide on the winner.

## Aquatic Noise 2019: The Fifth Meeting, Den Haag, The Netherlands

In considering the 2019 meeting (Fig. 9), Terri revisited the idea of using the Grand Hotel Amrâth Kurhaus in Den Haag, and this time, we were able to work out costs that would be fair to delegates and meet our budgetary needs. So, without looking anywhere else, Aquatic Noise 2019 went to The Netherlands.

Den Haag also had several features that made it appealing for our meeting, including being easily accessible from anywhere in the world (via a brief train ride from Amsterdam Schiphol International Airport). In addition, the village of Kurhaus, which is close to Den Haag, met all the requirements for our meeting. There were ample opportunities for evening outings at the end of a busy day at the conference, daytime activities for accompanying persons, and vacation destinations for families.

The organizing committee grew again. Our 2016 group of Art, Tony, Christine, Joe, and Frank was joined by Paul Lepper. We were able to get substantial funding from our regular contributors as well as from several new contributors and so were

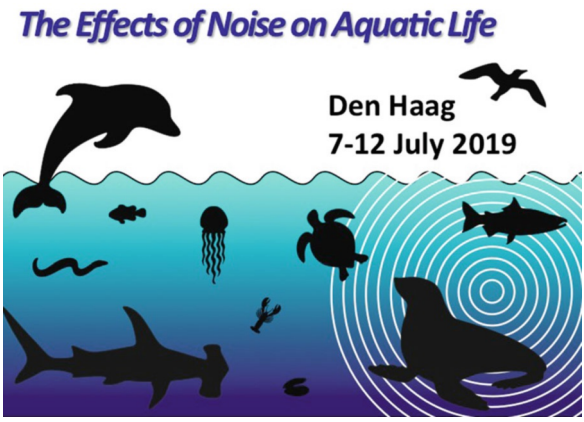

**Fig. 9** Den Haag logo

able to support the attendance of almost 100 delegates, most of whom were students or recent students.

### The Meeting

An overview of the meeting was published by Erbe et al. (2019). One of the issues that we encountered in the 2016 publication was that many presenters were reluctant to publish their work in *POMA*, a nonrefereed journal. So, through collaboration with the ASA, a strong supporter of the Aquatic Noise meetings from their inception to today, we worked out an arrangement whereby either delegates could publish in a special issue of *POMA* (https://asa.scitation.org/toc/pma/37/1) or they could submit papers for a special issue of *The Journal of the Acoustical Society of America* (https://asa.scitation.org/topic/special-collections/aqn2020?SeriesKey=jas) (see Thomsen et al. 2020).

## Aquatic Noise 2022: The Sixth Meeting, Berlin, Germany

Aquatic Noise 2022 (Fig. 10) proved to be a challenge due to the COVID-19 pandemic. We decided on a location and hotel before the start of the pandemic, but once the pandemic started, we were not confident that we could actually hold the meeting until early 2022. Indeed, we were greatly concerned about financial issues because we had financial obligations to the hotel and other groups that had to be booked in advance.

We spent most of a year planning and worrying about whether to hold the meeting or not. We decided that we did not want a virtual meeting because so much of a focus of Aquatic Noise is the opportunity for meeting people and networking. Moreover, a virtual meeting would have been very difficult to manage even if we focused on participants from Europe and the United States alone (something we did not want to do), and the up to 9-h time difference from the west coast of the United States to Europe would make scheduling of sessions very difficult.

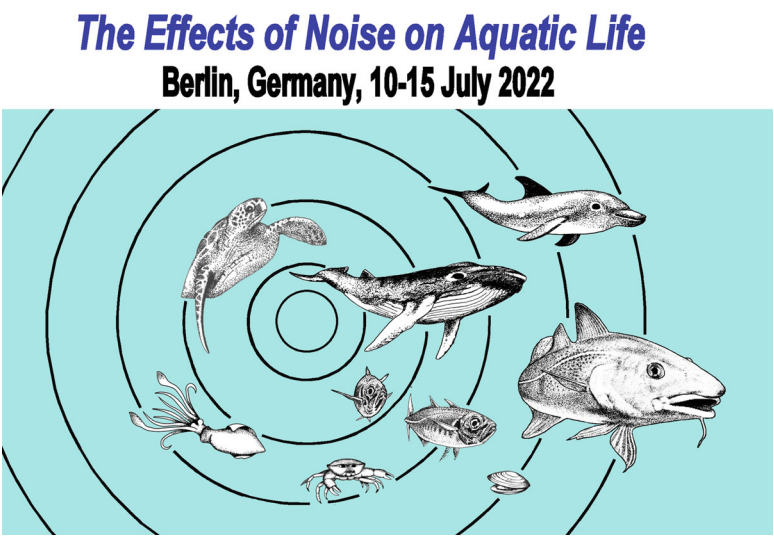

**Fig. 10** Some presenters at the Den Haag meeting

Thus, as the pandemic eased, we decided to hold the meeting, but we still had considerable concerns about whether people would register and come. To our delight, delegates were eager to attend in person, and although we did not have the same number of participants as in the past few meetings (Table 1), we still had 248 attendees.

One of the big changes for this meeting was in the function of the organizing group. Whereas in the past, the two of us were engaged in almost every detail of planning, we were less involved this time. We did stay on the organizing group, and we added Amy Scholik-Schlomer as a new organizer. Our friend Frank Thomsen took over as leader and did a brilliant job in moving us forward, particularly rising to the occasion in the face of the pandemic. And, of course, Terri and Venues World continued to be integral to the meeting.

Despite the problematic circumstances, Aquatic Noise 2022 turned out as much as a success as its predecessors. The scientific program was praised for its high quality and diversity of topics, including studies on lesser known taxa such as turtles, birds, invertebrates, and even seagrass. The participants seemed to be eager to interact in person again, and discussions were lively and engaged. Many participants made use of the many attractions and cultural events Berlin has to offer.

## The Future

As stated earlier, we anticipate that our involvement in Aquatic Noise will be minimal (if it exists at all) for any future meetings. However, we leave the future in excellent hands, with colleagues (and friends) who understand the discipline, appreciate deeply the value that the meetings hold, and appreciate the history and traditions of the meetings.

## Why No Meeting in North America?

But before making some recommendations, we want to answer a question that is often asked of us; why have the meetings been only in Europe and not in North America, especially considering the number of delegates from the United States and Canada. In fact, for almost every meeting, we have looked at various locations in the United States and Canada, but several factors have worked against these locations. When we found a city that met our travel expectations of reasonable access, hotel prices in the summer were far higher than in Europe, and hotels were not willing to make commitments to us 2 years in advance about rates. Indeed, we found a very suitable location in Baltimore, Maryland, for the 2019 meeting, but after several conversations, they would not commit to even holding rooms for us very far in advance.

Then, when we found places at reasonable cost, these were in locations that were hard to get to. For example, we found a great location in Canada and another in Maine, but getting to both would have taken three or four flight connections from Europe and often even several within the United States. Thus, for economic and practical reasons, Europe is still the most reasonably priced and accessible location. Hopefully this will change, and we encourage the organizers to consider the United States or Canada in the future.

## Our Recommendations

In closing, we do want to make several recommendations to the future organizers.

First, maintain the goals and principles on which we founded the meetings (and as discussed in section "Thinking About a Meeting"). We feel that these ideas have served us well and helped ensure that the meetings serve the community in very useful ways.

Second, in addition addition to focusing on support for younger colleagues, we feel strongly that an additional, equally important, focus of the meetings should be to reach out to groups who have not been well represented at our meetings, groups that in the United States are often referred to as underrepresented.

There are such groups in many countries, and ways need to be found to bring some of them to the meeting. Considering the breadth of the meetings, and the importance of the topic, it should be possible to use the meetings to excite young people from underrepresented groups to consider science and technology as career options and perhaps even set them on a path to such careers. So, our idea is that the focus not necessarily be on people already in the fields covered by the meetings, but the on "next generation," those students currently in university who are thinking about careers and who might be responsive to coming to the meetings, meeting with the participants, and being mentored by them.

We strongly support the idea of a publication from every meeting. And, after both requiring papers and only inviting them, we suggest that requiring papers provides the most value to the meetings and to our funders.

Finally, when we started the meetings, we were later in our careers and close to "retirement." Thus, we were able to find considerable time to handle much of the work associated with the meeting without impacting our other obligations.

However, the mantle of organization has passed to a younger generation who have substantial obligations to work, young families, students, and others, all of whom deserve a great deal of time. Thus, this generation of organizers, and we suspect organizers in the future, might need some more formal help in keeping the meetings going. We therefore suggest considering getting assistance from a part-time conference manager to work with the organizers to maintain to do a myriad of things, from communicating with potential participants to keeping databases to managing meeting finances. Such an arrangement would allow the organizers to focus on the content of the meetings and ensure that the high standards of past meetings continue.

**Acknowledgments** The Aquatic Noise meetings could not have taken place had we not had a cadre of extraordinary colleagues collaborating with us. We have mentioned many in this chapter, and we thank them all for their collaboration and for their friendship. We also thank the many people who have been on our advisory groups for their participation and advice.

We are also deeply grateful to the organizations and companies that have funded the meetings. In particular, we thank the leadership in many of these organizations, many of whom have become engaged with the meetings, who have assured us of continued support, and who work hard to ensure that we get their financial support on time. We apologize for not mentioning names, but those we refer to know who they are.

Finally, but most importantly, we thank Helen Popper and Susan Hawkins, not only for allowing us the adventures of conference organization but for being partners in developing and planning the meetings. Sue and Helen did not present papers, and we doubt they ever heard a single talk. But, their "fingerprints" are all over the meetings, and they were responsible for much of the "extras" that made the meetings so special. We also thank Helen for editing this chapter and Sue for providing a number of important memories.

**Abstract**

The effects of anthropogenic underwater sound on aquatic and marine life are an important environmental topic that has expanded considerably over the past decades. Since the first meeting in Nyborg, Denmark, in 2007. The Effects of Noise on Aquatic Life (AN) has emerged as a distinctive conference on this topic by bringing together experts from a variety of scientific fields, as well as those from the regulatory and industry communities.

**Keywords**

Sound · Noise · Marine mammals · Fishes · Invertebrates · International conference

## Introduction

The Effects of Noise on Aquatic Life (AN) conference in Berlin, Germany, in 2022 marked the 15th anniversary since the inaugural conference held in Nyborg, Denmark, in 2007 (Table 1). With this anniversary, it is an opportunity to discuss the evolution of AN, in terms of how the numbers of taxa and sound sources have changed, how international participation has expanded, and how these changes reflect the scientific advancement of the subject of aquatic noise over the past 15 years.

## Authorship and International Participation

The intent of AN has always been to offer a forum for scientists, regulators, industry, conservation groups, and others interested in this topic from across the globe to discuss and learn about the potential impacts of noise on marine life. Using the nationality of first authors as a surrogate means to gauge international participation over AN's 15-year history illustrates changing trends in participation (Fig. 1). For example, participants from the United States heavily dominated the earlier AN conferences (e.g., up to 51% in Cork 2010). However, over time, this has reduced

**Table 1** Locations and dates of past Aquatic Noise conferences

| Conference location | Date |
|---|---|
| Nyborg, Denmark | 2007 |
| Cork, Ireland | 2010 |
| Budapest, Hungary | 2013 |
| Dublin, Ireland | 2016 |
| Den Haag, the Netherlands | 2019 |
| Berlin, Germany | 2022 |

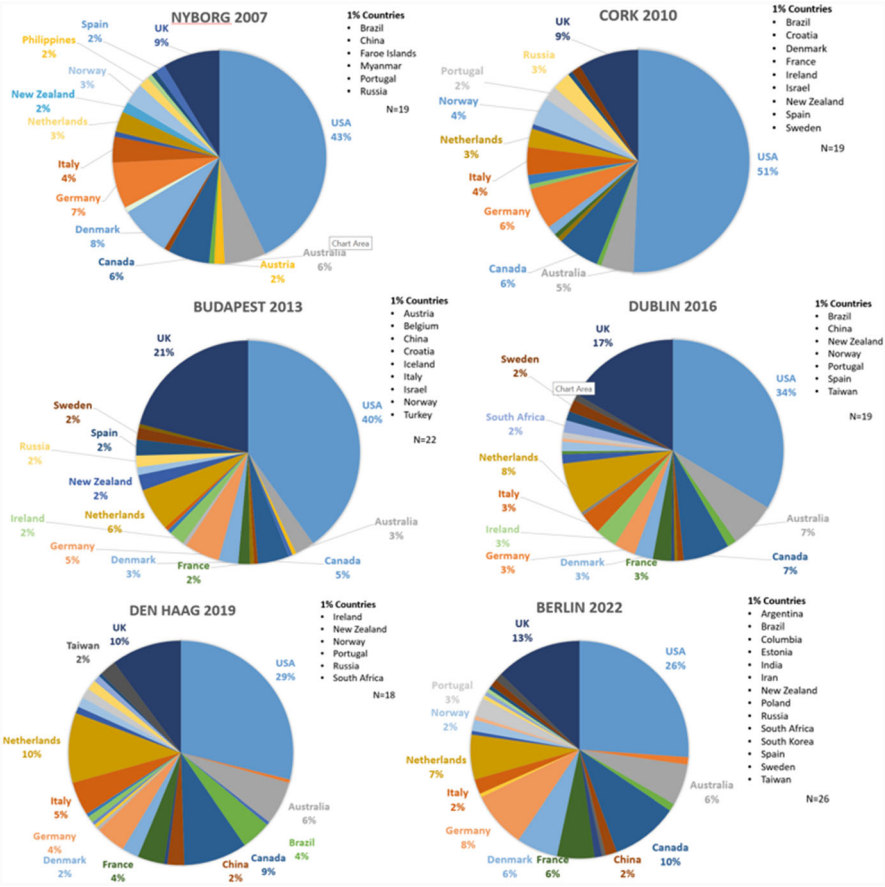

**Fig. 1** First-author participant by country over the 15-year history of Aquatic Noise showing countries with ≥2% participation. Countries with 1% participation are listed beside the corresponding pie graph. N indicates the total number of different countries for each conference

(e.g., 26% in Berlin 2022), and there has been a higher proportion of authorship (i.e., participation) from other countries.

Throughout AN's history, there has continually been a strong contingency of participants from North America (i.e., the United States and Canada), Europe (in particular, the United Kingdom, the Netherlands, and Germany), and Australia (Figs. 1 and 2). Additionally, overall the number of countries of first authors has gradually increased from Nyborg 2007 (n = 19) to Berlin 2022 (n = 26). However, participation from those in South America, Africa, and Asia notably lags behind. Whether this is because of other competing Asia- or Africa-specific bioacoustic conferences (e.g., Oceanoise Asia symposium or African Bioacoustics Community conference) or other reasons remains unclear. One notable reason may be financial. Thus, the preponderance of AN's funding has gone to support participation of students and of representatives from emergent countries. A recent review article (Becker et al. 2022) found that, at least in Africa,

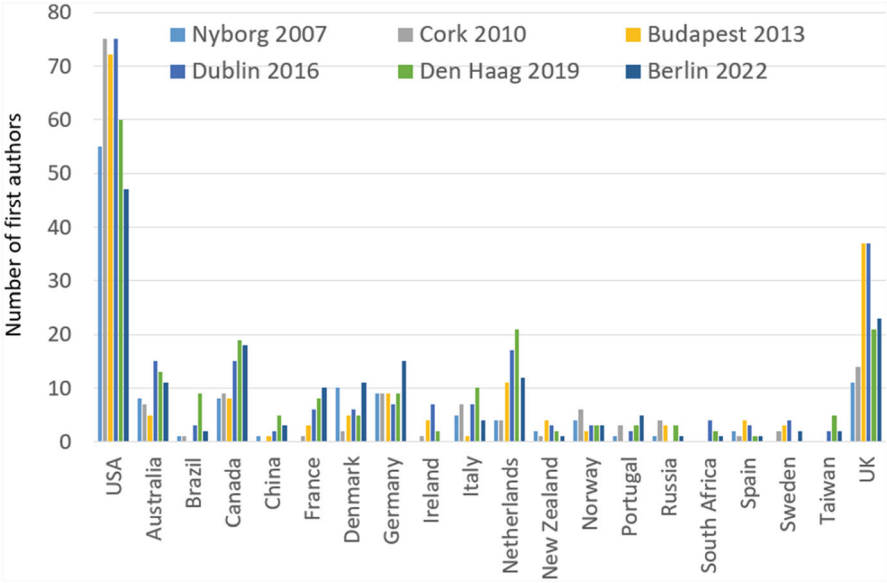

**Fig. 2** First authorship by top 20 countries over Aquatic Noise's 15-year history

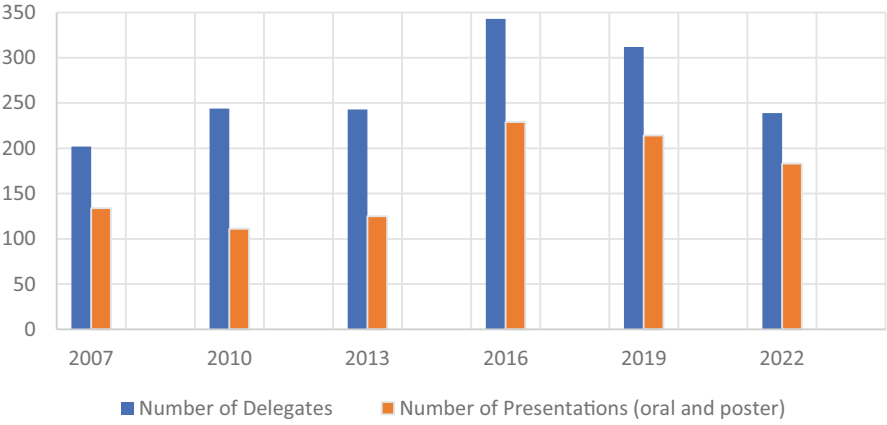

**Fig. 3** Statistics on number of delegates and presentations throughout Aquatic Noise's 15-year history

most bioacoustic research focuses on the terrestrial species, rather than aquatic or marine species, and that the majority of authors on these publications do not have African affiliations. Thus, there is an opportunity for the expansion of aquatic- and marine-focused bioacoustic research globally. Enhancing further international and diverse participation is a goal for future AN conferences.

Furthermore, the number of overall delegates and presentations has steadily increased from the first three conferences to the more recent conferences (Dublin 2016 and Den Haag 2019) (Fig. 3). There is a noticeable decrease in the number of

delegates and a slight drop in the number of presentations with the most recent conference in Berlin 2022, likely due to remaining concerns over COVID-19. Nevertheless, each of the AN conferences have sustained over 200 delegates and as many presentations since Dublin 2016.

## Taxa

The origins of early interest in the potential impacts of underwater noise on marine species date back to the early 1970s (Payne and Webb 1971). Momentum increased in the 1990s and 2000s with the Acoustic Thermometry of Ocean Climate (ATOC) program, North Pacific Acoustic Laboratory (NPAL) source, and the Heard Island Feasibility Test and the potential negative impacts particularly on marine mammals (e.g., Bowles et al. 1994; Au et al. 1997; Costa et al. 2003; Mobley 2005). Thus, while early studies may have focused on marine mammals, there has been increasing interest in understanding the effects of noise on other taxa such as fishes and invertebrates (Hawkins and Hawkins and Popper 2016; Popper et al. 2022).

Throughout AN's 15-year history, the number of taxa studied has increased. While marine mammal presentations, especially on cetaceans, dominated earlier conferences, the most recent conference in Berlin 2022 saw fishes being the dominant taxa in the overall number of presentations (Fig. 4). Presentations on invertebrates have also steadily increased over the years, especially since Budapest 2013, with a slight decrease for Berlin 2022. Marine bird species and sea turtles remain taxa with minimum representation in the conference program (< 5 presentations per conference). It is also interesting to see that later AN conferences included talks on plankton (since Dublin 2016), and the most recent conference in Berlin 2022 included a talk on the impacts of noise to seagrasses posidonia is impaired by human-generated noise.

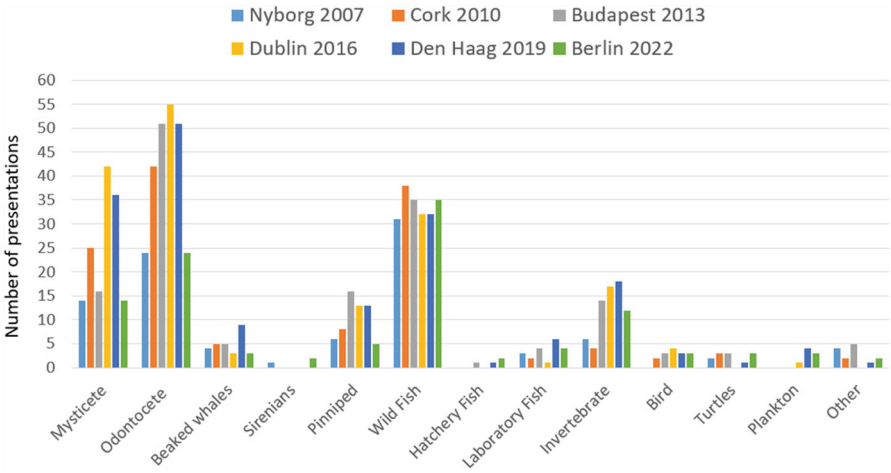

**Fig. 4** Statistics on the number of papers by taxa throughout Aquatic Noise's 15-year history

**Fig. 5** Evolution of Aquatic Noise logos (AN2007, 2010, 2013, 2016, and 2022 created by Anthony D. Hawkins; AN2019 created by Christine Erbe)

The logo over the years also reflects the expansion of a greater variety of taxa included in AN presentations (Fig. 5). The Nyborg 2010 logo only included a marine mammal, sea turtle, and fish, while AN 2019 and 2022 expanded to include numerous species of invertebrates.

The conference's evolution reflects a similar analysis published by Duarte et al. 2021. During their literature review (1973–2020), Duarte et al. 2021 reported on distribution of scientific studies by taxa, where odontocetes dominated, followed by fishes, mysticetes, invertebrates, pinnipeds, and sirenians (Duarte et al. 2021, indicated "a paucity of quantitative assessments for diving marine reptiles and seabirds"). In hindsight, with this AN analysis, it would have been useful to separate out harbor porpoise from other odontocetes, since this is one of the primary odontocetes studied in Europe and represents many of the presentations at AN (e.g., Tougaard et al. 2016; Wensveen et al. 2016; Schaffeld et al. 2020).

Finally, it is interesting to highlight the "other" category in Fig. 4, which has included past poster and oral presentations on the fishing cat (Malla et al. 2019), amphibians (e.g., Tennessen et al. 2016), sea otters (e.g., Ghoul and Reichmuth 2012), and humans Underwater Hearing and Noise Exposure Concerns in Humans.

## Sound Sources

Early attention to anthropogenic underwater sounds, especially from a management perspective, was primarily on those sources associated with serious acute impacts. Some examples include mortality associated with events, such as with certain

situations of beaked whale stranding and tactical sonar (e.g., Simmonds and Lopez-Jurado 1991; Cox et al. 2006; D'Amico et al. 2009) or fish barotrauma associated with coastal pile driving (summarized in Popper et al. 2019; Caltrans 2020). With this focus came the development of various acoustic criteria via scientific publications (e.g., Popper et al. 2014; Southall et al. 2019) and other management directives (e.g., Tasker et al. 2010; BfN 2012). Over time, the spotlight at AN has shifted from beyond acute noise sources to those that are capable of causing sublethal, chronic impacts, like commercial shipping.

Again, this AN 15-year analysis reflects the Duarte et al. 2021, literature review, in terms of the overall distribution of studies by sound source, with vessels (small and large) being a dominating sound source, followed by synthetic sound sources (e.g., laboratory-created tones and other signals), seismic air guns, sonar, and wind- and non-wind-related pile drivers (Fig. 6). With the AN conferences, there has been a steady increase over the years on papers especially related to large vessels, as well as presentations related to ambient noise. These increases are likely to also reflect the recent evolution of science that is now focusing more on chronic sources of noise, rather than noise that is typically more acute (e.g., tactical sonar, pile driving, and seismic air guns; although, it is important to point out that there is a peak in seismic presentations in Den Haag 2016, which likely reflects the special workshop on modeling seismic air guns held after the conference (Halvorsen et al. 2019).

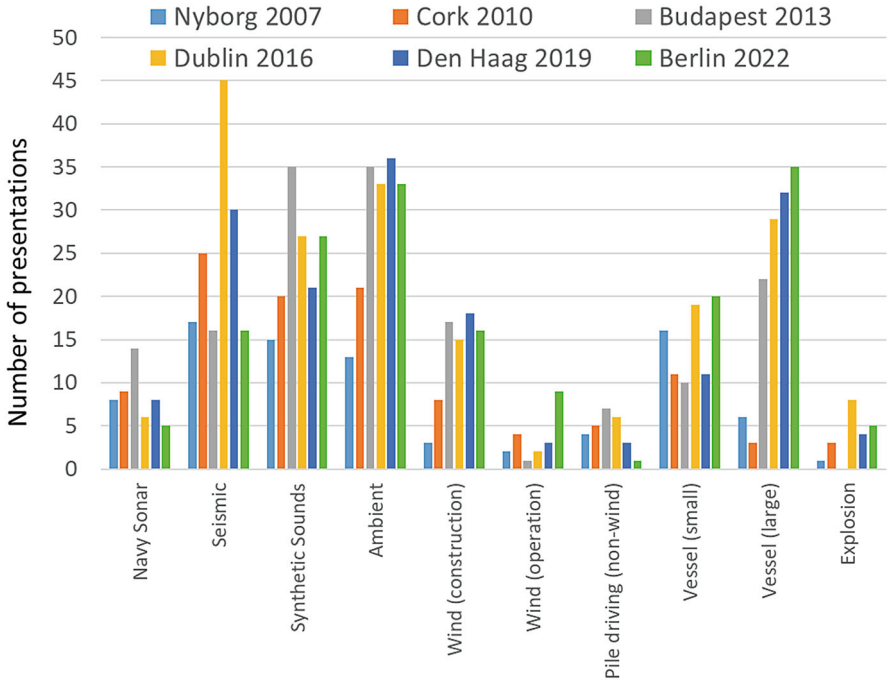

**Fig. 6** Statistics on the number of papers by sound source throughout Aquatic Noise's 15-year history

Specifically, in recent decades, there has been an effort to focus on broad-scale, long-term ambient noise measurements in Europe (e.g., Joint Monitoring Programme for Ambient Noise in the North Sea, https://northsearegion.eu/jomopans/; Joint Framework for Ocean Noise in the Atlantic Seas, https://www.jonasproject.eu/; The Baltic Marine Environment Protection Commission, https://helcom.fi/action-areas/marine-litter-and-noise/underwater-noise/; EU Interreg Italy-Croatia SOUNDSCAPE project, https://www.italy-croatia.eu/web/soundscape) and the United States (e.g., National Oceanic and Atmospheric Administration [NOAA]/National Park Service Ocean Noise Reference Station Network, https://www.pmel.noaa.gov/acoustics/noaanps-ocean-noise-reference-station-network; NOAA/US Navy SanctSound project, https://sanctuaries.noaa.gov/science/monitoring/sound/).

With offshore wind development increasing worldwide, presentations related to pile driving and wind farms have remained steady though AN's 15-year history. There was, however, a noticeable uptick in interest related to sound produced from operational wind farms that represents another form of chronic noise at the most recent conference in Berlin 2022. Interestingly, presentations on coastal pile driving (non-wind farm) have decreased since Budapest 2013.

Furthermore, other special topics, such as substrate vibration, particle motion, and kurtosis (Popper and Hawkins 2018; Müller et al. 2020; Hawkins et al. 2021) have steadily increased over AN's past 15 years, reflecting the increase in awareness and understanding of these topics especially to marine species (Fig. 7).

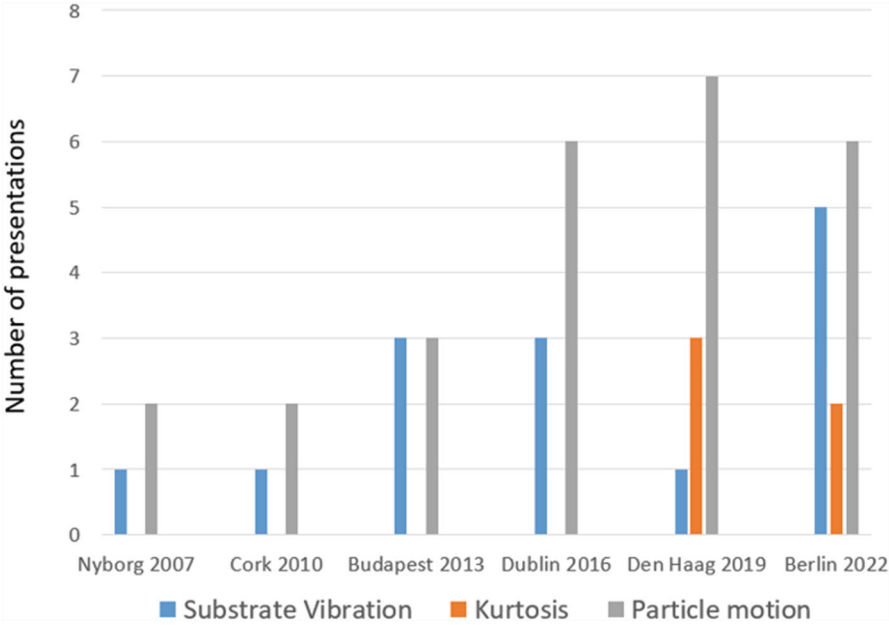

**Fig. 7** Statistics on the number of papers by special topic throughout Aquatic Noise's 15-year history

Kurtosis and substrate vibration even featured as keynote talks during the most recent conference in Berlin 2022. The Value of a Kurtosis Metric in the evaluation of Noise-induced Hearing Loss and Shaking up aquatic substrates: Taking lessons from biotremology

## Some Things Never Change

Despite the many aspects of AN that have changed and evolved over the past 15 years, some things have remained the same. For one, AN has been known for its scientific program, which has reflected the evolution of the science of this topic. Furthermore, the conference has not only focused on the science behind the issue of aquatic and marine noise but is one of the very few conferences that welcomes those from the regulatory, industry, and environmental communities to not only attend but also participate in presenting talks and posters. This valuable exchange between scientists and decision-makers is a unique feature of AN. Finally, AN encourages participation by students and postdoctoral researchers (and supports many of them financially), and in its very design, the meeting encourages networking between participants from all disciplines.

Furthermore, one of AN's strengths has been to have only one session at a time. This allows all participants to hear everyone's presentations and remain in the same room together to maintain the collaborative nature of talking and learning from one another before and after presentations. Again, this allows for a fruitful exchange between all disciplines ranging from underwater acoustics to animal physiology to regulation (Thomsen et al. 2020).

Finally, the unyielding support and effort by the conference's founding fathers Arthur Popper and Anthony Hawkins over the years have enabled AN to become one of the primary international conferences on the topic of underwater noise and aquatic and marine species. Today, AN is a conference many look forward to attending every 3 years. It will be interesting to see how AN evolves over the next 15 years.

**Acknowledgments** Many thanks goes to all the past Advisory Committee members who contributed to AN's continued strong scientific program throughout the years (in alphabetical order): Mathias Andersson, Michael Ainslie, Elizabeth Burkhard, Tom Carlson, Ben Colbert, Douglas Cato, Peter Cott, John Dalen, René Dekeling, Sarah Dolman, Rebecca Dunlop, Olga Filatova, Roger Gentry, Giacomo Giorli, Robert Gisiner, Mary Gray, Bruce Hanna, Vincent Janik, Craig Johnson, Ron Kastelein, Darlene Ketten, Anu Kumar, Christine Lamont, William Lang, Jill Lewandowski, Songhai Li, Klaus Lucke, Peter Madsen, David Mann, Nathan Merchant, Jennifer Miksis-Olds, Jim Miller, Lee Miller, Mirjam Müller, Sophie Nedelec, Michael Noad, Eric Parmentier, Marta Picciulin, Stephanie Plön, Roberto Racca, Vanesa Reyes, Denise Risch, Louise Roberts, Amy Scholik-Schlomer, Gail Scowcroft, Hans Slabbekoorn, Brandon Southall, Erica Staaterman, Jenni Stanley, Michael Stocker, Bill Streever, Alexander Supin, Mark Tasker, Jakob Tougaard, Sofie Van Parijs, Kathy Vigness-Raposa, Sander von Benda Beckmann, Magnus Wahlberg, Michael Weise, Jürgen Weissenberger, and Lidia Wysocki.

**Abstract**

The "Effects of Noise on Aquatic Life" conference took place in Berlin, Germany, in July 2022, and the presentations have been revised to become the chapters for this book. The conference considered potential effects of anthropogenic sounds on aquatic species that ranged from whales, dolphins, seals, turtles, marine birds, fishes, and lesser-known taxa including zooplankton, mollusks, and seagrasses. It also considered the sources of the noises that might impact aquatic life and brought together researchers, regulators, industry, and environmental groups to consider, together, the potential impact of man-made sounds on aquatic life. Indeed, the meeting, as reflected in this book, brought together individuals and the latest ideas from a great variety of disciplines, ranging from biologists interested in behavioral and physiological effects of exposure to sound, to acousticians and engineers with an interest in the physics of underwater sound generation, to regulators and conservations groups concerned with the protection of aquatic life. Sessions at the meeting, as reflected in this book, included the measurement and management of underwater noise, an overview of the critical environmental issues related to offshore wind development as alternative sources of energy, and descriptions of changing soundscapes around the world. A social program was designed to encourage more leisurely discussions among the conference participants in order to facilitate networking and the strengthening of relationships among participants from academia, industry, and regulation. The feedback from conference delegates was very positive.

## Introduction

6th International Conference on the Effects of Noise on Aquatic Life

Berlin, Germany
10-15 July 2022

Meeting Overview: AN2022

Research on the potential impacts of underwater sound on aquatic life is challenging. New technological developments are taking place within the offshore industry, especially with respect to offshore wind development. Those concerned with assessing the impact of anthropogenic sounds on aquatic organisms are investigating the biology, physiology, and ecology of species not readily examined in the laboratory and often must develop new methods that can be applied to free-living animals in the sea itself. Since the issues are complex and cross lines between many disciplines that often meet separately, it becomes imperative to bring everyone together to consider the broad issues on the potential effects of underwater sound on aquatic life. In order to best tackle the issues, it is imperative to include scientists from a variety of disciplines, ranging from acousticians with an interest in the physics of underwater sound generation to biologists interested in physiological and behavioral effects of sound exposure. It is necessary for scientists and engineers to communicate effectively with one another on these topics, although they have often had difficulties understanding one another in the past and limited opportunities to network and discuss these issues with each other. Moreover, since the issues raised are significantly related to the protection of species and other environmental concerns, any discussion must also include colleagues from diverse areas such as regulators, environmental groups, industry, and other areas so that all share ideas and learn from one another.

To continue to raise and explore relevant issues, the "Sixth International Conference on the Effects of Noise on Aquatic Life" in July 2022 (AN2022) was convened in Berlin, Germany, to bring together scientists, regulators, and representatives from industry and environmental groups for formal presentations on the effects of anthropogenic sounds on aquatic life and numerous informal opportunities to "network." *The papers presented at that meeting are the basis for the chapters in this book.*

The meeting, as with past Aquatic Noise (AN) conferences (Erbe et al. 2019; Erbe et al. 2016; Popper and Hawkins 2016; Popper and Hawkins 2012; Hawkins et al. 2008), provided extensive opportunities for participants to learn about the effects of noise on aquatic life and the opportunity to interact with people, who focus on different taxa, different sound sources, and different approaches to understanding issues of unwanted sound and its mitigation to protect aquatic life and their habitats. There was a strong emphasis at the meeting for the communication of ideas between participants from different backgrounds (e.g., academia, industry, and regulation), and there was a strong interest by the attendees in the topics that composed the primary session themes at the conference (see Table 1). The AN2022 conference, like its five predecessors, was a great success in providing opportunities for cross-fertilization of knowledge, experimental approaches, and ideas.

The AN conference series was originally initiated by Anthony D. Hawkins, Arthur N. Popper, and Magnus Wahlberg in Nyborg, Denmark in 2007 (Hawkins et al. 2008; ▶ Chap. 1 , "Brief History of "The Effects of Noise on Aquatic Life" Meetings"). The overwhelming positive feedback and success of this initial conference led to additional conferences on the same topic (▶ Chap. 2, "Evolution of "The Effects of Noise on Aquatic Life" Meetings: 2007 to 2022"). See Table 2 for a list of the organizers for the previous conferences on the Effects of Noise on Aquatic Life.

**Table 1** List of topics/themes of the conference session at the Sixth International Conference on the Effects of Noise on Aquatic Life in Berlin, Germany

| Topic/Theme |
|---|
| Detection of sound: what turtles, birds, and humans hear |
| Soundscapes around the world |
| Noise effects on lesser-known taxa: seagrasses, zooplankton, and mollusks |
| Intense sounds and their effects |
| Priorities for regulation and management |
| Noise effects on the hearing and behavior of marine mammals |
| Acoustics and underwater sound emissions from windfarms, tidal stream turbines, and ultrasonic anti-fouling equipment |
| Management of noise |
| Hearing in marine mammals and fishes |
| Risk management of noise |
| Short- and long-term effects of noise on marine mammals |
| Oil and gas sounds and their effects on marine animals |

**Table 2** List of AN conferences and the conference organizers (listed by last name in alphabetical order)

| Conference | Location | Conference organizers |
|---|---|---|
| AN2007 | Nyborg, Denmark | Anthony Hawkins, Arthur Popper, and Magnus Wahlberg |
| AN2010 | Cork, Ireland | Anthony Hawkins and Arthur Popper |
| AN2013 | Budapest, Hungary | Anthony Hawkins and Arthur Popper |
| AN2016 | Dublin, Ireland | Christine Erbe, Anthony Hawkins, Arthur Popper, Joseph Sisneros, and Frank Thomsen |
| AN2019 | Den Haag, Netherlands | Christine Erbe, Anthony Hawkins, Paul Lepper, Arthur Popper, Joseph Sisneros, and Frank Thomsen |
| AN2022 | Berlin, Germany | Anthony D. Hawkins, Paul Lepper, Arthur N. Popper, Amy R. Scholik-Schlomer, Joseph A. Sisneros, and Frank Thomsen. |

Berlin was selected for the sixth AN conference (AN2022) for many reasons, including that it is a cultural center of Germany and that Berlin is easily accessible from anywhere in the world (via the Berlin Brandenburg airport). The Hotel Palace Berlin, in particular, met all the requirements for this meeting's venue, in addition to being near the epicenter of Berlin where there were ample opportunities for nearby outings.

The number of participants at the AN2022 conference in July 2022 was surprisingly strong given the recent COVID era. The number of delegates, countries represented, and presentations given at the conference were comparable to that of previous five conferences (see Table 3).

Forty-three people, including all students (undergraduate and graduate students) and postdocs who requested support, were funded thanks to our generous funders (see "Acknowledgments").

**Table 3** Aquatic noise conference information related to the number of delegates, countries represented, and presentations given at each of the conferences

| Conference | Location | Number of delegates | Countries represented | Number of presentations |
|---|---|---|---|---|
| AN2022 | Berlin, Germany | 240 | 26 | 186 |
| AN2019 | Den Haag, Netherlands | 312 | 23 | 214 |
| AN2016 | Dublin, Ireland | 323 | 23 | 229 |
| AN2013 | Budapest, Hungary | 243 | 24 | 125 |
| AN2010 | Cork, Ireland | 244 | 22 | 111 |
| AN2007 | Nyborg, Denmark | 202 | NA | 134 |

## Scientific Sessions at the Meeting

The scientific conference presentations were a mixture of 15-min oral presentations, 4-min speed talks (with posters), and posters. Each speed talk presented the highlights of an accompanying poster of the same title. In addition, there were also four 40-min keynote presentations. The following sections give brief summaries of oral and poster presentations by themes.

### Keynote Presentations

There were four keynote presentations, each on a different day (except for Wednesday, which was a half day at the conference). The intent of the keynote talks at the AN meeting is to share new ideas and information about broader aspects of hearing and behavior that can inform and broaden the perspective of participants.

The first keynote was by Christine Köppl (Carl von Ossietzky University Oldenburg, Germany) who talked about the evolution of vertebrate hearing. Dr. Köppl reminded us that all vertebrates hear using a sensory organ that resides in the labyrinth of the inner ear, but not all vertebrates hear the same way. Köppl detailed how the vertebrate inner ear and its hearing sensitivity evolved from fishes to early land vertebrates and how such changes in the inner ear led to very characteristically different morphologies and hearing sensitivities in lizards, birds, and mammals.

In the second keynote, Wei Qui (State University of New York at Plattsburgh, New York, USA) talked about the value of using kurtosis as a metric in the evaluation of noise-induced hearing loss. He gave examples from animal experiments and epidemiological studies on how kurtosis can be used to adjust noise-risk predictions and facilitate estimates of noise-induced threshold shifts.

Louise Roberts (Liverpool University, UK) talked on the biotremology of aquatic substrates. Biotremology is a new and emerging field in the biological sciences that involves the study of the production, dispersion, and reception of mechanical

vibrations by organisms and covers all aspects of animal behavior associated with substrate-borne mechanical waves.

Finally, Andrew Gill (Centre for Environment Fisheries and Aquaculture Science, UK) enlightened us about some of the critical considerations needed to understand the interactions and outcomes of renewable energy development on the marine environment.

## What Turtles, Birds, and Humans Hear

This session began with a short history of the "Effects of Noise on Aquatic Life" conferences from the first in Nyborg, Denmark (2007), to the current in Berlin, Germany (2022), given by Arthur N. Popper and Anthony D. Hawkins. Popper and Hawkins (▶ Chap. 1, "Brief History of "The Effects of Noise on Aquatic Life" Meetings") detailed the history of how the origin of the idea for the conference came about, how the conference has evolved (also see ▶ Chap. 2, "Evolution of "The Effects of Noise on Aquatic Life" Meetings: 2007 to 2022"), and its impact on the field of study that investigates the effects of anthropogenic sounds on aquatic life since the conference's origin to our present conference. Other talks detailed underwater hearing and noise exposure concerns in humans and temporary threshold shifts in turtles. Finally, a series of talks discussed in-air and underwater hearing in birds and the potential effects of noise and substrate vibrations on nesting penguins.

## Soundscapes from Around the World

Topics in this session included the contributions of vessel noise to ambient sound in the form of deep-water particle motion and how it can potentially mask hearing in fishes, how sound levels in a southern California antisubmarine warfare range change during a deep-water multibeam mapping survey, and how climate impacts can influence ambient sound on underwater reefs and animal call rates in different ways. Other talks included the measurement of underwater sound levels in the North Adriatic Sea, the characterization and identification of fish choruses and species contributions to ambient sound in Pamlico Sound in North Carolina, and the characterization of ocean sound and regional and global soundscape modeling.

## Noise Effects on Lesser-Studied Taxa

This session had a series of talks on the effects of noise on lesser-known taxa that included seagrasses, zooplankton, and mollusks. We learned that low-frequency human-generated noise can affect seagrass root statocysts, which are used to sense gravity and sound vibrations. Such alterations in statocysts can potentially affect the health of seagrass populations and other sessile organisms. In contrast, we also learned in certain cases that broadband noise can actually increase survival and

fecundity in freshwater zooplankton. Finally, a talk was given on how different sound exposures can affect mussels differently in terms of valve closing and filtration rates, which should be considered when assessing and mitigating noise effects on these and other potentially similar invertebrates.

## Intense Sounds and Their Effects

This session began with a talk that detailed a method called deflagration that involves an explosion where the flame speed is lower than the speed of sound for lowering noise levels from the clearance of unexploded underwater ordinance. Later, a series of talks were given that detailed the physical effects on Pacific Mackerel and another on the effect of explosive sounds on its inner ear. In addition, a study was presented that examined through numerical modeling the impacts of intense impulse sound on the fish inner ear. Finally, a talk was given that detailed underwater noise that is produced during percussive pile driving and the factors that influence pile-driving noise.

## Priorities for Regulation and Management

In this session, talks focused on detailed priorities for the regulation and management of underwater sound. Talks specified some of the research priorities for sound and vibration effects on fishes and aquatic invertebrates from offshore wind energy development and how adaptative management is critical for the noise management of offshore activities. Others talks described how moderate reductions in vessel noise source levels can dramatically reduce the negative impacts to marine wildlife and how managing technical and environmental uncertainty of subsea noise can impact project design.

## Effects on Hearing and Behavior

During this session, talks described the effects of sound on the hearing and behavior of marine mammals. The session began with a summary of the 16 years of behavioral response studies on sea mammals, sonar, and safety, which was followed by talks on how vessel noise and impulsive (and non-impulsive) sounds can affect energy balance and hearing thresholds in marine mammals. Other talks included the description of frequency-weighted thresholds for hearing loss and behavior disturbance in porpoises and phocid seals, and the use of behavioral experiments to estimate hearing sensitivity in humpback whales.

## Acoustics

Talks in this session included the underwater sound emission from floating wind turbines and the assessment of long-term offshore windfarm noise and how it

influences fish chorusing. Other talks included the comparison of underwater operational noise of two tidal stream turbines and the modeling of single turbines versus turbine arrays. Finally, an interesting talk was given that described the sound emissions from ultrasonic anti-fouling equipment and how it can substantially impact marine life.

## Management of Noise

Two sessions were dedicated to noise management. In the first session, talks included how to best assess impulsive underwater noise in Europe during the next European Union (EU) Marine Strategy Framework Directive cycles and a description of the joint monitoring program for ambient noise in the North Sea. Other talks included real-time monitoring of underwater radiated noise levels from ships using a cable hydrophone system in shallow water, revised Danish guideline for underwater noise from the installation of impact- or vibratory-driven piles, evaluating the benefits of noise reduction mitigation, and autonomous surface vessel passive acoustic baseline monitoring of marine mammals offshore in West Africa.

The second session's talks included a presentation on the best available technology and best environmental practice for mitigating three noise sources: shipping, seismic airgun surveys, and pile driving. Other talks included the development of underwater acoustic deterrents for invasive species control, the response of harbor porpoise to an acoustic deterrent and subsequent piling during the construction of offshore wind farms, and a talk on encouraging quieter shipping.

## Hearing

This session started with a presentation in honor of the late Dr. Sam Ridgway and his extraordinary career in marine mammal research. The presentation was given in an innovative and interactive format that allowed Sam to tell his stories using a new interactive video technology. Other talks included measures and models of dugong hearing, susceptibility of harbor porpoise hearing to intermittent sound pressure, zebrafish hearing in relation to hearing loss, physiological stress, and behavioral changes due to noise. Finally, a talk was given on the use of kurtosis to describe down-the-hole pile installation sounds related to the frequency response of marine mammal hearing.

## Risk Management

Talks in this session included a presentation on an alternative methodology to assess quantifiable noise level risk using a combination of noise pressure and species distribution maps based on a Bayesian-inspired estimation method. Other

talks included an ecological risk assessment approach for underwater sounds from dredging operations, regional noise management in the Northeast Atlantic, the management of noise in a busy harbor porpoise protected area, and the limiting of motorboat noise on coral reefs as a means to boost fish reproductive success.

### Short- and Long-Term Effects

Topics in this session included the adjustment of song unit frequencies among humpback whales in response to small boat noise; minke whale swimming behavior relative to the environment; conspecifics and Navy sonar; and examination of how shipping noise affects the abundance and distribution of harbor porpoise during high levels of marine traffic in the Baltic Sea. The final presentation in this session was on the cumulative effects of multiple stressors on marine mammals using elephant seals as a model system.

### Oil and Gas Sounds and Their Effects

In this session, presentations were on the measurement procedures for underwater sound sources associated with oil and gas exploration and production activities, the measurement of sound source levels of mobile offshore drilling units, and the ocean seismic survey impacts on the movement and distribution of nearshore temperate marine species. The final talk was on the behavioral responses of spawning cod to seismic airgun exposure.

## Rodney Coates Award

The Rodney Coates Award for the best student presentation was given on the last day of the conference. This award was made possible by the generosity of the Coates family in the memory and honor of the late Rodney Coates, who attended several of our conferences and was very interested in the research that was presented at the conference. Candidates for the Coates award either had to be a registered graduate student or had to have received their doctorates in 2022 from a recognized college or university. Each candidate was assessed for presenting both a speed talk (4 min) and a poster on their work. A team of 13 judges drawn from the scientific community at the conference were asked to judge both the talk and poster. The 2022 judges were Sander von Benda Beckmann, Benjamin Colbert, Hilary Kates Varghese, Klaus Kucke, Nathan Merchant, Jennifer Miksis-Olds, Mirjam Müller, Michael Noad, Marta Picculin, Denise Risch, Louise Roberts, Kathy Vigness Raposa, and Jürgen Weissenberger. All agreed that the quality and standard of the presentations were of high quality. The judges had a difficult time assessing the winners because of the high standard and quality of the

presentations. Three prizes were given: first place (£1000 prize), second place (£500 prize), and third place (£250).

The first-place winner was Johannes Veith from Charité Universitätsmedizin Berlin, Germany, for his presentation on "Directional Hearing in *Danionella cerebrum*." The second-place winner was Kees te Velde from Leiden University, the Netherlands, for his presentation on "Habitat-associated soundscapes of a lowland Dutch river system: Potential and vulnerability of auditory cues to migratory fish." The third-place winner was Emilie Hernes Vereide from the Institute of Marine Research, Vestland, Norway, for her presentation on the "Impacts of airgun blasts used in seismic surveys – Small effects on small copepods."

## Social Program

The social program began on Sunday night with a welcome reception in the Hotel Palace Berlin. The conference opened on Monday morning with two lovely arias sung by Oleksandra Diachenko. The program ended early on Wednesday afternoon (a conference tradition) so that the delegates could network and enjoy the local sights of Berlin with friends and family. On Thursday evening, the Hotel Palace Berlin set up a disco at the hotel bar for the delegates to enjoy music and dance. The conference concluded with the banquet in the Hotel Palace Berlin banquet room with live entertainment from a Marlene Dietrich impersonator and singer.

## Participant Feedback

An on-line survey was set up at the end of the conference, and 75 participants responded. We had more male (61%) than female (39%) participants in the survey, with the largest percentage of responders being students and postdocs (Fig. 1). The attendance of these young investigators at the AN2022 conference was enabled by the strong external grant support that was received. Attendees that were supported to attend by conference grants were from 13 countries including Argentina, Australia, Brazil, Canada, Colombia, Germany, Italy, the Netherlands, Norway, Poland, Portugal, the United Kingdom, and the United States.

Figure 1 shows the distribution of the professions of the survey responders. Academics, which include students (undergraduate and graduate), postdocs, and faculty, made up the majority (75%) of the responders. One goal of the conference was to attract a diversity of stakeholders, including those outside of research, which was achieved at the conference and was not necessarily demonstrated by the number of responders in the survey.

Table 4 summarizes the responding attendees' score regarding a number of specific aspects of the meeting. Based on the percentages of scores 4 or 5 (liked or liked greatly) from the survey, there was a broad satisfaction with the conference including

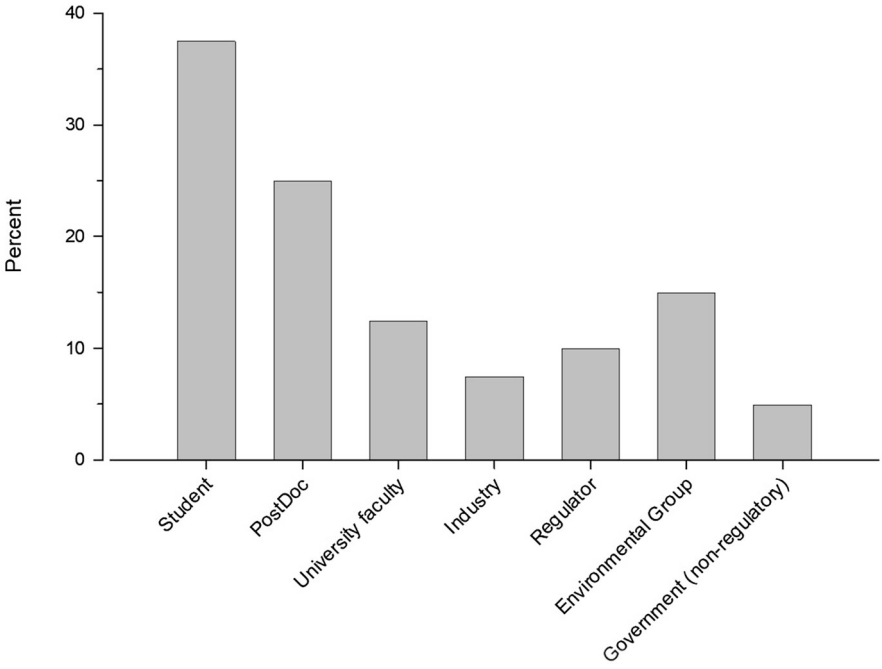

**Fig. 1** Profession of the survey responders. Note: the percentage of the responders exceeds 100% because some of the participants listed two professions, and both were counted

**Table 4** Scores for different aspects of the meeting (75 responders)

| | 1 (did not like) | 2 | 3 (neutral) | 4 | 5 (liked greatly) |
|---|---|---|---|---|---|
| Delivery of conference presentations (Oral, Speed Talks, Coates & Posters) | 0% | 1% | 7% | 44% | 48% |
| Meeting website | 3% | 3% | 17% | 53% | 24% |
| Abstract submission and site | 2% | 3% | 17% | 52% | 26% |
| Meeting registration (both website and in-person) | 0% | 0% | 23% | 41% | 36% |
| Information provided prior to the meeting | 0% | 3% | 19% | 33% | 45% |
| Welcome buffet and/or conference dinner | 2% | 3% | 28% | 19% | 48% |
| Sufficient break and lunches | 0% | 3% | 2% | 21% | 74% |

the delivery of conference presentations (Oral, Speed Talks, Coates & Posters) (see Table 4). We are very pleased that VenuesWorld, who handled the logistics of the meeting, also received very strong support from the attendees. Table 5 lists attendee-specific feedback on the scientific content of the meeting. As can be seen, there is a strong consensus that the scientific content was excellent, as further supported by the responses to several of the questions used to generate Table 5.

**Table 5** Verbatim responses (unedited other than spelling corrections and removal of duplicate responses from different delegates) to a question about the scientific content of the meeting

| | |
|---|---|
| Excellent | Very good |
| Very useful | Nice diversity |
| Good mix | Highly varied |
| Nice variety of subjects | Great content |
| Very high standard | Cutting edge and highly educational |
| Very interesting, complete and high level | Generally, talks were well done. |
| I enjoyed the breadth of the scientific content. | Mostly well-presented and researched |
| Inspiring!! So happy to learn a lot | Excellent across the board. |
| The best among the ones I've attended. | The scientific content was good |
| High level in general, pretty diversified | Talks were great! I learned so much! |
| Very useful and fits well with my research! | High, much better than most conferences |
| Good quality and variety | Great and very interesting topics |
| A good variety of topics/taxa/disciplines well covered. I learnt a few new things! | Good mix of recent research, rising topics/ issues, and practical topics. |
| Very cool. One of the best talks was the one about biotremology. | Great, sessions on turtles and birds, inverts, where good |
| Excellent and well organized. Matched well to the state of the field. | Very interesting, broad (animal group, kind of stressors, etc.) and relevant |
| It was a decent mix of research on biology and on underwater acoustics | I liked the flow of the program although the work presented was all very similar in method and content |
| Fabulous! the diversity was spot on, the continuum of subjects and how many of them built on each other and most importantly the single room aspect. my gosh what a great idea not to have to been torn between speakers. | Very good blend of topics. Good to include speakers from outside the field, very inspiring. |

## Conclusion

At the five-day AN2022 conference in Berlin we heard about new research on the effects of anthropogenic sound on marine animals including birds, turtles, fishes, and even humans. We also learned about how anthropogenic sound can impair seagrasses and invertebrates. Our understanding of the potential impacts on marine fauna and flora is growing, and we are beginning to have a better understanding of how anthropogenic sounds can affect aquatic life. At AN2022, we had the opportunity to discuss underwater anthropogenic sounds and their potential impacts on aquatic life with colleagues and fellow scientists, students and postdocs, industry representatives, government regulators and representatives, and members of non-government organizations. This AN conference, like the previous ones, has allowed our participants to get a better understanding of each other's concerns with regard to the potential impacts of anthropogenic sound and has allowed us to build relationships and grow as a community.

In conclusion, the organizers were very satisfied and pleased with the outcome of this year's conference and look forward to planning for the next AN conference in

2025. The venue for the next meeting in 2025 will be in Prague, the capital of the Czech Republic. Please keep an eye on aquaticnoise.org for updates.

**Acknowledgments** The conference leading to this book could not have taken place were it not for generous funders and numerous colleagues who graciously provided help, especially during uncertain times during the COVID era. We are indebted to our funders and sponsors, who enabled us to support the attendance of students, postdocs, and colleagues from developing countries. We thank our funding organizations: the Aquatic Noise Trust (UK), the Bureau of Ocean Energy Management (USA), the Marine Mammal Commission grant MMC21-036 (USA), the National Oceanographic and Atmospheric Administration grant NA20OAR4320271 (USA), the National Science Foundation grant OCE2136084 (USA), the U.S. Office of Naval Research award N00014-22-1-2814 (USA), the Naval Facilities Engineering Command (USA), and the U.S. Navy Living Marine Resources Program grant (USA).

We thank our silver sponsors JASCO Applied Sciences (Canada), the Bureau of Ocean Energy Management (USA), and Federal Agency for Nature Conservation (Germany). We thank our bronze sponsors: the Acoustical Society of America (USA), International Association of Oil & Gas Producers (UK), and Ørsted (Denmark). We thank all other sponsors: the Company of Biologists (UK), CSA Ocean Sciences Inc. (USA), Abyssens (France), HDR (USA), Ocean Sonics (USA), RS Aqua (UK), and Ocean Science Consulting Ltd.

We are also grateful to our Advisory Committee: Michael Ainslie (JASCO Applied Sciences, Netherlands), Ben Colbert (University of Maryland Center for Environmental Sciences (UMCES), USA), Christine Lamont (National Offshore Petroleum Safety and Environmental Management Authority, Australia), Songhai Li (Institute of Deep-sea Science and Engineering, Chinese Academy of Sciences, China), Klaus Lucke (JASCO Applied Sciences, Australia), Nathan Merchant (Centre for Environment, Fisheries and Aquaculture Science, UK), Jennifer Miksis-Olds (University of New Hampshire, USA), Jim Miller (University of Rhode Island, USA), Mirjam Müller (Umweltbundesamt, Germany), Sophie Nedelec (University of Exeter, UK), Michael Noad (CEAL, the University of Queensland, Australia), Marta Picculin (Ca′ Foscari University of Venice, Italy), Denise Risch (Scottish Association of Marine Sciences, UK), Louise Roberts (Cornell University, USA), Gail Scowcroft (University of Rhode Island, USA), Erica Staaterman (Bureau of Ocean Energy Management, USA), Jenni Stanley (University of Waikato, New Zealand), Sander von Benda Beckmann (TNO, Netherlands), and Jürgen Weissenberger (Equinor ASA, Norway).

We thank our media committee, consisting of Brooke Vetter (University of St. Thomas, USA), Marta Bolgan (Ocean Science Consulting Limited), and Sarah Marley (Scotland's Rural College, Scotland), who kept the community up-to-date via Facebook and Twitter. We also thank Michele Jacobs (University of Washington, USA), who handled much of the grant income and all of the finance reimbursements on our behalf.

**Abstract**

Marine seismic surveys are large-scale tests used to study the seabed and sub-seabed by utilizing sound reflected from the ocean bottom, generated from airgun arrays. Airgun arrays used in these experiments often exceed Sound Exposure Levels (SEL) as high as 220 dB (re 1 μPa), and thus it is important to understand the potential impact of these surveys on marine mammals. To mitigate any harm that may be caused to nearby marine life, propagation models should be implemented to estimate the sound exposure level as a function of range for a given environment. These models are complicated by both the source array design, which effects the propagation modeling, and the receiver array design, which alters the data processing by misrepresenting the acoustic field. The purpose of this manuscript is to examine, through simulation, the potential effects of both of these arrays on both modeling acoustic propagation and interpreting acoustic data from the experiments.

## Introduction

Marine seismic surveys are experiments designed for studying and mapping the geological characteristics of the ocean, often up to multiple kilometers below the seabed. These surveys typically consist of an airgun array, capable of generating source signals above 220 dB *(re 1 μPa)*, broadcasting sound focused toward the ocean floor, with the acoustic reflections measured by a receiving array towed by the same ship towing the source array. Guidelines for sound exposure levels (SEL) corresponding to permanent threshold shift (PTS) and temporary threshold shift (TTS) in marine mammals are provided by the National Marine Fisheries Service (NMFS) (National Marine Fisheries Service 2018), and though not as well regulated, this sound exposure can potentially impact other marine life as well. However, propagation models used for understanding the impact of airgun pulses on marine mammals need improvement based on the NMFS 2018 standard. An understanding of the array designs for seismic surveys and their effects on the propagation and measured data are critical to these models.

Some work has looked at propagation in seismic surveys using both simulations and actual seismic data (Deruiter et al. 2006; Abadi and Freneau 2019a, b), including work on characterizing the spectra of the airgun arrays, again both in simulation and experimentally (Diebold et al. 2010; Guo-Fa et al. 2010; Sertlek and Ainslie 2015; Duncan and Gavrilov 2019; Prior et al. 2021). Little attention has been paid to the design of receiver arrays, which will be described in section "Description of MGL1212" of this manuscript, perhaps because the design details are not always immediately obvious (or even included) in the cruise documentation.

The intent of this chapter is to examine the effects of the source and receiver array configurations on transmission loss in acoustic propagation models that utilize parabolic equation methods. The impact of the receiving array design is particularly essential when considering actual acoustic data collected during these seismic surveys. The airgun array beam pattern is critical when trying to accurately simulate the acoustic field expected in seismic surveys. Section "Description of MGL1212" describes the experiment that forms the basis for this analysis, followed by a section of results and analysis, and finally a summary of the main conclusions.

## Description of MGL1212

The MGL1212 experiment (Holbrook et al. 2012b) forms the basis for the simulations completed in this manuscript – providing the parameters for array design and approximate geometries and sound speed profiles to use in simulation. Further, experimental data will be considered here to justify this work, but experimental data will not be utilized in the results presented.

The MGL1212 experiment took place off the coast of Washington State (USA) in summer 2012 to further study the Cascadia Subduction Zone, covering the regions shown in Fig. 1. The source and receiver arrays utilized by the ship, the R/V Marcus G. Langseth, consisted of a four-string airgun array and an ~8 km towed hydrophone

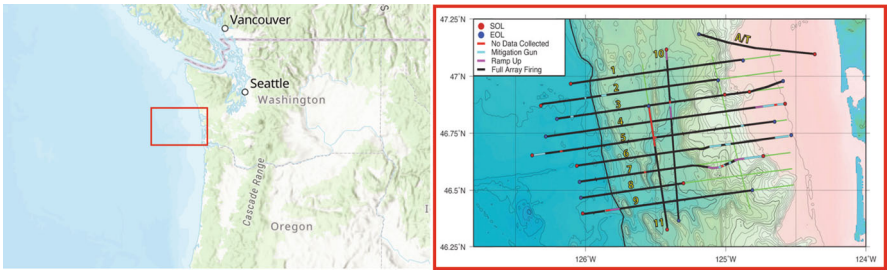

**Fig. 1** The approximate location and a detailed map of the MGL1212 seismic survey (Reproduced from Holbrook et al. 2012a, b). Black lines show the main track lines including nine east-west lines across the continental slope, two north-south lines along the strike of the continental margin, and one line northeast of the main survey area on the continental shelf

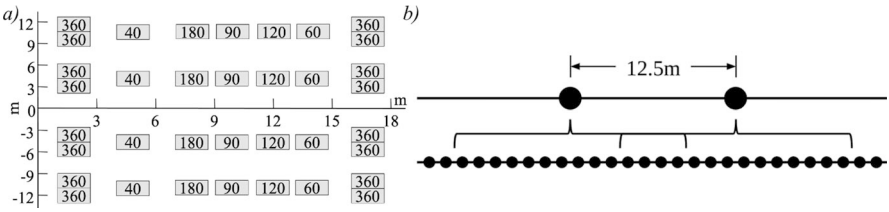

**Fig. 2** Array geometries from the MGL1212 experiment. The source array (**a**) consists of four identical lines of nine airguns with relative positions shown here. Each box represents an airgun with a volume in cubic inches corresponding to the number in the box. The receiver array (**b**) consists of groups of 14 hydrophones averaged together to give each channel output, with four hydrophones overlapping between each channel

array. Each string of the source array was identical, consisting of nine airguns of varying volumes, totaling 1650 $in^3$ per string (6600 $in^3$ for the full array). The receiver array consisted of 636 receiver channels, spaced 12.5 m apart, with the first receiver channel at 264 m from the center of the source array. Each channel, despite providing a single output, is an average of 14 hydrophones, spaced 1.25 m apart, with the channel position taken at the center of the group. Additionally, each group has four hydrophones overlapping with the neighboring groups. These geometries are laid out in Fig. 2a, b. The effects of these array geometries on the acoustic output are the primary focus of the remainder of this chapter.

The importance of understanding propagation characteristics of these experiments is shown in Fig. 3. Figure 3(a) shows a waterfall plot from a shot on line 6 (shown in Fig. 1) at roughly 2000 m depth, with range increasing with receiver channel, displaying the time domain output for every 15th receiver. Here the direct path, first reflection, and second reflection are all clearly visible. Figure 3(b) shows the corresponding sound exposure level (SEL) for this shot, as well as references for TTS and PTS levels for low-frequency marine mammals (as defined by NMFS 2018) and a line (red) for a cylindrical spreading model. While some aspects of the SEL curve are reasonably represented by a cylindrical spreading model, there are clearly

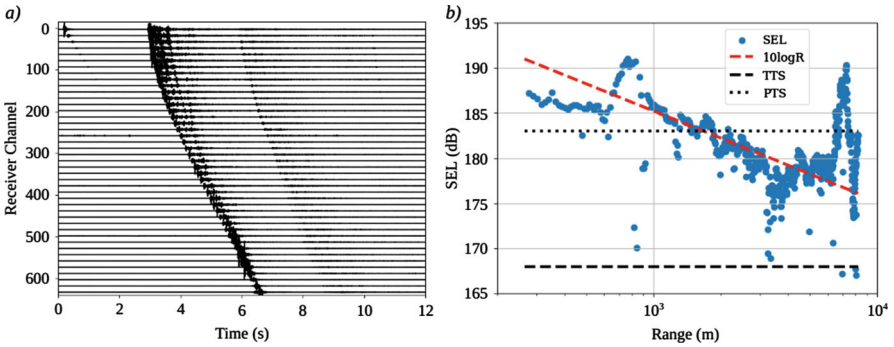

**Fig. 3** Results from a single shot in MGL1212. A waterfall plot (**a**) showing the time domain output for every 15th receiver, range increasing with channel number. Sound exposure level in dB (**b**) for the same data as a function of range, plotted on a log scale. The black lines represent the TTS (dashed) and PTS (dotted) thresholds for low-frequency marine mammals as defined in the NMFS 2018 document

some ranges, particularly between ~600–900 m and ~ 7 km, that vary significantly from this model, indicating that more complexity exists in the propagation than is considered by simplified spreading models. Thus, further analysis of experimental data and investigation of the impacts of various parameters on acoustic propagation is necessary. The first step to being able to analyze this data successfully is understanding the impacts of the experimental geometry (i.e. the source and receiver array designs) on the data itself. The next section considers these impacts from simulations of array geometries and acoustic propagation.

## Analysis and Results

The receiver array geometry is a simple linear array with equal receiver spacing; thus, the beam pattern can be calculated analytically (Kinsler et al. 2000). Figure 4(a) shows the directionality of the array for several frequencies, with 0° corresponding to horizontal propagation (along the array) and 90° corresponding to vertical propagation (perpendicular to the array and toward the sea surface and bottom). These patterns show that at low frequencies, such as 20 Hz, the beam pattern approaches an omnidirectional pattern. However, at higher frequencies, the difference in amplitude is highly angle-dependent, indicating that varying propagation angles will significantly impact the effects of receiver averaging. For example, a 100 Hz sound wave arriving at 50° relative to the horizontal will yield a channel output roughly 5 dB quieter than the physically present acoustic field. For a broadband SPL, applying appropriate weightings to the beam pattern and combining can yield a broadband beam pattern for analysis, shown in Fig. 4(b). The two curves show an unweighted (all frequencies of equal amplitude) and a weighted broadband beam pattern (a decay of 10 dB per order of magnitude of frequency is chosen for simplicity). In the weighted case, the low frequency components are much more significant, and thus a

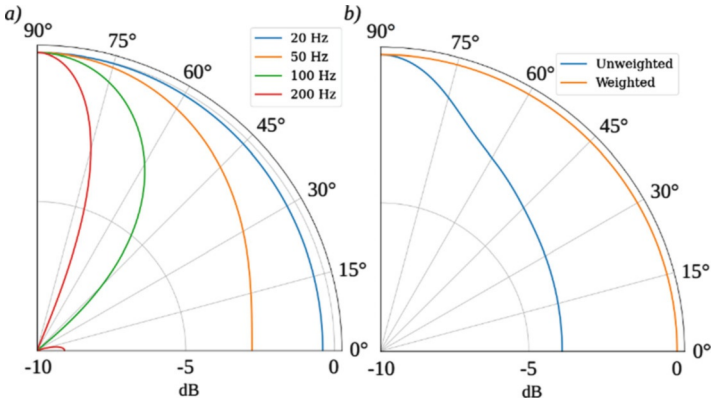

**Fig. 4** Beam pattern outputs for the MGL1212 receiver array geometry. Panel (**a**) shows the results for several individual frequencies, and panel (**b**) shows the result for a broadband signal between 20 Hz and 220 Hz with a flat spectrum (unweighted) and a spectrum with relative intensities decreasing by 10 dB per order of magnitude of frequency

nearly broadband beam pattern is achieved. In the unweighted case, the influence of the higher frequencies is clearly present. In reality, a more complex weighting exists that likely generates a beam pattern lying between these two curves.

For the source array, an analytic solution does not exist since each array element is of a different volume and the airgun spacing is not consistent. Thus, the beam pattern is calculated by choosing a point in the far field that corresponds to a given angle, calculating the acoustic field at this point from each airgun, and combining coherently, assuming each airgun is an independent point source with amplitude scaled by the cube root of its volume, and that all airguns are fired simultaneously. This is a notably simplified simulation, since the airguns are significantly more complex as sources, and the simulation ignores any interaction between airguns. Nevertheless, it provides insight into the importance of the array beam pattern. Figure 5 shows the same results as Fig. 4, for the airgun array rather than the receiver array, with notably different beam patterns resulting, due to the array complexity. In particular, side lobes start to appear at some of the higher frequencies, and the weighted and unweighted curves are actually more similar than one might expect, but still with non-negligible differences. As expected, the sound energy is focused in the vertical direction, as per the experimental design.

In order to evaluate the effects of these arrays on transmission through the water column, RAM simulations (Collins 1993) will be performed at multiple depths, incorporating environmental parameters specific to the MGL1212 experiment. Figure 6 shows the sound speed profiles used for the simulations, both in the water column (a) and the seabed (b). These are based on direct XBT measurements from the MGL1212 experiment for the water column (interpolated and extrapolated for deeper water), and an inversion result for the seabed. When the water depth was shallower than the profile presented here, it was simply truncated at the corresponding depth. The 0 value for the seabed profile corresponds to the water

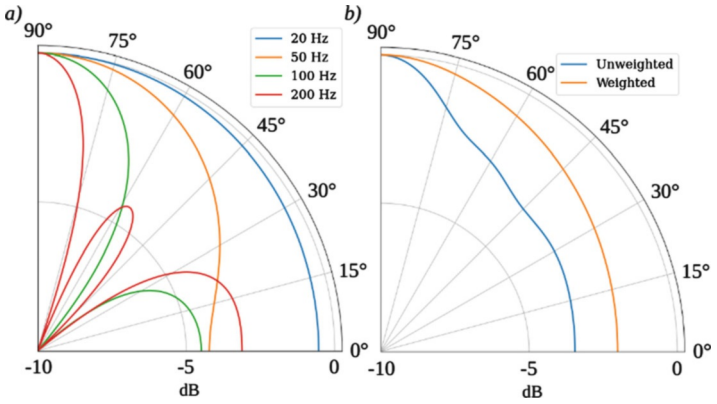

**Fig. 5** Same as Fig. 4 but for the source array. Airguns are modeled as point sources

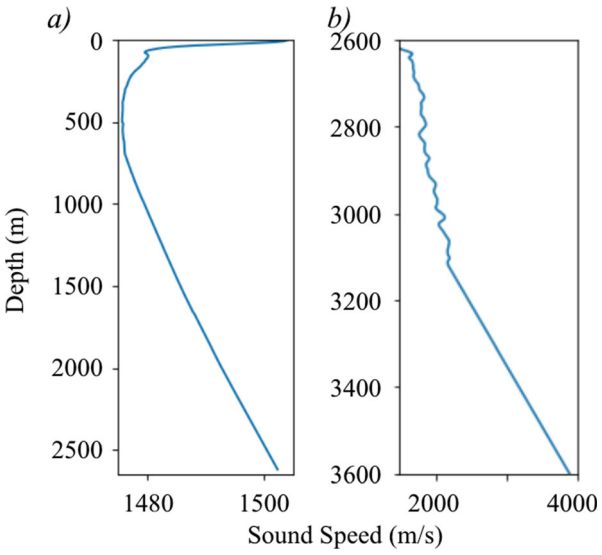

**Fig. 6** Sound speed profiles used for RAM simulations. The profile for the water column (**a**) is based on measurements taken during the MGL1212 experiment. The profile for the seabed (**b**) is based on an inversion result from MGL1212 data. The 0 m depth in the seabed profile corresponds to the water column/seabed interface

column/seabed interface. Here, the effects of the source array and receiver array geometry will be considered together. However, there is a notable difference between the effects of these two arrays. The airgun array, as an active source, will generate a beam pattern in the physical application; thus, its effects are important to consider for simulating propagation, but the received data does not need adjustment to represent the physical field. However, the receiving array output is the result of an array averaging process, and thus the effects of the array beam pattern are not physical but are rather a result of a signal-processing step. Thus, for array data to accurately represent the physical field, the beam pattern must be compensated for.

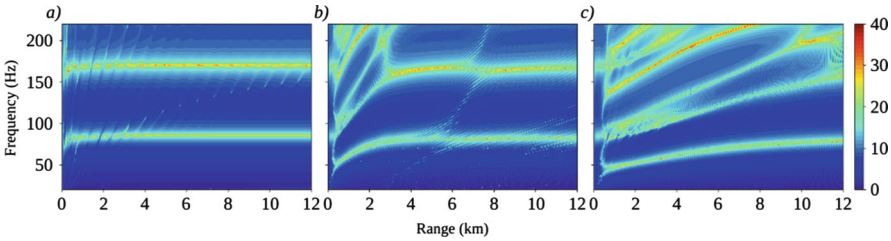

**Fig. 7** The differences in dB between two scenarios: the two arrays shown in Fig. 2 and a case with a single point source (with volume equivalent to the array total) and no group averaging for the receiver array. This is shown for three depths, 50 m (**a**), 670 m (**b**), and 2618 m (**c**)

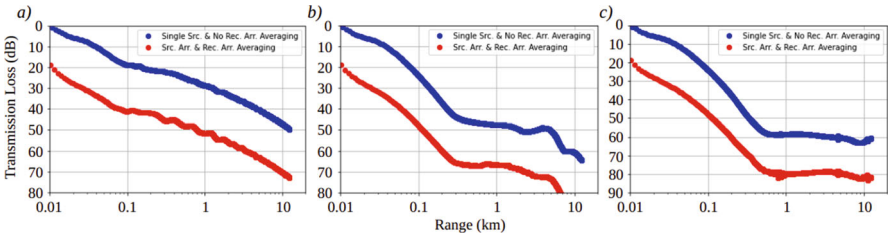

**Fig. 8** TL curves for two cases, one with the arrays shown in Fig. 2 (red curve), and a case with a single omnidirectional source (with volume equivalent to the array total) and no group averaging at the receiver array. This is shown for three depths, 50 m (**a**), 670 m (**b**), and 2618 m (**c**)

The impact of these beam patterns can be significant factors in calculating the acoustic field in simulation, especially at frequencies significant for the array geometries. This influence is dependent on the signal spectrum, so it is worth knowing the impact as a function of frequency. Additionally, since the beam pattern is angle-dependent, the range-dependence will vary as a function of bathymetry. Figure 7 summarizes the impacts of the arrays as a function of frequency and range for various depths. Here, the plots show the differences between a case with a single omnidirectional source (with the same amplitude as the total source array from MGL1212) and single omnidirectional receiver, and a case with source and receiver arrays based on the MGL1212 geometry. The panels show the results for depths of 50 m (a), 670 m (b), and 2618 m (c), each of which is based on geometry and sound speed profiles from the MGL1212 experiment. In each of these cases, it is notable that the influence of the array geometry remains relatively constant after ranges of roughly 7.5 times the depth of the water channel are reached. Prior to that distance, the influence of the array geometry is highly range dependent. Additionally, depending on the frequency, the differences can approach nearly 40 dB, having a potentially major effect on the overall SEL.

The differences between SEL and TL when accounting for these array effects can be quite significant. Figure 8 shows the TL differences for the same environments used in Fig. 7, for unweighted broadband signals. The results in this Figure show differences of up to 20 dB between the two cases, indicating the significance of

including these geometries in any models or simulations used to evaluate SEL in seismic surveys. This difference will vary significantly depending on the frequency weighting, with larger differences, when the frequencies corresponding to higher values in Fig. 7 have a higher weighting.

## Conclusion

The simulation results presented in this proceeding provide several key conclusions. First and perhaps most significant, the influence of array design can generate up to 10–20 dB differences in predicted versus actual TL or SEL. The effects of receiver array averaging are much more significant contributors to this difference and relevant when analyzing acoustic data collected during these surveys. The source array design is still an important factor as well, particularly for simulating the acoustic field. Second, the differences in received levels will vary as a function of frequency and range, up until a range of ~7.5 times the channel depth is reached, at which point the range-dependence becomes insignificant. Lastly, the effects of the array design can be captured as angle-dependent beam patterns, either at individual frequencies, or as a broadband beam pattern if information about the signal spectra are available.

**Abstract**

Lab-based bioacoustics experiments on fish enable control of confounding factors, yet these experiments often use small tanks that are spatially complex in terms of particle motion and sound pressure levels (SPL). One solution is to submerge an arena in water so the influence of the walls on the acoustic environment is greatly reduced. The experiment answered the following: (1) Can the sound pressure homogeneity in small tanks be improved? (2) Can the particle acceleration (PA) levels in small tanks be reduced? (3) Does submerging small

tanks allow the sound field to be reliably described by progressive plane waves? The first setup consisted of a rectangular tank surrounded by air (in-air tank) and the second setup was a cylindrical arena submerged in water (submerged arena). Measurements of a 1 s, 125 dB tone at 400–2000 Hz were taken and mapped. The submerged arena possessed less heterogeneity in SPL and lower levels of PA than the in-air tank. The predicted PA (calculated to fulfill research question three) was a better approximation to the submerged arena than the in-air tank. This study demonstrates that the submerged arena gave greater control over the stimulus that a fish experiences in lab-based experiments.

## Introduction

Both laboratory and in situ bioacoustics experiments on fish have benefits and disadvantages. Experiments that are either fully in situ or in a pen have high behavioral and acoustic validity but low experimental control (Slabbekoorn 2016). Conversely, tank experiments lack acoustic validity due to heterogeneous sound pressure levels (SPL) and particle motion, in which both the amplitude and the directional components vary substantially. While experiments in situ may be more favorable in terms of acoustic validity, indoor tank experiments have a much higher degree of experimental control (Akamatsu et al. 2002). This is advantageous for behavioral studies in which external factors, such as water temperature and ambient noise, may compromise the behavior more so in situ than in the lab (Akamatsu et al. 2002; Johnsson and Näslund 2018). However, the effect of confinement in a tank on the behavior of fish has long been a concern for its potential to generate deviations from wild behavior (Hawkins et al. 2015; Hawkins and Popper 2016; Popper and Hawkins 2018).

Small tanks have complex soundscapes owing to their small size, the elasticity of the tank walls, and the large impedance differences between water and air at the tank boundaries (Rogers et al. 2016). For example, consider a rectangular tank made from glass or acrylic which will have five hard surfaces (four sides and a bottom) and the water surface in close proximity to each other. In such circumstances there is a large degree of scattering from all the boundaries. The tank characteristics, particularly the tank size, shape, and the impedance difference, give rise to reverberation, in which the acoustic field cannot be regarded as homogeneous (Akamatsu et al. 2002).

In acoustic experiments, inhomogeneous sound fields mean that the sound level received by a subject vary according to their position within the experimental arena. In the problem we consider, the received SPL and particle motion experienced by a fish would be subject to a high level of uncertainty. For example, the addition of a fish may perturb the sound field to one that differs from that measured in a fish-less

tank, e.g. because of scattering from the swim bladder (which would, of course, also happen if the fish were in the field) (Stanton 1989; Diachok 2001; McKelvey and Wilson 2006). Additionally, the complex nature of the sound field makes it challenging to reproduce.

A practical way to improve sound pressure and particle motion fields, while using readily available equipment, is to alter the experimental methodology, exploiting the reduction in acoustic intensity as the wavefront propagates away from the source. This may involve setups in the field (Debusschere et al. 2014) or in a pen (Hubert et al. 2020). However, the use of tanks allows control of environmental factors which would be impossible in the field (Akamatsu et al. 2002; Gray et al. 2016; Currie et al. 2021). To increase the extent to which a tank is homogeneous and isotropic, large impedance differences should be removed. It would be impractical, and for many experimenters prohibitively expensive, to try to improve sound field homogeneity through the use of (very large) anechoic wedges on the arena walls. For the frequencies in question, these wedges would be of ≈1 m in length (Kolaini and Crum 1994), requiring a very large anechoic tank to provide a working space free of the niches provided by wedges in which the fish could be contained (e.g., by a net). Hence, this study tests a more affordable and practical method, exploiting the reduction in acoustic intensity as the wavefront propagates away from the source (rather than its conversion to heat by wedges) to homogenize the sound field. The experiment aimed to answer the following research questions: (1) Can the sound pressure homogeneity in small tanks be improved? (2) Can the particle acceleration (PA) levels in small tanks be reduced? (3) Does submerging small tanks allow the sound field to be reliably described by progressive plane waves?

## Methods

Two experimental setups were considered. The first setup consisted of a rectangular tank surrounded by air (in-air tank) and the second setup was a cylindrical arena submerged in water (submerged arena). For both setups, the sound field was mapped and then compared.

### Experimental Setup 1: In-Air Tank

Acoustic mapping was carried out in an experimental arena (86 cm length × 30.2 cm height × 30.8 cm depth) situated within a custom-made still water rectangular acrylic tank (300 cm × 30.8 cm × 30.2 cm; 12 mm thickness; 27 cm water depth; mean ± sd temperature 18.8 ± 1.4 °C) in September 2019 at the University of Southampton's International Centre for Ecohydraulics Research (ICER) facility, UK. The tank was situated on concrete blocks and surrounded by air on all sides (Fig. 1). Two underwater transducers (Electro-Voice UW-30; maximal output 153 dB re 1 μPa at 1 m for 150 Hz, Lubell Labs, Columbus, OH, USA) were

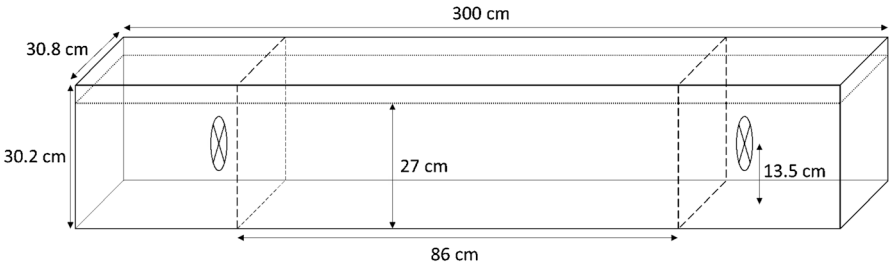

**Fig. 1** The rectangular in-air tank (300 cm length × 30.2 cm height × 30.8 cm depth) and experimental arena (86 cm length) in relation to the water level (dotted line, 27 cm water depth). Two transducers were suspended centrally at either end of the experimental arena and behind an acoustic baffle (dashed line)

suspended centrally, 13.5 cm from the bottom of the tank and 5 cm away from baffles that flanked the experimental arena.

## Experimental Setup 2: Submerged Arena

Acoustic mapping was carried out in a white medium-density polyethylene cylindrical arena (modified 100 L Round Water Tank; 55.5 cm diameter, 45 cm height; 4 mm thickness; 30 cm water depth; Direct Water Tanks, Retford, Nottinghamshire, UK) in November 2020 at the University of Southampton, UK. The submerged arena was mounted on a bespoke metal frame and suspended in a large tank (8 m length × 8 m width × 5 m depth) (Fig. 2). An underwater transducer (Electro-Voice UW-30) was suspended 70 cm below the arena.

### Acoustic Stimuli and Sound Mapping

Sinusoidal 1 s tones at five frequencies (400; 600; 800; 1000; 2000 Hz) were produced in MATLAB (Version 2019b, The Mathworks, Inc., Natick, USA) using a laptop connected to a DAQ (NI USB-6212; National Instruments, USA) operating at 25.6 kHz, transmitting the signal through an amplifier (Prosound Power AMP 200; frequency response: 20 Hz–20 kHz), and was emitted via the UW30 underwater transducer. Acoustic stimuli were standardized such that the SPL (125 dB re 1 μPa) was reached in the center of the experimental arena. Use of artificial stimuli allowed for control of the specific acoustic components tested.

The sound pressure field was measured and mapped using a calibrated hydrophone attached to a manual slider (for the in-air tank: 8103, manufacturer-calibrated sensitivity −211 dB re: 1 V μPa, Brüel & Kjær; for the submerged arena: 8105, manufacturer-calibrated sensitivity −205 dB re: 1 V μPa, Brüel & Kjær). Point measurements were recorded at three depths (in-air tank: 7 cm, 13.5 cm, 20 cm; submerged arena: 5 cm, 15 cm, 25 cm). At each depth, measurements were taken 5 cm apart (in-air tank: 80 measurements; submerged arena: 76 measurements). The

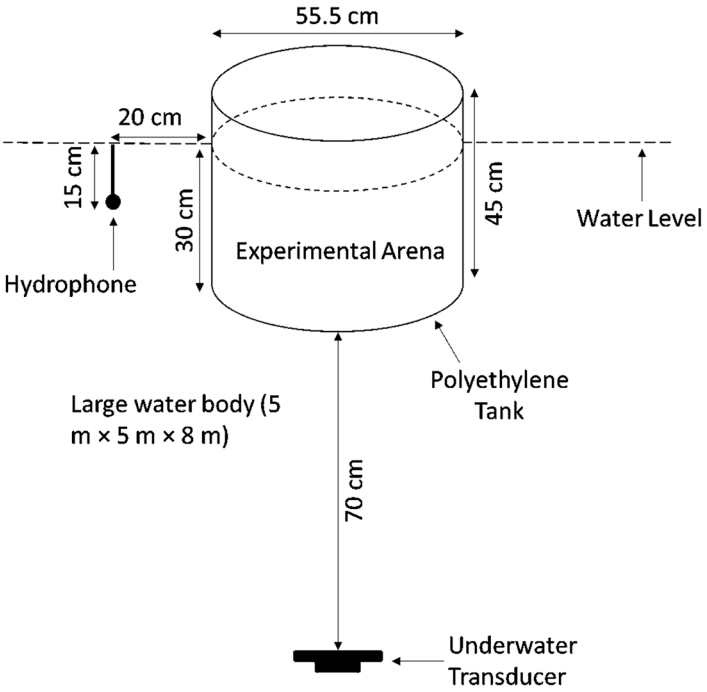

**Fig. 2** The submerged arena (55.5 cm diameter × 45 cm height) inside a large tank of dimensions (8 m length × 8 m width × 5 m depth) in relation to the water level (dotted line, 30 cm water depth). The transducer was suspended 70 cm below the tank, and a hydrophone placed 15 cm below the water level and 20 cm away

data capture and stimulus generation were synchronized to facilitate computation of the PA. Both SPL and PA were quantified to create maps of the sound field. The PA, $a$, may be calculated from the same dataset using a gradient-based approximation:

$$a = -\frac{1}{\rho}\nabla P, \tag{1}$$

where $\rho$ is the ambient density and $\nabla P$ is the pressure gradient (Kinsler et al. 1982).

The pressure gradient was computed using the measurements of the pressure signal. The root mean square (RMS) of the pressure difference was calculated in three directions (x, y, and z), in which the difference between two pressures was computed and then the RMS of that difference was calculated. The pressure gradient was calculated by dividing by the distance between measurements, while the PA RMS (Eq. 1), in all three directions, was calculated by dividing the pressure gradient by the water density. The total PA RMS was determined by combining the obtained values for all three directions and then expressing the results in decibels (dB re 1 mm $s^{-2}$).

## Data Analysis

All statistical analyses were performed in R (version 3.6.3: https://rstudio.com/), while acoustic maps were produced in MATLAB (version R2019b: https://mathworks.com/). Particle motion and sound pressure residuals followed a Gaussian distribution, determined by visual inspection of qq curves. Two-sided *F*-tests were conducted to compare variance of PA and SPL data between the in-air tank and submerged arena setups for each frequency. Similarly, two-sided, Welch's *t*-tests were used to compare the means of PA and SPL between the submerged arena and in-air tank for each frequency.

To determine if a sound field can be described using a plane wave, an expression for the PA under plane wave conditions was considered, (2). The predicted PA could then be compared to the experimental PA to determine which setup better allowed the stimulus to propagate as a plane wave. For a plane wave with no absorption (assuming no absorption in water over the frequency band of interest here is reasonable; Everest and Pohlmann 2015), then $u = p/(\rho c)$, where $u$ is particle velocity and $c$ is speed of sound underwater (Leighton 1994). If the plane wave assumption is satisfied, the gradient in acoustic pressure measured by paired hydrophone measurements in three orthogonal directions can be used to calculate the vector of acoustic particle velocity. For a plane wave, where $f$ is frequency, PA is

$$a = \frac{p2\pi f}{\rho c}. \tag{2}$$

The SPL and PA are expressed in dB using reference values of 1 $\mu Pa$ and 1 mm $s^{-2}$, respectively, via:

$$SPL = 20\log_{10}\frac{p}{10^{-6}}, \tag{3}$$

$$PA = 20\log_{10}\frac{a}{10^{-3}}. \tag{4}$$

The PA computed based on a plane wave assumption was then compared to the experimentally measured PA using the $\chi^2_{red}$ statistic such that (Andrae et al. 2010):

$$\chi^2_{red} = \frac{1}{\mathrm{k}}\sum\frac{\left(PA_e - PA_p\right)^2}{PA_p}, \tag{5}$$

where $PA_e$ was the experimental PA, $PA_p$ was the predicted PA (using a plane wave approximation), and $k$ is the degrees of freedom. The closer the $\chi^2_{red}$ value to one, the more unified the distributions, hence, the greater the agreement with the plane wave assumption (Andrae et al. 2010). Thus, for large values of $\chi^2_{red}$, it can be assumed that the sound did not propagate as a plane wave.

## Results

### In-Air Tank Setup

For the in-air configuration the SPL subjectively appeared heterogeneous across the horizontal plane for each frequency (Fig. 3), with greatest variation observed at the highest frequencies (shortest wavelength), i.e., at 1000 Hz and 2000 Hz (Table 1). The mean SPL differed by ≈6 dB between the top and bottom of the tank. The experimental PA was greater than that predicted based on the plane wave assumption, with 400 Hz exhibiting the highest levels of PA (Fig. 3). Had the sound propagated as a plane wave, the PA was predicted to increase with frequency (Table 2); however, the measured PA did not follow this trend. Hence, the two distributions were dissimilar, which resulted in large values of $\chi^2_{red}$.

### Submerged Arena Setup

In contrast to the in-air configuration the SPL in the submerged area was relatively homogeneous across the horizontal plane for each frequency (Fig. 4), with greatest variation observed at 2000 Hz (as expected, given the shorter wavelengths) (Table 3). The mean SPL differed by ≈11 dB between the top and bottom of the tank. The measured PA was lower in value than the in-air tank (Fig. 4). As with the in-air tank, had the sound propagated as a plane wave, the PA was predicted to increase with frequency (Table 2) and the experimental PA follow this trend (except for the lowest frequency considered, 400 Hz), resulting in smaller values of $\chi^2_{red}$ for 400–1000 Hz compared to the in-air tank (Table 4).

## Comparison of Setups

No difference in the variance of experimental PA was detected between the in-air tank and the submerged arena for frequencies of 400, 600, and 1000 Hz ($F = 1.450 – 0.788$; $p = 0.095 – 0.381$) but a difference in variance was detected for 800 and 2000 Hz ($F = 4.500 – 0.395$; $p = <0.001$). The type of setup had an effect on the variance of SPL for all frequencies and depths ($F = 5.533 – 2268.7$; $p = <0.001$). Results suggested that the SPLs of the in-air setup were more heterogeneous than the submerged arena.

Welch's *t*-tests were carried out, detecting experimental PA to differ between the two setups, with PA being higher in the in-air tank than the submerged arena for 400–1000 Hz ($t = 14.608–40.527$; $p = <0.001$) and lower for 2000 Hz ($t = -5.254$, $p = < 0.001$). Additionally, Welch's *t*-tests detected that the setup influenced the SPL at all frequencies and depths ($t = 6.559–28.299$; $p = <0.001$). The in-air tank setup exhibited higher mean SPLs at all depths compared to the submerged arena setup.

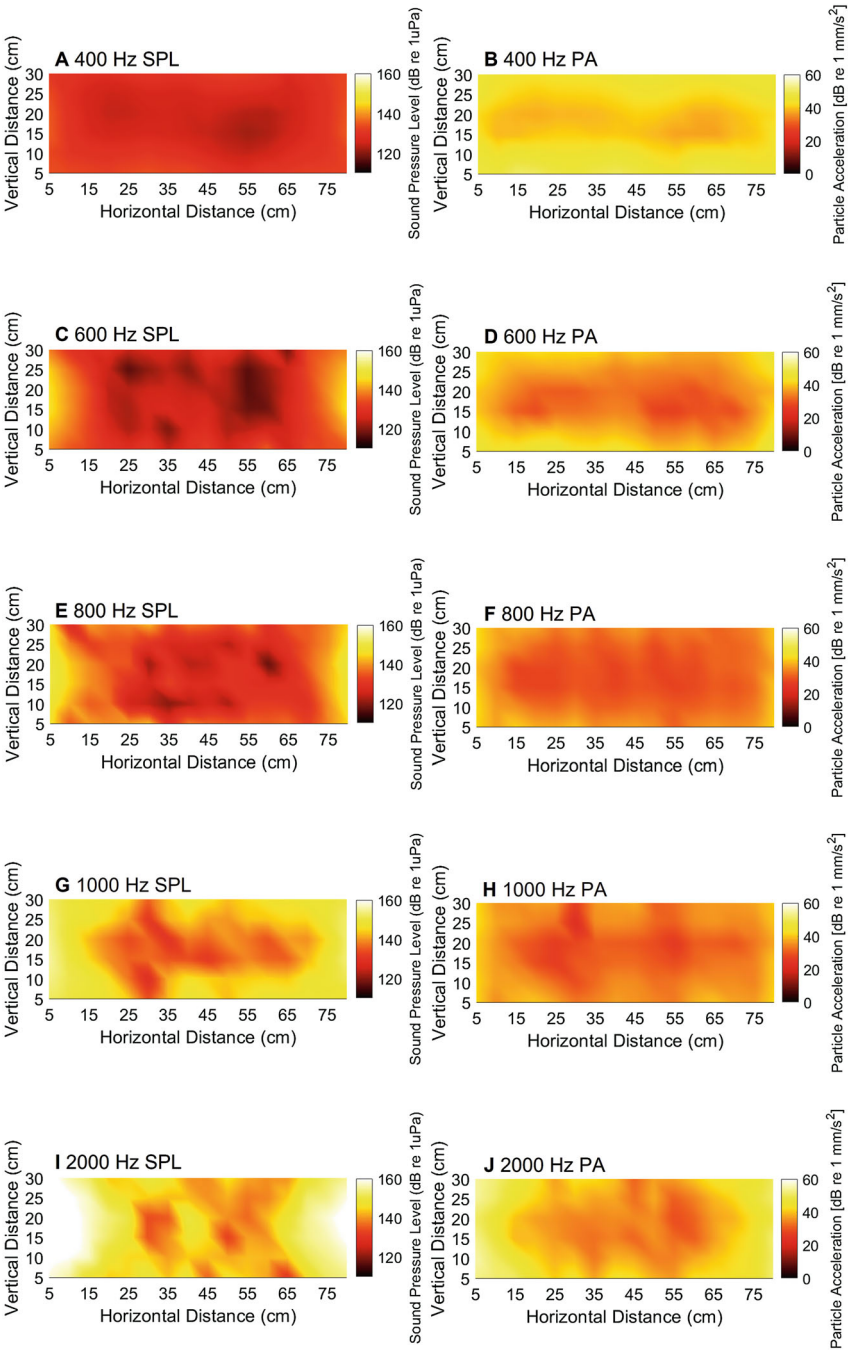

**Fig. 3** SPL maps (**a, c, e, g, i**) and PA maps (**b, d, f, h, j**) (13.5 cm depth) of a 1 s pure tone calibrated at 125 dB re 1 μPa in the center of a rectangular experimental arena (80 cm × 30.8 cm × 30.2 cm) within acrylic in-air tank (300 cm × 30.8 cm × 30.2 cm) at frequencies of 400; 600; 800; 1000; 2000 Hz

**Table 1** The mean SPL ± standard deviation of a 1 s pure tone calibrated at 125 dB re 1 μPa in the center of a rectangular experimental arena (80 × 30.8 × 30.2 cm) within acrylic in-air tank (300 × 30.8 × 30.2 cm) at frequencies of 400; 600; 800; 1000; 2000 Hz. Point measurements were taken at 3 depths (7, 13.5, 20 cm). Center SPL refers to the SPL in the center of the tank

| Frequency (Hz) | 7 cm (dB re 1 μPa) | 13.5 cm (dB re 1 μPa) | 20 cm (dB re 1 μPa) | Center SPL (dB re 1 μPa) |
|---|---|---|---|---|
| 400 | 124.3 ± 4.4 | 128.8 ± 3.4 | 131.4 ± 2.9 | 125.0 ± 0.5 |
| 600 | 128.5 ± 7.5 | 129.3 ± 7.4 | 134.8 ± 5.6 | 125.0 ± 1.4 |
| 800 | 134.6 ± 7.6 | 136.1 ± 9.2 | 138.6 ± 6.8 | 125.1 ± 2.8 |
| 1000 | 136.6 ± 8.2 | 137.7 ± 9.8 | 144.0 ± 6.2 | 125.1 ± 6.7 |
| 2000 | 136.5 ± 8.2 | 137.6 ± 9.8 | 143.9 ± 6.2 | 125.0 ± 6.7 |

**Table 2** The mean PA ± standard deviation of a 1 s pure tone calibrated at 125 dB re 1 μPa in the center of a rectangular experimental arena (80 × 30.8 × 30.2 cm) within acrylic in-air tank (300 × 30.8 × 30.2 cm) at frequencies of 400; 600; 800; 1000; 2000 Hz. Point SPL measurements were taken at 3 depths (7, 13.5, 20 cm) and PA (Experimental) was calculated from those values. PA (Predicted) was calculated using the plane wave approximation and the difference between experimental and predicted PA (Experimental – Predicted) was recorded

| Frequency (Hz) | 13.5 cm (dB re 1 mm/s$^2$) Experimental | 13.5 cm (dB re 1 mm/s$^2$) Predicted | $\chi^2_{red}$ In-air |
|---|---|---|---|
| 400 | 43.3 ± 3.4 | 12.9 ± 3.4 | 79.9 |
| 600 | 37.5 ± 5.1 | 16.8 ± 7.4 | 42.9 |
| 800 | 33.3 ± 4.3 | 19.3 ± 7.4 | 17.0 |
| 1000 | 34.3 ± 4.2 | 29.7 ± 9.8 | 4.72 |
| 2000 | 41.0 ± 6.6 | 35.6 ± 9.8 | 3.16 |

The predicted PA was calculated for both the in-air tank and the submerged arena setup, which determined the PA had the sound propagated as a plane wave. The predicted PA was then compared to the experimental PA using the $\chi^2_{red}$ statistic. For the in-air tank, the difference between the predicted PA and experimental PA was on average 15.0 ± 11.5 dB. The submerged arena had a smaller difference between the experimental and predicted PA at 10.9 ± 8.1 dB on average, depending on the frequency. The $\chi^2_{red}$ was closer to 1 for the submerged arena than the in-air tank for all frequencies except 2000 Hz. This suggests that the plane wave assumption provides a better approximation for the PA in the submerged arena than in the in-air tank.

## Discussion

Small tanks have been a subject of debate among underwater bioacoustics researchers, due to their sound field complexity, starting with the classic work of Parvulescu (1964, 1967; also see Rogers et al. 2016). If a laboratory study is necessary (due to lack of access to the field or to remove a variable that may be present in such conditions), the sound field used in this study is valid. This study consisted of two experimental tank setups and categorized a novel setup in terms

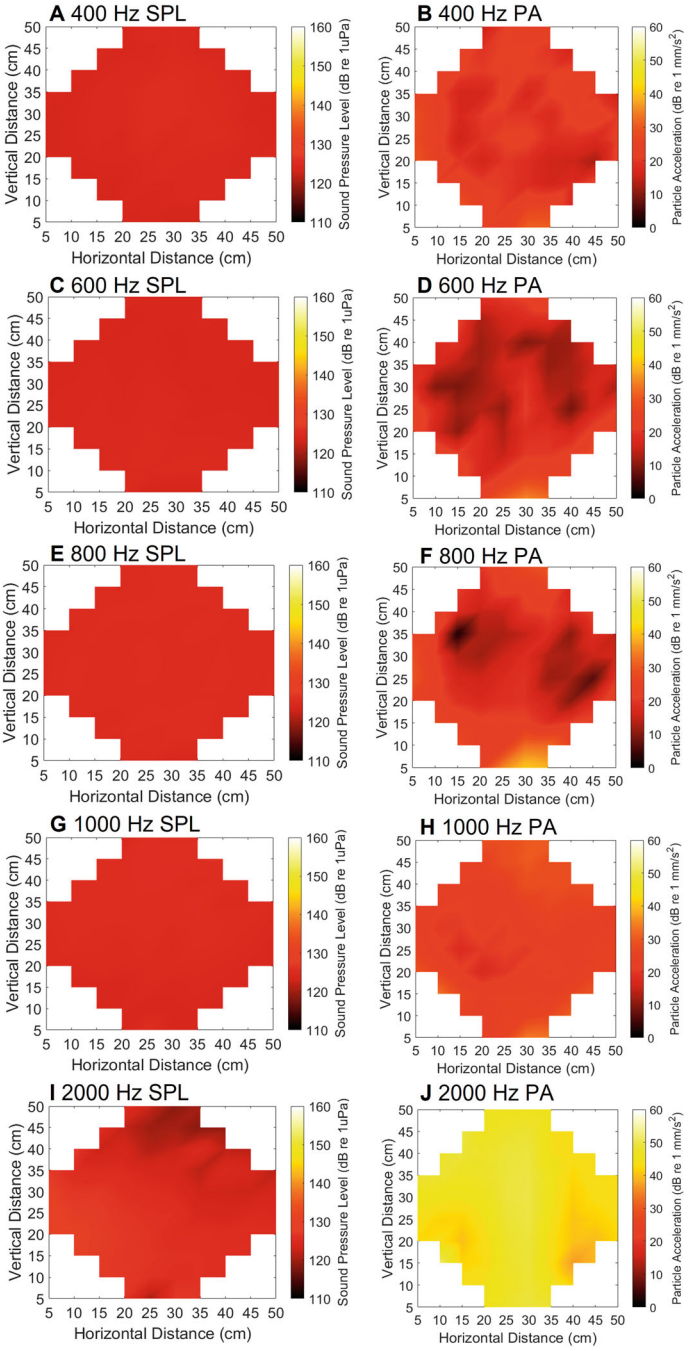

**Fig. 4** SPL maps (**a, c, e, g, i**) and PA maps (**b, d, f, h, j**) (15 cm depth) of a 1 s pure tone in the center of a cylindrical arena (55.5 cm × 45 cm) submerged in a tank (8 m × 8 m × 5 m) at frequencies of 400; 600; 800; 1000; 2000 Hz

**Table 3** The mean SPL ± standard deviation of a 1 s pure tone calibrated at 125 dB re 1 μPa in the center of a cylindrical arena (55.5 cm × 45 cm) submerged in a tank (8 × 8 × 5 m) at frequencies of 400; 600; 800; 1000; 2000 Hz. Point measurements were taken at 3 depths (5, 15, 25 cm). Center SPL refers to the SPL in the center of the tank

| Frequency (Hz) | 5 cm (dB re 1 μPa) | 15 cm (dB re 1 μPa) | 25 cm (dB re 1 μPa) | Center SPL (dB re 1 μPa) |

|---|---|---|---|
| 400 | 21.1 ± 3.8 | 8.5 ± 0.4 | 21.4 |
| 600 | 17.9 ± 5.6 | 11.9 ± 0.3 | 5.81 |
| 800 | 20.3 ± 6.8 | 15.1 ± 0.2 | 5.02 |
| 1000 | 24.8 ± 3.5 | 16.9 ± 0.5 | 4.57 |
| 2000 | 45.3 ± 3.1 | 22.7 ± 2.4 | 24.5 |

of its acoustic validity, as well as experimental control. The SPL heterogeneity was highest in the in-air tank, followed by the submerged arena, indicating that the submerged arena setup is an ideal substitute for creating a homogeneous sound field. The PA was also higher in the two in-air tanks than the submerged arena, suggesting that the submerged arena tank walls were acoustically transparent, hence reducing boundary reflections. When the experimental PA was compared to a PA predicted using a plane wave equation, the submerged arena provided a better approximation. This study provided an alternative experimental setup for performing bioacoustics studies on fish that gave greater control over the stimulus that a fish experiences in lab-based experiments in terms of SPL and PA.

For open-water fish species, experimental conditions should replicate far-field acoustics in which the PA and SPL increase proportionally (Slabbekoorn 2016). However, if in-air tanks were used for open-water species, the PA would be disproportionally larger than SPLs compared to those open waters (Parvulescu 1967; Rogers et al. 2016). Therefore, the small in-air tanks would not be representative of an open-water habitat and may lead to misleading results (Popper and Hawkins 2018). Nonetheless, fish species inhabiting shallow waters would encounter inhomogeneous sound fields due to turbulence (Tonolla et al. 2009), close top and bottom boundaries, and volume reverberation (Hawkins and Myrberg 1983;

Lynch and Newhall 2017). However, we recommend that if non-uniform sound fields were required for a particular study, it would be more valid to modify a homogeneous sound field to the desired inhomogeneity. This approach would ensure the replicability of the sound field.

The results of this study are of particular importance to hearing experiments that were historically undertaken in small, in-air tanks. However, it is also recommended that lower frequencies are also tested, since this study used frequencies above 400 Hz, which is higher than the sensitive frequencies for many fish. While the effect of small in-air tank acoustics on hearing studies has been discussed extensively elsewhere (see Rogers et al. 2016), the results from this study further suggest that some hearing experiments may be invalid due to the setup and the complexity of the sound field. In such conditions, the received level and source level may have been contradictory..

The submerged arena vastly improved the PM and SPL aspects of the sound field, primarily by reducing the average PM and reducing both SPL and PM variance. Submerging the tank in water removed air as a surrounding medium which meant the impedance and reverberation, factors that increase sound field complexity, were minimized (Rogers et al. 2016). When comparing the submerged arena to other setups, the behavioral validity remains low compared to field-based experiments but retains high experimental control, practicality, and feasibility (Slabbekoorn 2016). Compared to field-based methodologies, the acoustic validity is lower given that there was some scattering from the air-water interface, so it would be wise for a future study to compare the sound field as the submerged tank is placed further from the surface boundary (although this will make sound field mapping more difficult). An additional consideration is the effect of the swim bladder and the fish itself on the sound field (see Chapman and Hawkins 1973) and hence requires further investigation. However, there is a vast improvement to sound field homogeneity compared to small tank studies since a plane wave approximation was feasible. To be specific, the submerged arena used here, with its acoustically transparent walls, allowed the source to be placed outside of, and so at a greater range from, the working arena, which tended to decrease the radius of curvature of the wavefronts in the arena and so make the use of Eq. (2) (with its inherent plane wave assumption). This is an important consideration, especially if there is no independent way to validate the estimated PA, as is often the case in such studies. It is recommended that when cost, practicality, and experimental control limit the use of in situ studies, a submerged tank would be a suitable alternative.

## Conclusion

This study investigated two experimental setups: a ‘typical’ setup of a rectangular acrylic arena surrounded by air and placed on concrete blocks with two transducers situated in the arena and a setup of a cylindrical arena submerged in a large water tank with a speaker situated underneath. A submerged arena setup was chosen to

reduce sound field inhomogeneity so that the level received by the fish is constant and known to the experimenter, and the study is replicable. The in-air tank exhibited an inhomogeneous field with high levels of PA, while the submerged arena possessed a homogeneous sound field with PA measurements satisfying the plane wave approximation to a larger degree. While the behavioral validity of the setup does not compare with in situ studies, submerging an experimental arena greatly improves the sound field homogeneity essential for acoustic and behavioral replicability in bioacoustics studies with fish.

**Abstract**

As acoustic particle motion has been shown to be an important sensory cue for many underwater animals, particle motion fields are frequently measured and reported on for studies on these taxa. However, few studies describe the biologically relevant directional information encoded within these fields. This chapter introduces measures of eccentricity in the context of particle motion, indicating how strong the directional cues in acoustic particle motion fields are. The measures of spectral and broadband eccentricity described here can be utilized for validating acoustic fields in experimental setups, in addition to providing insight into the ability of fishes and invertebrates to determine the directions of sound sources. With the development of measures – such as eccentricity – providing a quantitative language to report on particle motion directionality, researchers are better equipped to interpret the biological relevance of the particle motion fields animals are exposed to.

## Introduction

Over the past decade, commercial vector sensors for measuring underwater particle motion have become widely available to researchers. As all fishes and many sound-sensing underwater invertebrates are sensitive to particle motion (Popper et al. 2019; Dinh and Radford 2021; Day et al. 2019), measuring and reporting this sound field component is quickly becoming standard practice within studies on these taxa (Nedelec et al. 2021). However, while vector sensor measures of particle motion inherently record biologically relevant directional information, few studies report this.

The directional information coded within particle motion allows animals to estimate the direction of sound sources, thus aiding localization (Zeddies et al. 2012; Popper et al. 1973). This is critical for behaviors related to feeding, soundscape orientation, predator avoidance, and reproduction (Nedelec et al. 2016). While previous studies have examined directional responses to sounds (Holles et al. 2013; Rollo and Higgs 2008; Mirjany et al. 2011; Schuijf and Buwalda 1975; Nelson 1967), there has been a lack of methodology for measuring the strength of directional cues coded within these sounds.

Acoustic signals can be conceptualized as sinusoidal oscillations of particle motion or sound pressure. Where pure tones are composed of a single oscillation frequency – a sine wave – broadband signals can be thought of as a superposition of these sine waves across a frequency spectrum. When measuring particle motion, a pure tone summed across the axes of a vector sensor results in a particle motion ellipse with a shape that is defined by the phase difference between the sensor axes measurements. Broadband signals summed across multiple sensor axes can also be conceptualized as superpositions of these particle motion ellipses (illustrated in Fig. 1). For a theoretical, ideal plane wave, the particle motion summed across vector sensor axes is expected to result in a straight line – where all sensor axes measure the same phase. In practice, however, there will always be small phase differences between the axes measurements, resulting from interference from reflections, environmental background noise, or limitations of the vector sensor itself, producing measures of elliptical particle motion.

Eccentricity is a standard geometric measure which describes how circular or linear an ellipse is. It's defined as

$$e = \sqrt{1 - \frac{b^2}{a^2}},$$

where $a$ and $b$ are the lengths of the semi-major and semi-minor axes of an ellipse. A value of 1 indicates an ellipse resembling a line, while a value of 0 indicates a perfectly circular ellipse. In the context of acoustic particle motion, eccentricity can be applied to particle motion ellipses to measure how directional an acoustic signal is. Signals containing strong directional cues are expected to give high eccentricity values, while non-directional, ambient sounds are expected to result in low eccentricity values (see Fig. 2). The following sections detail how to apply eccentricity to particle motion measurements in both spectral and broadband contexts. The applications of eccentricity introduced in this chapter provide a quantitative measure of how reliably the direction of a sound source can be estimated.

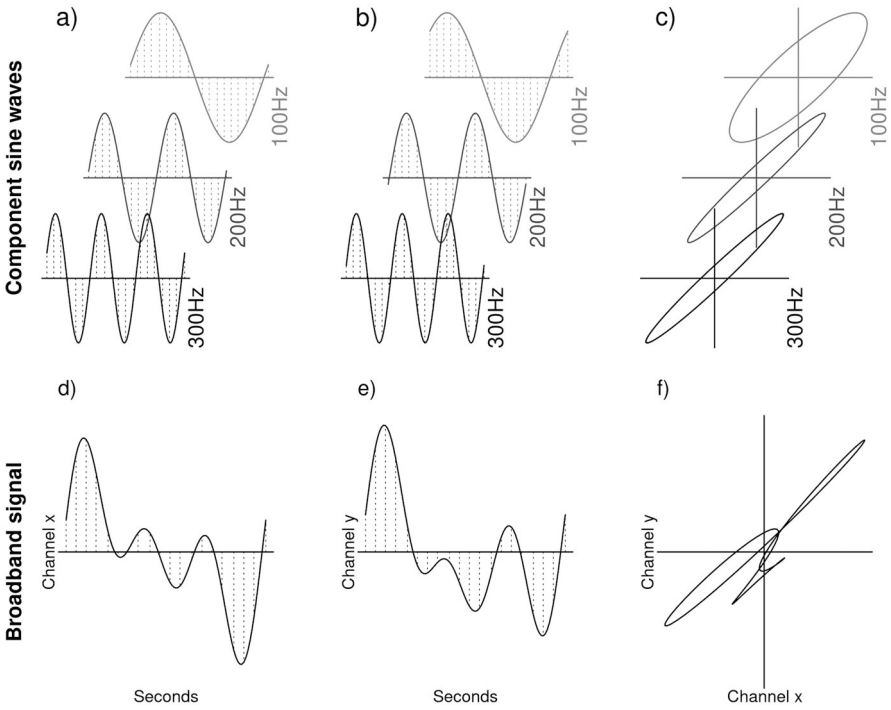

**Fig. 1** (**a**) and (**b**) show a series of sine waves which combine to make up the broadband signal measured on the horizontal channels of a vector sensor, (**d**) and (**e**), respectively. (**c**) shows the particle motion ellipses resulting from vector summing the sine waves in (**a**) and (**b**); (**f**) shows the broadband particle motion along the horizontal plane, composed of the superpositioned particle motion ellipses in (**c**). Broadband signals measured by vector sensors can be conceptualized as a spectrum of superpositioned particle motion ellipses

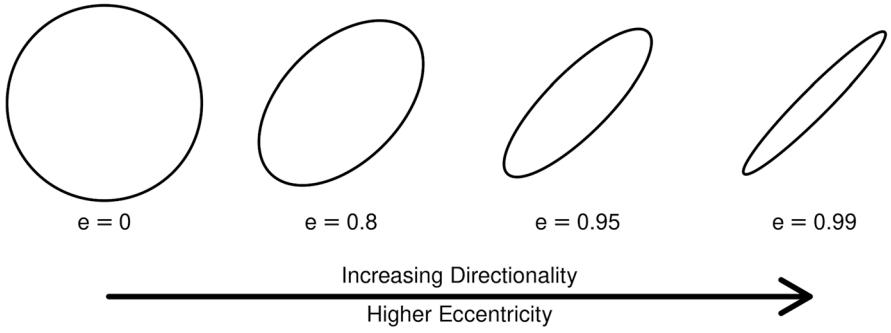

**Fig. 2** An illustration of ellipses covering a range of eccentricity values. Higher eccentricity results in more linear particle motions paths. Values of 0 result in non-directional, or perfectly circular, particle motion paths

## Spectral Eccentricity

To calculate the particle motion eccentricity for a particular frequency of a broadband signal – here termed spectral eccentricity – a discrete Fourier transform can be taken of the x and y channels, $X_f$ and $Y_f$, of the recorded sound. For a given frequency, $f$, the magnitude and phase can be used to construct a particle motion ellipse

$$\vec{p}(t) = \vec{c}_1 \cdot \cos(t) + \vec{c}_2 \cdot \sin(t),$$

where

$\vec{c}_1 = \vec{x}_0 + \vec{y}_0 \cdot \sin(\delta)$,
$\vec{c}_2 = \vec{y}_0 \cdot \cos(\delta)$,
$\delta = \arg(Y_f) - \arg(X_f) + \frac{\pi}{2}$,
$\vec{x}_0 = (|X_f|, 0)$, and
$\vec{y}_0 = (0, |Y_f|)$.

The above ellipse formula is parameterized by the vectors $\vec{c}_1$ and $\vec{c}_2$ which represent conjugate half-diameters. We can reformulate this in terms of the ellipse's semi-axes, $\vec{d}_1$ and $\vec{d}_2$, with

$$\vec{p}(t) = \vec{d}_1 \cdot \cos(t) + \vec{d}_2 \cdot \sin(t),$$

where

$\vec{d}_1 = p(t_0)$,
$\vec{d}_2 = p(t_0 + \frac{\pi}{2})$, and
$\tan(2 \cdot t_0) = \left(2 \cdot \vec{c}_1 \cdot \vec{c}_2\right) / \left(\vec{c}_1^{\,2} - \vec{c}_2^{\,2}\right)$.

Finally, the lengths of the semi-major and semi-minor axes can be measured:

$$a = \max\left(\left|\vec{d}_1\right|, \left|\vec{d}_2\right|\right) \text{ and}$$

$$b = \min\left(\left|\vec{d}_1\right|, \left|\vec{d}_2\right|\right)$$

Eccentricity can then be calculated from $a$ and $b$. Figure 3 shows an example application of this.

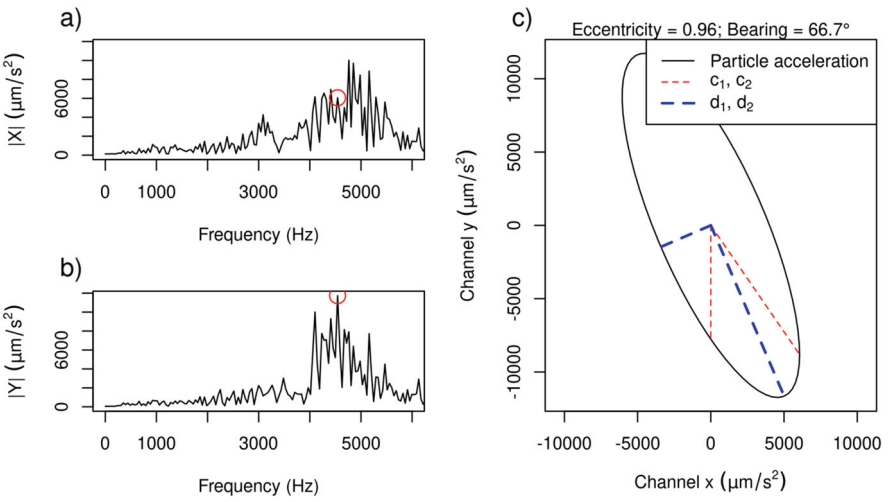

**Fig. 3** An example calculation of spectral eccentricity at 4542 Hz in the horizontal plane of a vector sensor. The signal is a particle acceleration recording of boat noise, bandpass filtered between 100 and 5000 Hz. Panels (**a**) and (**b**) show the complex modulus of the one-sided discrete Fourier transforms of the channels in the horizontal plane, x and y. Panel (**c**) shows the particle motion ellipse constructed from the complex modulus and arguments at 4542 Hz. $\vec{c}_1$ and $\vec{c}_2$ are conjugate half-diameters of the ellipse, while $\vec{d}_1$ and $\vec{d}_2$ show the semi-axes from which eccentricity can be calculated. The bearing reports the angle of the major semi-axis, $\vec{d}_1$, clockwise from the +x axis

## Broadband Eccentricity

Broadband sounds, of course, do not follow elliptical particle motion paths. In this case, eccentricity can be calculated from the confidence ellipse surrounding the particle motion measurements in the horizontal (or vertical) plane. Singular valued decomposition can be applied to the covariance matrix of the measurement axes to retrieve the axes of the confidence ellipse. Where $\vec{x}$ and $\vec{y}$ are the measured signals on the horizontal plane axes of the vector sensor, eccentricity is given by

$$e = \sqrt{1 - \left( \frac{\min\left(\text{diag}^{-1}(D)\right)}{\max\left(\text{diag}^{-1}(D)\right)} \right)},$$

where

$UDV' = \Sigma$, and
$\Sigma = \text{cov}\left(\vec{x}, \vec{y}\right)$.

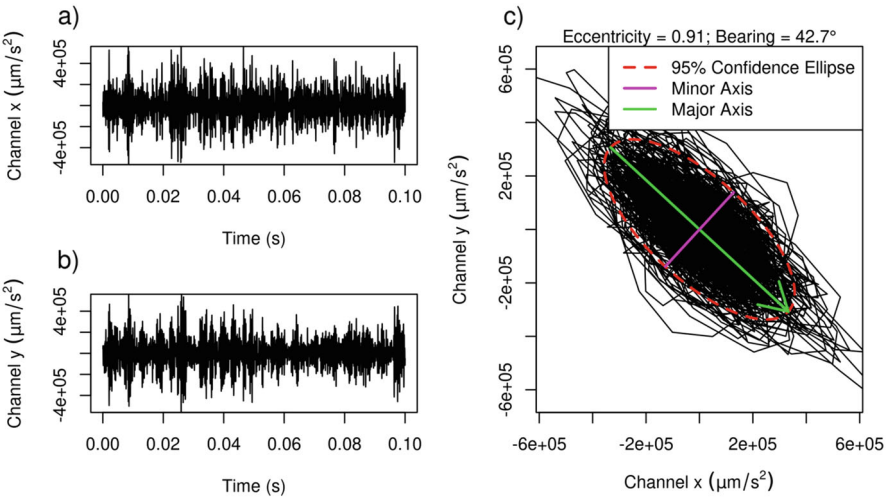

**Fig. 4** An example calculation of broadband eccentricity in the horizontal plane of a vector sensor. The example recording is the same used in Fig. 3. The red dashed line is the confidence ellipse of particle acceleration measures from which eccentricity can be calculated from the major and minor axes

*U*, *V*, and *D* represent the left singular vectors, right singular vectors, and singular values, resulting from singular valued decomposition of the covariance matrix, Σ. The maximum and minimum values of the diagonal entries of *D* give the squared major and minor axes, $a^2$ and $b^2$, respectively. Figure 4 illustrates eccentricity calculated from broadband signals.

## Discussion

As the use of vector sensors in underwater sound studies becomes commonplace, a new suite of bioacoustic measurements is called for that considers the directional nature of acoustic particle motion. To investigate ecological processes that make use of sound source localization, measurements which first describe the directional information coded within acoustic particle motion are required. The broadband and spectral eccentricity measures introduced here provide an intuitive measure of the strength of these directional cues.

The interpretation of particle motion eccentricity in the context of sound source localization is simple. Sounds with strong directional cues – loud sounds, relative to ambient, from a single source which travel along direct paths – result in more linear particle motion and high eccentricity. Sounds with weak or convoluted directional cues – resulting from interference from multipath reflections, ambient sources, or low signal to noise ratios – will give lower eccentricity values and are expected to be difficult to localize.

While eccentricity can be calculated from any particle motion component: displacement, velocity, or acceleration; particle acceleration is a natural choice for

calculating eccentricity as it is in accordance with best practice guidelines on particle motion measurements (Nedelec et al. 2021) and fishes are expected to directly sense particle acceleration (Fay and Edds-Walton 1997). Finally, eccentricity can easily be calculated for particle motion in 3D space.

A natural application of particle motion eccentricity is the validation for experimental sound fields. Acoustic conditions in experimental setups, particularly in small aquaria, have long been a focus of criticism (Parvulescu 1967; Rogers et al. 2016). Reporting values of eccentricity for directional sound stimuli, along with the particle acceleration and pressure fields in aquaria, provides a comprehensive description of acoustic conditions, facilitating comparisons to natural environments.

Additionally, little is understood about the challenges of localizing sounds in natural environments. Often, fish and invertebrates live in acoustically complex environments, surrounded by hard, reflective substrate. Hence, ecologically important sounds can be expected to contain confounding directional information. Examining the quality of naturally occurring or anthropogenic directional acoustic cues may provide insights

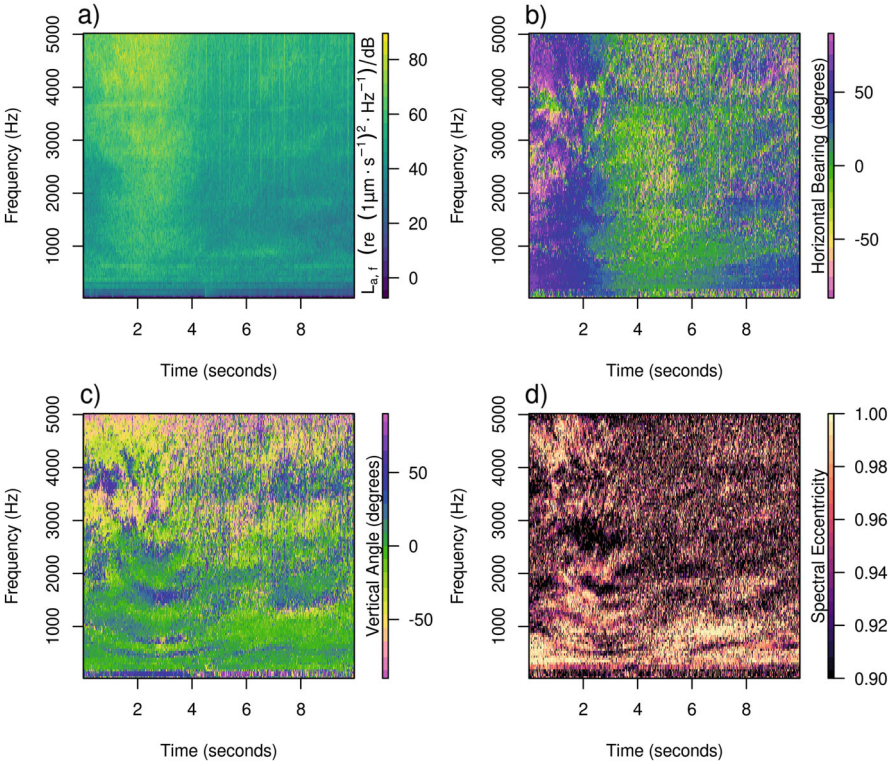

**Fig. 5** Directional bearings and spectral eccentricity calculated from three axes of a vector sensor. The example recording is the same used in Figs. 3 and 4. (**a**) shows a spectrogram of particle acceleration. (**b**) and (**c**) show the horizontal and vertical particle acceleration bearings – the major axis of particle acceleration – of the passing boat. (**d**) shows the particle acceleration spectral eccentricity measured in three dimensions. High vertical angles (40–50°) are associated with low eccentricity, suggesting that these values contain weak directional cues

into the behaviors and life history of animals residing in these complex environments. Highlighting the complexity of directional sounds, Fig. 5 shows a directional spectrogram (also termed "directogram") of a boat passing a coral reef, recorded by a vector sensor. The vertical angles reported are frequency dependent, varying from 0° to 50° as the boat passes. When taking into consideration spectral eccentricity, many of the high vertical angles are correlated with low spectral eccentricity – suggesting confounding directional cues at these high vertical angles. Here, a single anthropogenic sound source results in frequency-dependent localization bearings and eccentricity values, providing a convoluted sound field to localize.

In conclusion, while the reporting of directional sound in underwater bioacoustic literature has so far been sparse, these eccentricity measurements provide a quantitative language for discussing the strength of directional acoustic cues. It's hoped that this introduction of particle motion eccentricity will stimulate the development of further descriptive acoustic metrics.

**Acknowledgments** We thank Geospectrum for supplying the M20 vector sensor used to measure the sounds reported in this chapter.

**Abstract**

Sound pressure and particle motion form the basis of discussions regarding potential effects of anthropogenic signals on fishes and aquatic invertebrates. However, there is a growing need to acknowledge, and understand, a third class of stimuli involving substrates. The vibrational channel is a major sensory mode in the animal kingdom. Numerous terrestrial animals, from the fruit flies to the largest of land mammals, use substrate-borne vibrations to find prey, detect

predators, sense environmental change, and to communicate. Yet although many aquatic organisms reside on, in, and around substrates, how animals use vibrational information in this environment has, to date, been largely overlooked. This is all the more important given that many anthropogenic activities directly contact the seabed, eliciting significant vibrations in the substratum. To better understand the role of vibrational signals to aquatic animals, lessons can be taken from the terrestrial environment, from the discipline of biotremology. This chapter provides a refined definition of biotremology to allow inclusion of aquatic systems and discusses the alignment of terminology required to apply vibrational principles to the aquatic world. Future discussions in this area are necessary to aid the progression of both underwater noise and aquatic biotremology research.

## Introducing Biotremology

### Vibrational Waves

This chapter discusses substrate-borne mechanical waves. These occur in the boundary between two media where particle motion is perpendicular to the direction of wave travel. These waves, detected by a nonpressure detecting sensor or structure, are utilized by a range of animals for vibrational sensing and communication, and are studied in a rather new discipline of study known as biotremology (Hill and Wessel 2016; Hill et al. 2019a, b) (Fig. 1). The strict definition of biotremology will be discussed in later sections. Bioacoustics as a discipline is here distinct, defined by the

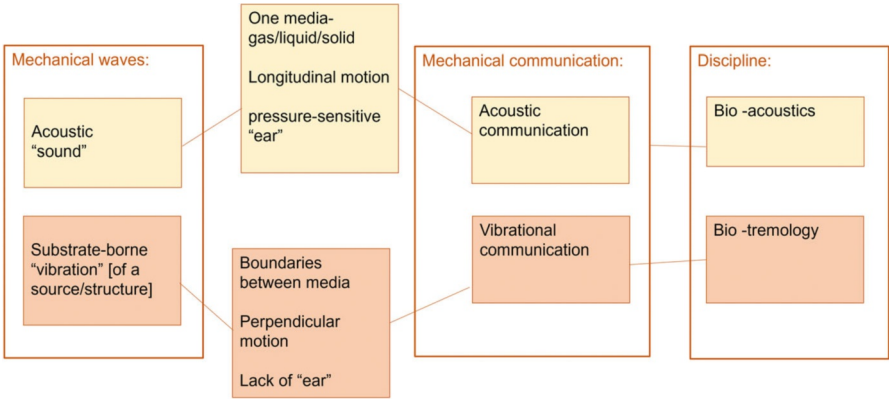

**Fig. 1** Distinctions between bio-oscillology disciplines: bioacoustics and biotremology (a table adapted from Hill and Wessel 2016)

study of acoustic (compressional) waves ("sound"), traveling in one medium, detectable by a pressure sensitive ear, or pressure difference, sensitive organ, the ear (Ewing 1989).

There are several different vibrational waves, characterized by wave speed and particle motion direction (Markl 1983; Aicher and Tautz 1990). These include compressional (sound) P-waves, transverse S-waves, and surface waves at boundaries. Studies have found, however, that terrestrial animals using vibrations are sensitive to surface waves, either Rayleigh (Sholte in aquatic) or Bending or Love waves (this last being only described as used for one situation, Aicher and Tautz 1990). These waves are termed "substrate-borne vibration." Vibrational waves propagate through a wide range of substrates), with the variability of substrates (e.g., soil, sand, clay, leaves, etc.) affecting vibrational transmission (e.g., Athanasopoulos and Pelekis 2000; Magal et al. 2000; O'Connell-Rodwell et al. 2001).

## Measurement of the Vibrational World

Vibrations, like sounds, are all around us. Substrate-borne vibrations form a vibrational landscape recently called the vibroscape (Roberts and Elliott 2017; Šturm et al. 2021). The vibroscape includes geophysical, anthropogenic, and biological vibrational components, in addition to indirect vibrations caused by airborne sounds. By pointing a laser at the stem of a red clover plant (*Trifolium pratense*), for example, researchers have eavesdropped on a world of vibrational signals, which vary with season, plant species, and location (Šturm et al. 2021). The acoustic equivalent of this is termed the soundscape (a collection of sounds, Pijanowski et al. 2011).

Measuring vibrations (and sound) depends largely upon the study animal or surface in question (Nieri et al. 2022). For example, the drumming of a ghost crab (Ocypode *spp,*) can be measured both as an airborne or ground-borne sound (microphone, Fig. 2 upper right), or as a vibration on or within a substrate (geophone, accelerometer, piezodisc – Fig. 2, left). Vibrations may also be measured via a noncontact laser doppler vibrometer, pointed at the crab body (Fig. 2 upper right).

## Terrestrial Animals Using Vibrations

Which animals are using substrate-borne vibrations? The most recent biotremology book documents animals from bees, planthoppers, beetles, ants, caterpillars, to frogs, mole rats, birds, and snakes (Hill et al. 2022), although the list of animals extends way beyond these (Hill 2008).

For many animals, vibration plays a significant role in communication (e.g., courtship, group co-ordination), as well as sensing the environment (e.g., source localization, predator–prey interactions, abiotic source detection) (Hill 2001, 2008, 2009). The chewing vibrations of caterpillars such as the beet armyworm (*Spodoptera exigua*), for example, can be recorded on leaves (Velilla et al. 2020). Other caterpillars such as the masked birch caterpillar (*Drepana arcuata*) produces

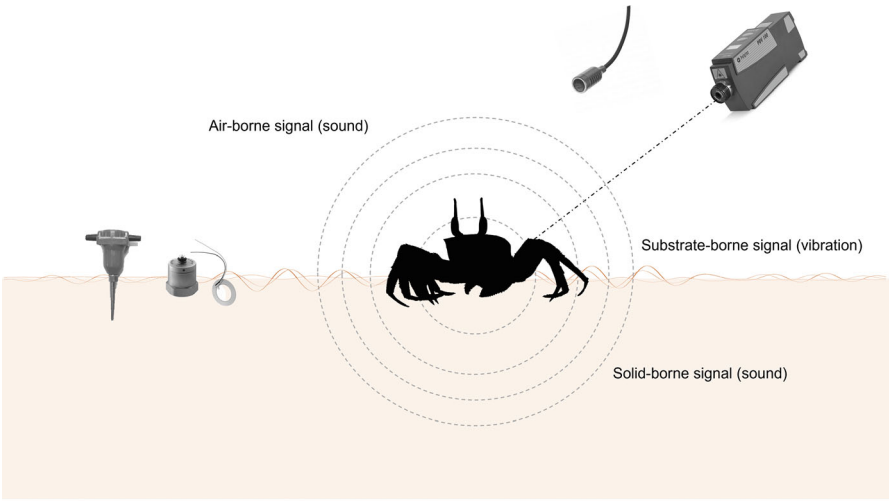

**Fig. 2** A ghost crab (Ocypode spp.) drumming on the sand producing signals that may be measured above, below, and at the surface of the sand as sounds and vibration

vibrational signals to defend its silk shelter on the leaf surface (Yadav et al. 2017). Underground, rhino beetle larvae (*Trypoxylus dichotoma*) actively beat against their pupal case when approached (Kojima et al. 2012), and white grubs (Scarabaeidae larvae) stridulate (Görres and Chesmore 2019). Other vibrational behavior is more visible and functions as a prey lure, such as the twitching of cane toad toes (*Chaunus marinus*) and the paddling of bird feet (Tinbergen 1962; Hagman and Shine 2008). More examples are explored in Roberts and Wickings (2022).

## Aquatic Vibrations

### Vibrational Waves in Aquatic Substrates

Much less is known about vibrations in aquatic environments (Roberts and Elliott 2017). Yet there are a range of substrates present, from biological surfaces (e.g., macroalgal fronds, sessile animals), abiotic surfaces (soft, hard sediments, the water surface), and even anthropogenic surfaces (supporting structures of offshore platforms, shipwrecks), which may transmit vibrations. As in terrestrial environments, vibrations may be produced directly, or indirectly (e.g., via water-borne sound), traveling long distances through denser surfaces making the seabed an additional communication medium. Animals may be in contact with vibrations when hidden inside substrates, traversing substrate surfaces, or both. The time in contact with substrates will vary according to life stage, time, and activity. While not traditionally charismatic, many of these species may be commercially relevant, and crucial to the ecosystem.

## Aquatic Animals Using Vibrations

The collection of evidence to support aquatic biotremology within the broader discipline of biotremology includes definite examples, plus some suggestions (reviewed in Roberts and Wickings 2022). Collated vibrational sensitivities of aquatic organisms to vibrations (unspecified mechanical wave types) show that a range of aquatic groups can detect vibrations (Frings and Frings 1967; Budelmann 1992; Roberts and Elliott 2017), though it is currently unclear *which* substrate waves are relevant to aquatic animals. It is hypothesized that Sholte (Rayleigh) waves are likely involved due to their propagating further than other substrate-borne waves and because they are also used extensively by terrestrial animals.

On the seashore, semiterrestrial crabs, the fiddler and ghost crabs (family Ocypodidae), are well-documented vibrational "drummers" and "rappers" producing substrate-borne signals (reviewed in Popper et al. 2001). Other crustacean producers include (terrestrial) hermit crabs residing on the seashore (*Coenobita* spp.) which produce "chirps" measurable as sand vibrations (Roberts 2021). Underwater, mantis shrimps (*Hemisquilla californiensis*) produce a low frequency "rumble" from within and around burrows in sediment (Staaterman et al. 2011), though so far measured only in the water but a strong contender for a vibrational signal.

Near the seabed, haddock (*Melanogrammus aeglefinus*) produce "knocks" and "hums" and other water-borne mechanical vibrations known as "sounds," while either on or close-by to the bottom (Casaretto et al. 2014; Hawkins 2022). Other fishes, such as the three-spined toadfish (*Batrachomoeus trispinosus*) "hoot" and "grunt," or "croak" and "drum" (e.g., the Sciaenidae), while directly contacting the bottom (Ramcharitar et al. 2006; Rice and Bass 2009).

Mollusk and urchins feeding directly on algae covered substrates use a specialized structure, the radula, to "scrape" and "rasp" (for example, in limpets, Barber et al. 2015). Vibrations of limpets scraping upon rocks are therefore measurable on the shell (Parpagnoli and Chelazzi 1995) and are likely measurable upon the substrate. Sounds of urchin feeding translate indirectly into the water column (Radford et al. 2008) yet the substrate vibrations of this feeding have not been measured directly.

## Humans as Vibration Producers

Another key contributor of aquatic vibrations are humans (Roberts and Elliott 2017; Hawkins et al. 2021). Just as any animal touching a substrate can create vibration (Aicher and Tautz 1990), so too can any human or human technology. In much the same way as sediment type and particle size is related to benthic communities (Sivapriya et al. 2022), sediment and substrate composition relates to vibrational wave propagation (Elias et al. 2010). There is evidence that vibrational noise has similar effects as acoustic noise, including physiological and behavioral changes, and in some cases damage (Roberts and Howard 2022). However, the range of species tested is limited so far in both terrestrial and aquatic environments (Roberts

and Howard 2022). The lack of research attention may be due to a human bias toward air or water-borne sounds, which they more easily detect.

Transport, energy development, harvesting, and construction, directly and indirectly, produce vibrations in the seabed and other substrates (Roberts and Elliott 2017; Hawkins et al. 2021). Crucially, these vibrations radiate outward from a source and travel kilometers trapped in the surface (Hazelwood and Macey 2016). Further details of these waves are provided in Hawkins et al. (2021). Example sources include pile driving, dredging, trawling, explosions, and seismic surveys. These sources produce low frequency Sholte waves known as seabed vibrations or ground roll, which can also cause evanescent pressure waves in the water above (Hawkins et al. 2021).

Estimates of the impact ranges of various vibrational sources related to flounder (*Paralichthys dentatus, Pseudopleuronectes americanus*), American lobster (*Homarus americanus*), hermit crab (*Pagurus bernhardus*), and mussel (*Mytilus edulis*) sensitivities have been undertaken (Roberts et al. 2015, 2016; Miller et al. 2016). As an example, blasting and dredging are detectable by hermit crabs up to c.a. 300 m and c.a. 200 m from source, respectively (Roberts et al. 2016). Note however, in a similar way to water-borne sound, impact ranges of vibrational sources are highly contextual and source-receiver dependent.

Perhaps this may seem too speculative, but it is accepted now that many fishes detect particle motion alone, despite only a few species being directly tested (reviewed most recently in Popper et al. 2019; Popper and Hawkins 2018; see also Chapman and Sand 1974; Hawkins and Johnstone 1978). In contrast, vibrational sensitivity thresholds have been experimentally defined for around 10 invertebrate species (Roberts and Elliott 2017) and including tests on some fishes (Berghahn et al. 1995). However, as with fish hearing studies, there is currently no standardized method for establishing vibrational sensitivity.

## Alignment with Biotremology Terms

### Aquatic Biotremology

The majority of the research within the discipline of biotremology so far has been based upon terrestrial animals residing on substrate-air boundaries. However, the same principles are applicable to water-substrate and water-air surfaces. Given the infancy of the aquatic research area, it seems helpful to begin a discussion of terminology and suggest an alignment of terms between terrestrial and aquatic environments before terms diverge. The discussion here should be viewed as a starting point for future discussions between both disciplines. A conversation analysis will be necessary to aid the progression of underwater noise and aquatic biotremology research.

**Textbox 1. The Discipline of Biotremology, as Defined by Hill and Wessel (2016)**
"Biotremology is the study of mechanical communication by surface-borne waves.

Surface-borne waves: waves (Rayleigh or bending [or Love]) at a boundary between two distinct media-particles oscillate in all three dimensions with the major amplitude perpendicular to the direction of the wave and the plane of the surface."

First, consider the original definition of biotremology (Textbox 1). Does this current definition incorporate aquatic animals and surfaces? How does this definition deal with the water or sediment surface? The answer depends on definitions of "surface," "surface-borne waves," and "boundary." For clarity, these are now defined more clearly in our proposed redefinition of biotremology, given in Textbox 2.

**Textbox 2. A Revision of the Current Definition of Biotremology, Based Upon Textbox 1**
"Biotremology is the study of organismal vibrational behavior and biocommunication in regard to mechanical *substrate-borne waves* at media boundaries (boundary and surface waves).

Substrate-borne waves: (Rayleigh, Sholte and Love waves) propagate along the *boundary between two media* with different properties in terms of density, stiffness and viscosity; particles of the more dense/stiff/viscous medium, i.e. the substrate, oscillate in all three dimensions with the major amplitude perpendicular to the direction of the wave.

The media boundary is a more or less steep gradient in the media properties (and is regarded as boundary if the gradient steepness in relation to wavelength allows for the development of surfaces waves) and has therefore a *depth."*

The main change here is a shift from "surface" to the broader term "substrate"-borne waves. Note that this change is in line with a previous suggestion (Hill et al. 2019a, b). Surface does not account for the "depth" of a substrate, and there are difficulties when considering the water column. Instead "substrate" is defined in Textbox 2 as the more dense/stiff/viscous medium of the substrate, within which particles undergo the elliptical oscillations of interface waves. This means, according to the definition, that water could be classed as a substrate at the boundary with air, and not as the substrate at the boundary with sediment.

Previously, substrate was defined as "the surface of solid matter an animal is living on, be it a wooden or soft part of a plant, terrestrial or underwater ground, or the surface of water to air" (Hill and Wessel 2016) in line with the ecological

definition of substrate. For example, aquatic substrates could encompass firm sediments, solid substrata, human artificial structures, algal fronds, and perhaps even sessile animals themselves, that is, those maintaining a structural integrity underwater, being denser than water. The gray area there, however, was "solid," which does not account for fine particulate soft-bottom sediments, for example.

In Textbox 2, the boundary of the media is defined, allowing inclusion of (a), but exclusion of (b):

(a) **Near-field "sound,"** i.e., in air or in sediment and water as "evanescent sound waves" (Hawkins et al. 2021); oscillation without the establishment of a P-wave, thus, no energy propagation (energy loss) occurs. The transformation of waveforms is accompanied by loss of mechanical energy, i.e., heat production, at the media boundary.
(b) **Substrate(-borne) sound**, i.e., the solid-borne compressional fraction of the signal, traveling as pure P-waves in homogeneous extended substrates; termed "solid compression waves" (Hawkins et al. 2021).

Use of "substrate" is also preferable in aquatic systems, rather than "sediment," "seabed," or "seafloor," since it is a broader term encompassing more breadth of physical location and habitat. The term "seismic" is avoided since aquatic substrates transmitting vibrations may include more than the ground alone. Within marine ecology, there are also terminology differences for this water-sediment boundary (e.g., deep sea benthic ecology versus benthic ecology), which the term "substrate" bypasses.

Given the novelty of this subject in aquatic systems, appending "aquatic" to biotremology is suggested for clarity, to emphasize the distinction from the terrestrial literature base (and therefore other interfaces) for the near future.

## Water-Borne Particle Motion

In aquatic bioacoustics the terms "water-borne particle motion" and the broad term "particle motion" are used extensively (Nedelec et al. 2016; Popper and Hawkins 2018). For the sake of this section these are termed "particle motion" (here discussing particle motion rather than flow). In the far field, particle motion and pressure are related (reviewed in Nedelec et al. 2016) with reflective boundaries changing this relationship. Currently, aquatic particle motion detectors fall within aquatic *bioacoustics* and *hearing* studies, although they are often described as being *vibrational* detectors. Is there a case for these animals being part of aquatic biotremology? From a biotremologists perspective, the question would be: What triggers depolarization of the detectors? If pressure, then study of these belongs to bioacoustics. If particle motion, then study of these *could* belong to biotremology.

Varying definitions of "hearing," "vibration," "particle motion," "boundary," and "substrate" between disciplines, however, make this discussion difficult. Substrate-borne vibration, for example, is used solely for boundary waves in biotremology (see

above), whereas in aquatic bioacoustics the term includes solid compressional waves. Often "vibration" is used synonymously with sound (especially in earlier literature, but even today), regardless of medium, while biotremologists are more specific. Along similar lines, particle motion could be "sound" or "vibration" depending on the discipline.

What biotremologists call sound and vibration is linked to historical usage, more than a strict definition based in physics. Sound and substrate-borne vibration are propagated as mechanical waves that can be described as both vibrational and acoustic waves in nature. The separation is based in the well-established use of "sound" for all mechanical waves that propagate as P-waves and are detected by animals with some sort of ear, using pressure or pressure-difference receivers. Biotremologists, who are acknowledged as mostly studying terrestrial animals (section "Terrestrial Animals Using Vibrations"), are attempting to develop a cohesive vocabulary at the same time as the discipline is expanding to include gray areas such as aquatic zones. Additionally, the vocabulary development is occurring at a time when publications within biotremology are increasing exponentially in number (Hill et al. 2022). Is there an argument that a watery medium can be a substrate? This is a new challenge still being explored, but it looks promising.

From a physical viewpoint, as described above, substrate-borne motion directly *at* media boundaries is more complex and mechanically different than particle motion away from boundaries. Substrate-borne motion cannot be calculated from pressure measurements. Is it then distinct from particle motion in a single medium?

Particle motion encountering a boundary may excite substrate-borne waves, and, in fact, across the air-solid boundary, waveforms in one excite waveforms of the other across the boundary. Thus, one event can initiate both sound and vibrational waves, detected as sound or substrate-borne vibration by animals at the boundary.

A benthic animal very likely detects both the water-borne particle motion and the substrate-borne waves using the same sensory structures, even though research focused on this distinction is still expanding. It is accepted that the majority of fishes and invertebrates detect particle motion rather than pressure, lacking a pressure-related organ/"ear" and also air-filled cavities (Budelmann 1992; Popper and Hawkins 2018). These receivers fall firmly in the *biological* definition of biotremology, due to using a nonpressure sensor to detect particle motion. As an example, flatfish such as the European plaice (*Pleuronectes platessa*) are sensitive to particle motion (Chapman and Sand 1974; Sigray et al. 2022) and are also responsive to substrate vibration from shakers (Berghahn et al. 1995). Use of the term particle motion to describe plaice hearing, then, would be an incomplete description of sensory capabilities, while also omitting substrate motion. Note, "hearing" in *biotremology* only includes animals detecting pressure from sound waves (but definitions of hearing vary between the disciplines – another area ripe for discussion). P-waves, as all mechanical waves currently known to us, also propagate via particle motion, but the detection is performed (exclusively) by pressure or pressure-difference receiver organs (tympana, swim bladders or other gas-filled organs in fishes: termed "acoustic transformers"; Popper and Hawkins 2018), which convert it to the particle motion in the inner ear.

## Anthropogenic Stimuli

A number of synonymous terms are used currently to describe vibrational stimuli of anthropogenic origin within an aquatic substrate (Table 1). At present, these are not typically aligned with particular substrate waves (e.g., compressional, shear, or Sholte/Rayleigh).

A workshop to discuss the use of these terms would be extremely valuable to the field. However, in the meantime the following is suggested. Although terms such as "ground, seabed, sediment and seismic" cover the applied side of aquatic biotremology (e.g., anthropogenic noise), they do not address all biologically relevant aquatic substrates and therefore should be avoided. The use of "particle" terms may cause confusion with water-borne stimuli, see previous section. "Vibration" and "underwater vibration" alone are too broad.

Given the common use of "water borne particle motion," a substrate-based version could be used, "substrate borne particle motion." However, given the previous explanation this should be avoided due to the following reasons: (1) the

**Table 1** Terms currently used in the aquatic literature relating to substrate-borne vibrations (Roberts et al. 2015, 2016; Spiga et al. 2016; Roberts and Elliott 2017; Fitzgibbon et al. 2017; Morris et al. 2018; Roberts and Laidre 2019; Day et al. 2019, 2020, 2022; Cote et al. 2020; Aimon et al. 2021; Hawkins et al. 2021; McCauley et al. 2021; Popper et al. 2022; Roberts and Howard 2022; Jézéquel et al. 2022). Organized by a first grouping term, and appended second term, e.g., "Ground acceleration," "Ground motion," "Ground vibration"

| First term | Second term |
|---|---|
| Anthropogenic | Vibration |
| Ground | Acceleration<br>Magnitude<br>Motion<br>Vibration<br>Roll |
| Ground-borne | Acceleration/velocity<br>Vibration<br>Signal |
| Interface waves | |
| Mechanical | Vibration<br>Wave |
| Particle | Motion in the seabed<br>Velocity/acceleration |
| Seabed | Vibration |
| Sediment | Vibration |
| Seismic | Noise<br>Interface waves |
| Substrate-borne | Particle motion<br>Energy<br>Vibrations<br>Vibrational noise |
| Substrate | Motion |
| Underwater | Vibration |
| Vibration | |
| Vibrational | Stimuli<br>Noise |
| | Wave |

term implies that particle motion of water and substrate are in the same direction of travel, and are the same wave types; (2) this may lead to measurement confusion and assumptions, such as that measuring particle motion may allow estimation of substrate-borne vibration, and vice versa.

It is suggested that aquatic terms are aligned to current biotremological terminology. That is, using the term "substrate-borne" appended accordingly, and "vibrational noise." Where a noise source is measured as a seismic interface wave, it is suggested that "groundroll" is appropriate (Hawkins et al. 2021) with the caveat that the term alienates the aquatic literature from the terrestrial. More precise terms such as Sholte waves, would be encouraged, as long as keywords of "substrate-borne" are additionally included.

## Conclusions

Here a necessary refinement and update of the definition of biotremology allows an incorporation of aquatic animals and associated surfaces. This brings the terrestrial and aquatic systems into alignment, increasing connectivity of both research areas.

Researchers are encouraged to develop approaches to analyzing sensitivities and responses to vibration in the aquatic environment and to measure substrate-borne vibration (alongside water-borne particle motion and pressure, where appropriate) in *any* noise exposure study involving animals residing upon, in, or just above a substrate. This is particularly important given that many anthropogenic activities directly contact the seabed, eliciting significant vibrations in the substratum.

Most importantly, this chapter highlights a need for standardization of terminology between the disciplines of bioacoustics and biotremology. However, to standardize terms, they must be discussed *within* and *between* each discipline. As an example, there is disagreement in terms between researchers studying different animal groups, as well as different stimuli.

What overall conclusions can be drawn? Only a cautionary note, rather than a recommendation; it is suggested that aquatic researchers consider the range of habitats that their study animal occupies. Should the animal encounter water-sediment or water–air interfaces at any time, then the use of "particle motion" in relation to hearing and noise creates confusion between the two disciplines and only elicits the question "which type of mechanical wave is being detected?" However empirical data are required to investigate whether such animals respond to substrate-borne waves, before they could be definitively classed within the realms of biotremology.

**Acknowledgments** Thank you to the late Richard Hazelwood for his contribution to this research field, and for all our inspiring discussions throughout the years, including discussion regarding this manuscript.

Thank you to the AN2022 organizers for the keynote talk invitation, and to the audience for their support and enthusiasm about the talk topic. Peggy Hill and Arthur Popper are thanked for discussions, revisions, and advice. Shane Guan is thanked for terminology discussions. Recordings taken by the following researchers were played out during the associated AN2022 talk (with

permissions): John Sloggett, Rick Shine, Africa Gomez, Estefania Velilla, Jayne Yack, Jernej Polajnar, Rok Šturm, Carolyn Görres, Ken Catania, Erica Staaterman, and Anthony Hawkins. Talk illustrations were by scientific illustrator Ann Sanderson (www.annsciart.com).

**Abstract**

The Adriatic Sea hosts numerous Natura 2000 sites and protected areas but it is an underwater noise hot spot in the Mediterranean Sea. This calls for managing measures. The SOUNDSCAPE project developed for a transnational assessment of the underwater sound in the Northern Adriatic Sea. Underwater sound modeling at the basin scale was performed by Quonops© by using oceanographic data developed by CNR-ISMAR as input data, together with automated information system (AIS) vessel data. Acoustic measurements based on nine monitoring stations were used to calibrate the model. A yearlong (2020) 3D simulation was run, and two sets of monthly maps were produced: the "natural ambient noise" based on the oceanographic data and the "baseline ambient noise" created by adding to natural maps the ship traffic (AIS data). Maps showing sound pressure levels for four one-third octave bands centered at 63 Hz, 125 Hz, 250 Hz, and 4000 Hz were calculated for three depth ranges. This first atlas of maps contributes to filling a relevant knowledge gap about the underwater sound distribution in the study area.

Underwater noise · Acoustic modeling · North Adriatic Sea · SOUNDSCAPE project

## Introduction

The attention on the underwater noise as emergent pollutant is growing in the last decades. Human activities have been recognized as relevant sources of underwater noise for the seas and oceans (Duarte et al. 2021). Dealing with such a pervasive, transnational pollutant is the future challenge for policymakers and environmental managers. Natural and anthropogenic noise sources are distributed along the coast and the open sea. The underwater sound levels are the result of the sources distribution and the sound propagation, which, in its turn, is influenced by environmental factors, such as bathymetry, seabed sediment type, water temperature, and salinity. Despite this high level of complexity, numerical simulation based on acoustic modeling allows to estimate the spatiotemporal distribution of sound levels at basin scale (Jensen et al. 2000).

The Marine Strategy Framework Directive (MSFD) 2008/56/EC, adopted by the European Union in 2008, directly addresses the underwater noise as new pollutant (Merchant et al. 2022) and prescribes to monitoring and mapping the underwater noise linked to maritime transport. The calculation of the underwater sound levels generated by anthropogenic activities using numerical models can support the legislative requests and the evaluation of potential impact on species of interest. Following MSFD guidance, several international programs dedicated to underwater noise have been developed in Europe covering important European seas (reviewed by Merchant et al. 2022). Nevertheless, long-term information on continuous underwater sound levels in the Mediterranean Sea is still poorly available. To fill this gap, the Italy-Croatia Interreg SOUNDSCAPE project developed a first basin-scale, cross-national underwater acoustic monitoring in the Northern Adriatic Sea (NAS) recording acoustic data from March 2020 to June 2021 at nine monitoring stations (Fig. 1; see also Petrizzo et al. in the present issue for further detail). The SOUNDSCAPE study area includes the northern part of the Adriatic Sea, as well as the northeastern part of the Mediterranean Sea, extending as north as 45°47’ N, until a transect from Split (Croatia) to Pescara (Italy). NAS has been recognized as an underwater noise hotspot, and it requires managing measures due to its high biodiversity, hosting numerous Natura 2000 sites and protected areas (Maglio et al. 2016). The in situ collected data, that have been recently publicly released (Petrizzo et al. 2022, 2023), were used to calibrate a 3D sound prediction model. In its turn, the modeling results provided a first statistical quantification of the spatiotemporal distribution of sound levels produced at a basin scale in the Mediterranean Sea for the whole year 2020.

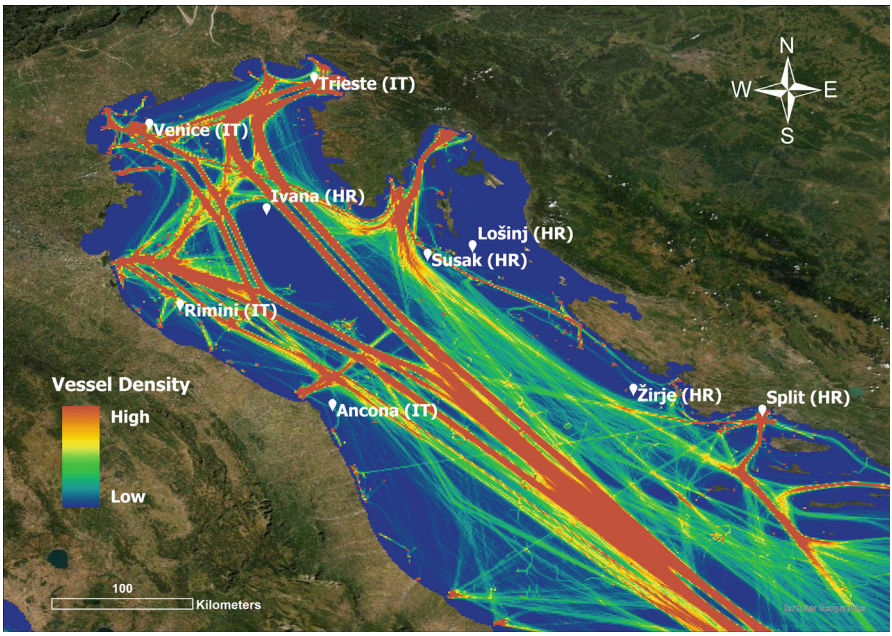

**Fig. 1** Location of acoustic monitoring stations in the North Adriatic Sea SOUNDSCAPE study area. Cargo vessel traffic is also represented as total number of cargo vessel passages per year (2020) as obtained from EMODnet Human Activities, Vessel Density Map. (Revision date 2022-03-21). Geographic map was created using ArcGIS software by Esri

## Sound Propagation Modeling

The Quonops© underwater sound prediction system (Folegot 2009), implemented over NAS, is built on the same principle as oceanographic or meteorological prediction systems (Jensen et al. 2000). The models embedded in the Quonops platform solve the Helmholtz equation of wave propagation based on parabolic equation (Collins et al. 1996) and, for the higher frequency range, on Gaussian energy distribution ray modeling (Porter and Reiss 1984), which reflects the geometric distribution of noise in the water column. The three-dimensional variability of the speed profiles of sound in water, depending on water temperature, salinity, and pressure (or depth), is considered in the model. To account for the variability, stochasticity, and uncertainties of key physical and environmental parameters, a statistical approach based on Monte Carlo simulation (Robert and Casella 2004) is used. This approach has the advantage of estimating the sensitivity of the model to both the variability and uncertainty inherent in input variables. Many noise sources can therefore be modeled and used to calculate the median values (50th percentile) of

noise at every given location. The other percentiles represent the description of the distribution of the noise in each point of the domain and can be associated to most frequent situations. For example, the underwater ambient noise is described by the percentiles from 25th to 75th, corresponding to noise levels occurring 25–75% of the time; *au contraire*, most intense noise events are described in the smallest percentiles, i.e., 1th to 25th percentile, with noise levels occurring 1–25% of the time. Natural noise is represented by the 95th and above percentiles.

The modeling has been carried out at the center frequency *fm* of each one-third octave in the frequency band of the acoustic sources. The SOUNDSCAPE project dealt specifically with monitoring continuous low-frequency sound as covered by the MSFD indicator 11.2.1. Therefore, the one-third octave band center frequencies of 63 and 125 Hz (re 1 μPa) were the focus of the modeling within SOUNDSCAPE. In addition, two other bands were investigated: the 250 Hz and the 4 kHz one-third octave bands. Petrizzo et al. (present issue) describe in detail the reasoning for the choice of these frequencies.

The Quonops© implementation covers the Northern Adriatic domain (Lat 42.8, 45.8; Long 12.1, 17.9), slightly larger than the study area to avoid numerical effects on the border. The calculation is performed on regular grid with a resolution equal to 181 × 179 m.

Two different sets of monthly maps were produced: (i) a mapping of the "natural ambient noise" using as input oceanographic data such as temperature, salinity, sea state, and bottom properties and (ii) the mapping of the "baseline ambient noise" obtained by adding also the information about ship traffic using automated information system network (AIS) data. Specifically, the oceanographic input data (temperature and salinity of the water column) were generated by a three-dimensional, high-resolution, calibrated oceanographic model SHYFEM developed by CNR-ISMAR for the study area (Ferrarin et al. 2019); the wind data used are consistent with the hydrodynamic input data; bathymetry and bottom grain size were obtained by consulting public databases such as EMODnet (https://www.emodnet-bathymetry.eu/) and the NAVOCEANO bottom-type database (Fleischer et al. 2011). In some specific areas along the coast the bathymetric data were updated using the data adopted by the hydrodynamic model or kindly provided by Dr. Pikelj (*pers. com*). AIS data was provided by marine traffic provider (www.marinetraffic.com). A fusion data processing has been carried out by integrating into QO-AIS database, which is connected to the modeling service. Acoustic measurements from SOUNDSCAPE stations have been used to calibrate the sound model.

The results of the modeling were presented as monthly and annual statistical sound maps, considering four frequencies (63, 125, 250, and 4000 Hz one-third octave bands), seven percentiles, and three layers of depth (0–15 m, 15–30 m, and 30 m bottom). An example of monthly statistical sound maps for natural and baseline conditions is shown in Fig. 2; it refers to the entire water column considering 125 Hz one-third octave band. According to the map, the noisiest hotspots are mainly located in the central area of the NAS basin, partly mimicking the shipping routes

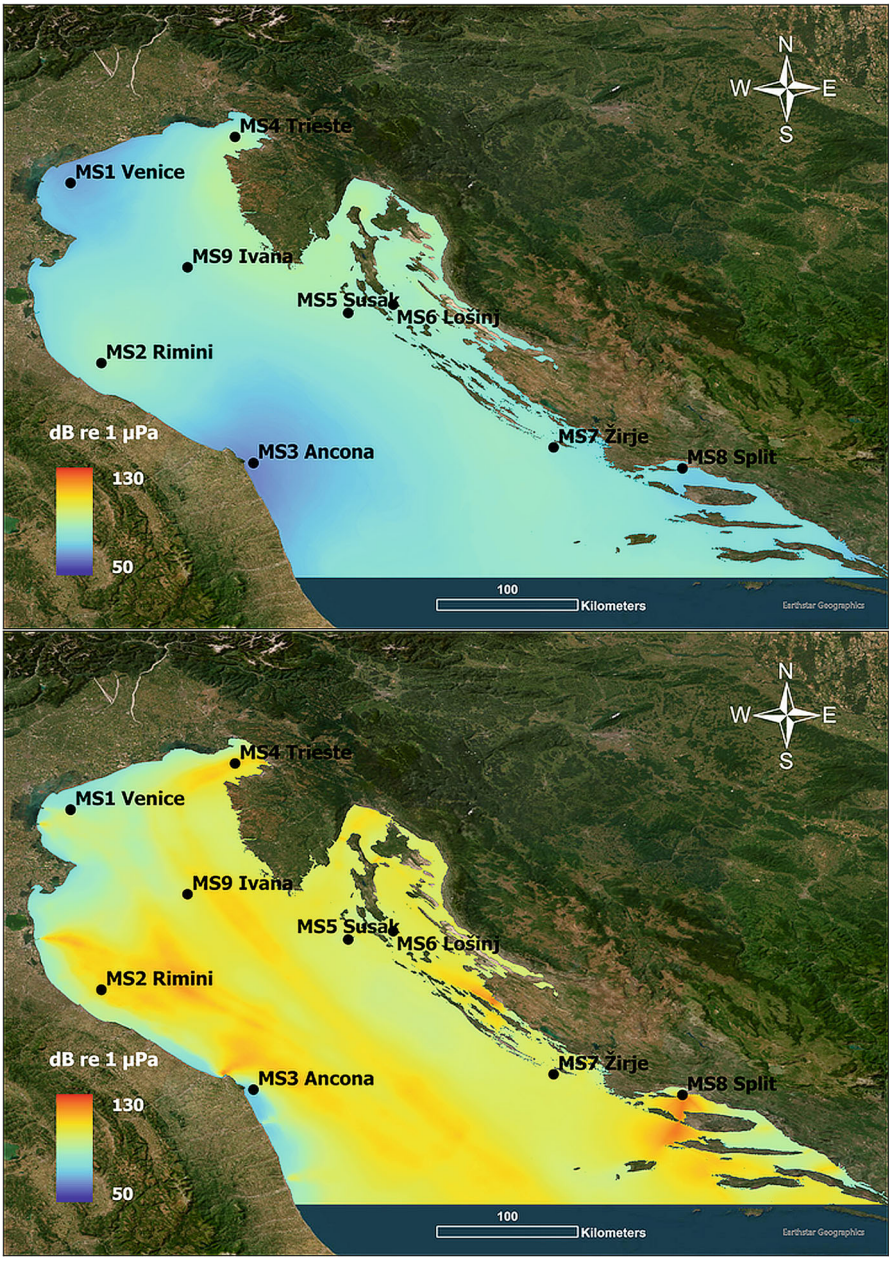

**Fig. 2** Statistical natural and baseline sound map (July 2020; 125 Hz 1/3 octave band, entire water column); 50th (upper panel) and 10th (lower panel) percentile, respectively. Statistical sound data have been obtained by Quonops© Online Services, by Quiet-Oceans (https://qos.quiet-oceans.com/). All right reserved. Geographic map was created using ArcGIS software by Esri

of the cargo traffic (see Figs. 1 and 2 for comparisons). Variations in the sound pressure levels can also be possibly related to: (i) the sediment composition, which is mainly sandy along the Italian coast and rocky along the Croatian coast, and (ii) the water depth, that is generally shallower on the Italian coast.

## Conclusions

A first atlas on underwater noise maps in the North Adriatic Sea was achieved by the EU Interreg Italy-Croatia SOUNDSCAPE project. The noise maps provide an estimate of the spatiotemporal distribution of noise levels in the Northern Adriatic Sea during the year 2020, which is also an exceptional period since it includes the pandemic lockdown time. The modeling results contribute to filling a relevant knowledge gap about the underwater noise distribution in the Mediterranean Sea.

**Acknowledgments** This work was financed through the project SOUNDSCAPE, funded by the EU Interreg V-A Italy-Croatia CBC Program 2014–2020 (Project ID: 10043643) and endorsed by the RELIANCE project, funded under call "Implementing the European Open Science Cloud" (H2020-INFRAEOSC-2018-2020). Many researchers have been involved in the project and allowed it to successfully achieved the described results, in particular: Barbanti Andrea, Bastianini Mauro, Farella Giulio, Ferrarin Christian, Galvez Daphnie, and Menegon Stefano from CNR-National Research Council, ISMAR (Italy); Biagiotti Ilaria, Centurelli Michele, Costantini Ilaria, and Leonori Iole from CNR-National Research Council, IRBIM (Italy); Felli Mario from CNR-National Research Council, INM (Italy); Hrvoje Mihanović, Dadić Vlado, Muslim Stipe, and Predrag Vukadin from IOF (Croatia); Jaroslaw Tegowski and Zdroik Jakub from University of Gdańsk (Poland); Barfucci Giulia, Codarin Antonio, and Soldano Giulia from Regional Environmental Protection Agency of Friuli Venezia Giulia (Italy); Falkner Raffaela, Pleslić Grgur, Radulović Marko, and Rako-Gospić Nikolina from Blue World Institute of Marine Research and Conservation (Croatia); and Pari Alice, Pari Sauro, and Sabbatini Davide from Fondazione Cetacea (Italy).

**Abstract**

Even with widespread evidence of the ecological importance of fish sounds for signaling and communication, and an increasing awareness of the negative impacts of anthropogenic sound, research into fish sound production still faces ongoing challenges limiting growth. To acquire quantitative data on research into fish sounds and assess topics related to their study, a systematized review was conducted to survey over 3000 references for published examinations of sound production by fish species. Additional information was further extracted on the study of marine, subtropical species from a subset of the assembled references. The review findings showed that the rate of soniferous fish species discovery remains inefficient for understanding even a sizeable portion of the behaviors of the 34900 extant fish species known to exist. In the literature surveyed, there was also no standardized sound nomenclature, fish species were not frequently tested in multiple environments, and sound visualizations were inconsistently provided. Advancements in these areas would improve the ability to document, describe, and synthesize fish sounds, which would in turn increase understanding of their global scope and the anthropogenic threats that they face.

## Introduction

Over 1000 documented fish species produce active sounds in numerous behavioral contexts, including feeding, courtship, aggression, defense, and social interactions, and many more may be actively soniferous (Kasumyan 2009; Looby et al. 2022a, b;

Rice et al. 2022). Among vertebrates, fish have the largest diversity of sonic organs and are one of the largest groups of active sound-producers (Ladich and Fine 2006; Ladich and Winkler 2017). Fish are capable of sound source segregation and auditory scene analysis, similar to humans, and can thus use the information embedded within acoustic cues (Bregman 1994; Fay 2009). Other organisms including birds (Hansen et al. 2017) and crustaceans (Hughes et al. 2014) may use fish sounds as a sensory cue to hunt prey, avoid predators, or find suitable habitat. Some fishes can be identified to the individual based on their calls (e.g., Vieira et al. 2015), and certain fish species may even have different call parameters between geographically distinct populations, suggesting the presence of dialects among fish (Fine 1978; Noel and Johnston 2015; Phillips and Johnston 2008). While the capacity to produce active sounds in fishes may not be taxonomically ubiquitous, the substantial extent of known actively soniferous fishes demonstrates an ecological importance analogous to other highly soniferous taxa, such as birds and marine mammals (May-Collado et al. 2007; Odom et al. 2014; Rice et al. 2022).

In addition to active sounds, all fish can produce passive sounds incidentally, which may also carry information (Kasumyan 2008; Rountree et al. 2018). For example, feeding sounds and hydrodynamic sounds can be acoustically distinguished, and they may both have varying characteristics with differing fish sizes and species (Kaparang et al. 1999). Swimming speed (Fujieda et al. 1994) and the type of food being chewed (Kim 1977) can also be differentiated acoustically. Fishes are attracted to both incidental feeding and swimming sounds, further demonstrating their ecological signal potential (Banner 1972; Kim 1977). Although only 219 species have so far been documented to make passive sounds, this is likely due to a lack of emphasis on the topic in research rather than being representative of the extent that they are produced and used for information acquisition (Looby et al. 2022a, b).

As the number of fish species known to use acoustic cues continues to increase, so too do the potential effects of anthropogenic sound (Looby et al. 2022a). In recent years, the capacity for anthropogenic activity to impact the ability of fishes to interact with soundscapes has become indisputable (Cox et al. 2018; Duarte et al. 2021; Rountree et al. 2020b). Anthropogenic sound now contaminates aquatic ecosystems globally, attributed to expanding commercial, recreational, and research sectors (Hildebrand 2009; Shannon et al. 2016). As a pollutant, anthropogenic sound has the potential to disrupt active and passive fish sounds, with consequences for their associated ecological functions and uses, including foraging ability, reproductive success, and predation risk (Cox et al. 2018; de Jong et al. 2020).

In addition to their ecological importance and anthropogenic threats, fish sounds can be used in remote monitoring applications through passive acoustics. Passive acoustic monitoring (PAM) of active fish sounds is used for a variety of applications, such as detecting and measuring fish spawning (Lowerre-Barbieri et al. 2013) or mapping the spread of invasive species (Rountree and Juanes 2017). Passive fish sounds, in contrast, have been primarily used in aquaculture operations, such as to monitor feeding (Mallekh et al. 2003), though they have other possible applications (Rountree et al. 2018, 2020b). Continued advances in the automated detection of fish sounds through machine learning and in online libraries of fish sound recordings will

further increase the value of fish sounds for ecological monitoring (Lindseth and Lobel 2018; Parsons et al. 2022; Sattar et al. 2016).

There is wide-ranging and ever-increasing evidence of the ecological importance of fish sounds, the anthropogenic threats they face, and their PAM applications. Nevertheless, the field of fish bioacoustics remains limited in the ability to document, describe, and synthesize fish sounds on the scales needed to comprehensively understand the soniferous behavior of the estimated 34900 extant fish species (Froese and Pauly 2022). In this chapter, data collected through systematized reviews are used to discuss the history of research into fish sounds and several ongoing challenges for the field, including an insufficient rate of soniferous species discovery, a lack of standardized sound nomenclature, limited testing for sound production in multiple environments, and the inconsistent provisioning of sound visualizations.

## Methods

### Basic Information on Global Fish Sound Production Research

In this review, the data compiled by Looby et al. (2022b) were used to describe global research into soniferous fish diversity. Looby et al. (2022a) conducted a systematized review (Grant and Booth 2009) to compile a dataset of published examinations of a fish species for sound production from 1874 to 2020. Looby et al. (2022b) used the same methods described in Looby et al. (2022a) to update the dataset to include the year 2021 as well as several studies missed by the original review methodology. Looby et al. (2022b) described basic sound production information (i.e., whether a species produces active and/or passive sounds) for 1214 species studied in 920 references. The Looby et al. (2022b) data were accessed through its associated online data repository (Looby et al. 2021).

### Additional Information on Marine, Subtropical Fish Sound Production Research

An additional systematized review was conducted of the marine, subtropical fish species that were determined auditorily to be actively soniferous in an English, peer-reviewed journal article or in Fish and Mowbray 1970. Using the 2018 version of the Looby et al. 2022a dataset that covered the years 1874–2018 (Looby et al. 2021), a follow-up review was conducted of descriptors, testing environments, and visualizations associated with sound production. In this review, only English, peer-reviewed journal articles were considered, to maintain consistency in language (e.g., to only assess sound descriptors in English) and scientific validation (i.e., through peer-review), respectively. Fish and Mowbray 1970, a book documenting surveys of sound production and associated behaviors of over 200 fish species, was also included as it is a highly regarded information source in

the field of fish bioacoustics (Rountree et al. 2002). Data were collected only on marine, subtropical fish species (Boettiger et al. 2012; Froese and Pauly 2022) to keep the data collection feasible. The species were then limited to include only fishes that were examined for sound production auditorily (i.e., documentation of the presence of audible sounds through listening live or on a recording) and found to produce active sound, as determined by Looby et al. 2021. The resulting data compilation comprised 186 fish species and 194 publications, with a total of 450 investigations (i.e., individual auditory documentations of actively soniferous behavior by a species in a reference).

Data were collected on what sound names or descriptors (i.e., one to a few words used to identify and describe different types of fish sounds) were reported as produced by the actively soniferous marine, subtropical species in the publications surveyed. Because numerous synonyms could be used to describe the same type of sound, each of the terms authors used to describe sound types was documented. The descriptors were standardized grammatically, so terms such as grunt, grunting, grunted, and grunts were all combined into one category. Similar descriptors, such as tick and fast repetitive tick (FRT) or crunch and scrunch, were also combined into singular categories. Species may have produced multiple types of sounds, which could have been described in the same or multiple publications. Sound descriptors used for active or passive sounds were not differentiated, as both may have been produced within the same study. Sound descriptors may have been tentative (i.e., if the authors speculated about a certain sound) and/or cited (i.e., as opposed to determine through testing within the study). For the purposes of this chapter, all tentative, nontentative, cited, and noncited entries were included in the subsequent data analyses and visualizations.

Data were also collected on the testing environments of the examined species. Testing environments were distinguished between three broad categories: captivity, semi-wild and wild. Captivity included any testing conducted in laboratories, tank environments, or other completely artificial, human, or captive environments. Semi-wild included any testing conducted in a natural environment with artificial/human enclosures for the study animals, such as outdoor pens, or relatively large human-made environments, such as artificial ponds. Wild included any testing conducted in a natural environment without any type of artificial or human enclosures for the study animals. The testing environment may have also been unclear or unreported by the study authors. Species may have been tested in multiple environments in the same or multiple publications.

Finally, data were collected on what types of sound visualizations were provided for a particular species. Whether any oscillograms (i.e., waveforms), spectrograms, and/or power spectra were provided for a species examined was determined for each reference. Visualizations included in the main text of the article or in electronically available supplementary material were all considered valid for the data collection.

All data collected were based on the reviewer's interpretation of the authors' intentions and meaning to mitigate reviewer bias. As such, data collection was conducted by a single person to maintain internal consistency. To validate the data collected, the data categorizations associated with over 100 of the 450 investigations

surveyed, including any that were ambiguous or uncertain, were assessed by a second reviewer.

### Data Visualization and Analysis

All data analyses and visualizations were conducted in R (R Core Team 2022) version 4.2.1 (2022/06/23). All taxonomic and water body information on the fish species were accessed through the R package rfishbase version 4.0.0 (Boettiger et al. 2012) with the FishBase version set to 22.02. The climate zone information was accessed from the FishBase website, which only designates a single primary climate zone per species as opposed to rfishbase which designates any climate zones the species is found in (Boettiger et al. 2012; Froese and Pauly 2019). A rarefaction and extrapolation analysis of actively and passively soniferous species discovery was also conducted, following the methods outlined in Looby et al. (2022a) with the data updated to those included in FishSounds Version 1.1 (Looby et al. 2020b). Other visualizations were created using the R packages ggplot (Wickham 2016) and wordcloud (Fellows 2018). All the data used to create the figures are available in a supplemental information file in the FishSounds Data Repository (Looby et al. 2021), and all the data collected in both systematized reviews are available on the FishSounds website (Looby et al. 2022b) and in the FishSounds Data Repository (Looby et al. 2021).

## Global Fish Sound Production Research

### History of Fish Sound Production Research

Research into fish sound production and detection has an extensive history. Pliny the Elder and Aristotle described fish sounds and possible fish hearing over 2000 years ago (Aristotle 1862; Pliny the Elder 1938). Contemporary scientific research on fish sound production began in the late 1800s (Abbott 1877; Dufossé 1874) then underwent a considerable expansion in the middle of the twentieth century due to innovations in underwater acoustic equipment. Technical advances and research were motivated in part by naval interests in distinguishing between sounds produced by marine organisms or by human activities (Fish et al. 1952), as well as increasing business investment in auditory attractants for fish ranching and acoustic fishing methods (Choo et al. 1988; Takemura et al. 1988). Scientific interest in fish bioacoustics was further driven by questions surrounding the physical mechanisms of sound production, the ecological implications of fishes' perception of and contribution to the prevailing soundscape, the impacts of anthropogenic activities, and the potential to monitor soniferous fish populations remotely (e.g., Carriço et al. 2020; Ladich and Winkler 2017; Rountree et al. 2020b). Consequently, the rate of studies examining fish species for sound production has steadily increased from the mid-1900s to the present (Fig. 1a).

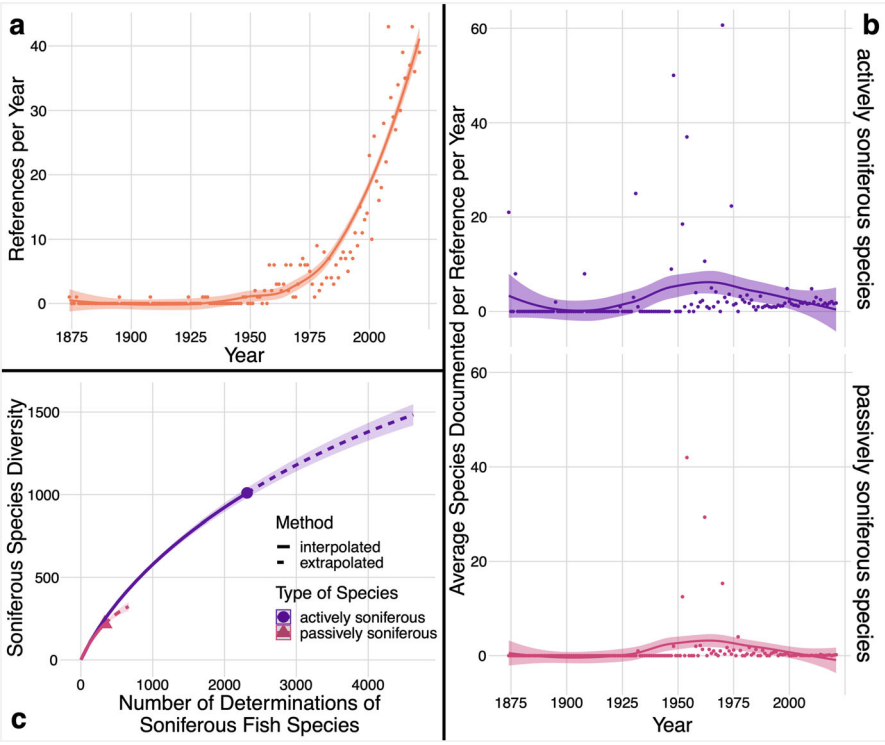

**Fig. 1** (**a**) The number of references per year with independent (i.e., not cited) fish sound production examinations and (**b**) the average number of actively and passively soniferous species documented per reference per year, with lines plotted using the local polynomial regression fitting method (Looby et al. 2022b; Wickham 2016); and (**c**) rarefaction and extrapolation curves of the number of actively and passively soniferous fish species if the numbers of determinations of each type of soniferous fish species were doubled (Looby et al. 2022a, b)

Despite considerable advancements in fish bioacoustics, the prevalence of sound production among extant fish species remains indeterminate. There have been numerous efforts to catalog soniferous fish species, such as within a particular region (e.g., Fish 1954; Fish et al. 1952; Rountree et al. 2019) or fish taxa (e.g., Colleye et al. 2011; Hallacher 1974; Kaatz and Stewart 2012). More recently, a review of known fish sound production was conducted using systematized review methodology to create a comprehensive global inventory of documented examinations of a fish species for sound production that was later made available on a public website (Looby et al. 2022a, b). Only about 4% of extant fish species have been examined for sound production, however, and active sound production in fishes has evolved independently multiple times (Looby et al. 2022a; Rice et al. 2022). As a result, the number of actively soniferous fishes globally remains difficult to estimate and many aspects of fish sound production behavior are still unknown (Parmentier et al. 2021; Rice et al. 2022).

## Rate of Soniferous Species Discovery

While the publication rate of studies about fish sound production has been increasing to the present day (Fig. 1a), the number of soniferous species documented per reference has decreased from its peak in the middle of the twentieth century (Fig. 1b). A relatively larger proportion of studies earlier in the contemporary scientific literature focused on surveying greater numbers of species for sonifery, including many publications that featured independent examinations of dozens if not hundreds of fish species (e.g., Burkenroad 1931; Fish and Mowbray 1970; Fish et al. 1952). In contrast, with increasing rates of publications in recent years, there were also increasing numbers of studies focusing on only one species to describe soniferous behaviors in greater detail (e.g., McIver et al. 2014; Noel and Johnston 2015; Phillips and Johnston 2008), with only three references since the year 2000 that documented examinations of more than 15 species for sound production (Kaatz and Stewart 2012; Kaatz et al. 2010; Tricas and Boyle 2014). This decrease is even more pronounced for studies of passive fish sound production compared to active fish sound production, with passive fish sounds remaining understudied despite their ecological signal potential and assumed widespread occurrence in fishes (Fig. 1b; Kasumyan 2008; Looby et al. 2022a).

Even with increasing numbers of scientific publications on fish sound production, and in part because of the decreasing numbers of soniferous species studied per reference, the current rate of soniferous species discovery remains insufficient to describe the thousands of soniferous species thought to exist (Fig. 1c; Looby et al. 2022a; Rice et al. 2022). FishBase lists 34900 extant fish species (Froese and Pauly 2022), of which only roughly 4% have been studied for sound production and even fewer of which have been documented as producing active and passive sounds (Looby et al. 2022a). Furthermore, an extrapolation and rarefaction analysis showed that if the scientific effort studying sound production in fish species from 1874 to 2021 was doubled, only a total of 1483 ($\pm$63) actively soniferous fish species and 324 ($\pm$27) passively soniferous fish species would be documented to exist. The low estimates of soniferous fishes produced through extrapolation reflect the paucity of studies on fish sounds relative to the number of extant fish species. Because active sound production is not an ancestral trait among fishes, active sonifery cannot be assumed among all fish taxa (Rice et al. 2022). Additionally, there has been evidence of possible losses of sound production behaviors in certain species, further signifying that active sound production may be difficult to speculate taxonomically (Boyle et al. 2014; Kaatz 1999; Rice et al. 2022).

The unique challenges in studying fish sound production have caused this research to lag behind other soniferous taxa. Documenting soniferous fishes can be highly uncertain, with many authors reporting doubt in at least some of their conclusions (Looby et al. 2022a). Fish sound production behavior can be highly context-dependent, and the fish sounds themselves may be rare, noncontinuous, or low in amplitude (e.g., Brantley et al. 1993; Lowerre-Barbieri et al. 2013; Wall et al. 2014). Community science efforts, like those that have been so successful for documenting bird and frog sounds (FrogID 2022; Macaulay Library at the Cornell

Lab of Ornithology 2022), have not yet been implemented as extensively to research fish sounds because of the technological limitations of recording underwater. There are also thousands of extant fish species – a much greater number than the roughly 200 species of marine mammals, almost all of which have been confirmed to make active sounds underwater (Parsons et al. 2022). Research into fish sound production is not unique in these challenges – the study of underwater invertebrate sounds faces similar difficulties (Hawkins and Popper 2017), – but considering the ecological, economic, and cultural importance of fishes globally, the rate of soniferous fish species discovery needs to increase to improve knowledge of fish behavior, signaling, and communication. This strengthened understanding is necessary to assess the effects of anthropogenic sound on fish acoustic communication and to effectively apply passive acoustics to monitoring, conservation, and fisheries management.

## Marine, Subtropical Fish Sound Production Research

### Sound Descriptors

There were 60 different terms used to describe the sounds produced by the 186 marine, subtropical fish species about which additional information was collected (Fig. 2). These included knocks, choruses, rasps, snitches, booms, erks, ticks/FRTs, wheezes, sneezes, chants, gurgles, moans, and complex calls. Sound descriptors were largely onomatopoeic in nature (e.g., boom), though a few were used to describe sounds based on frequency composition (e.g., tonal/harmonic) or calls composed of multiple smaller sound units (e.g., complex call, chorus). Pulse – as both a sound name and frequently used word to describe subunits of sounds – was the most common term found (Fig. 2). Other common terms included grunt, tonal/harmonic, knock, chorus, thump, and drum, all of which were used in over 50 investigations to describe sounds. Many sound descriptors were rarely used in the

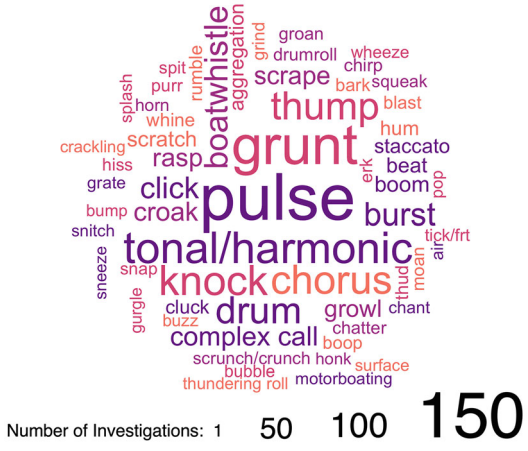

**Fig. 2** Word cloud showing the 60 sound descriptors identified in the data collection, with the font size of the words representing the number of investigations (i.e., individual auditory documentations of actively soniferous behavior by a species in a reference) in which a sound descriptor category was used

references assessed, with 9 terms only used once (e.g., motorboating, thundering roll) and 31 others used in less than five investigations (e.g., purr, bump). Beyond the short sound descriptors that were quantified, authors also often used longer phrases to describe particularly abnormal sounds, such as the "bubbling of a giant percolator" associated with the choruses of the hardhead catfish (*Ariopsis felis*; Kellogg 1955; Tavolga 1971), or the sustained clicks produced by the gray triggerfish (*Balistes capriscus*) that "resemble the tearing of canvas cloth" (Fish 1954).

The sound descriptors found were inconsistently used. Often, multiple sound names were applied to similar or identical sounds, creating redundancy and confusion. The terms grunt and thump typify this as both describe low-frequency sounds of relatively short durations, with little to distinguish between them, though they could still be used differentially between species even within the same reference (e.g., Fish and Mowbray 1970). Alternatively, multiple names could be used in different references to describe the same type of sound produced by the same species. For example, the plainfin midshipman (*Porichthys notatus*) produces three primary types of sounds (i.e., hum, grunt, growl; McIver et al. 2014) but had ten sound descriptors (e.g., buzz, groan) associated with it in the 11 publications surveyed. The overlapping nature of some passive and active sounds meant that they could be described using similar terms as well, making them more difficult to differentiate. For instance, scrapes could describe both the incidental sounds produced by parrotfishes (Family Scaridae) feeding on hardened substrates as well as the agonistic sounds produced for communication by the southern puffer (*Sphoeroides nephelus*; Burkenroad 1931; Sartori and Bright 1973). These inconsistencies affect the ability to understand the types of sounds being described as well as to compare findings among similar sounds or species.

Individual studies may do a thorough job in defining the different sound descriptors used within them (e.g., McIver et al. 2014; Sartori and Bright 1973), but the field of fish sound production research still lacks a widely applied, standardized sound-naming and description system. Naming systems exist for other soniferous taxa, such as the onomatopoeic naming system of bird songs (Pieplow 2017), the standardized division of whale songs into themes then sound units (Garland et al. 2013), or the norms around using dolphin sound types (Jones et al. 2020). Such systems allow for more effective communication about the characteristics of the sounds being described (Jones et al. 2020). To be successful, the development of such a system for fish sounds must consider their relatively simplified nature; coordinate among a global and diverse assortment of researchers, species, and sounds; and balance the needs for technical descriptions based on acoustic characteristics (e.g., sounds described in terms of their frequency, duration, or structure) and meaningful engagement of the public with more evocative terms (e.g., purr, boop).

## Testing Environments

Researchers may use different testing environments (i.e., captivity, semi-wild, and wild) when studying soniferous behavior, any of which can impact the results of

their studies. Testing for sound production in captivity, for instance, ensures correct species and associated behavior identification and allows for lab experimentation of environmental and situational variables of interest (Diamond 1983; Sprague and Luczkovich 2001). Some fishes, however, may not display soniferous behaviors in captivity, and others may behave differently in the wild and in the lab due to environmental and physiological changes (e.g., Bolgan et al. 2020; Holt and Johnston 2014; Rountree and Juanes 2020). Small tank environments can also have more ambient sound, reverberation, and resonance that may cause acoustic interference and distortions (Akamatsu et al. 2002; Bart et al. 2001). Though these effects can sometimes be counteracted, the results of fish bioacoustic studies conducted in tanks are still treated with caution unless validated in open water environments (Akamatsu et al. 2002; Slabbekoorn 2016).

As a result of the challenges with captivity testing, many researchers study fish sound production in wild (e.g., Fine 1978) or semi-wild (e.g., Brown et al. 2021) conditions, though these also present their own difficulties. Wild or semi-wild testing environments may provide a more accurate assessment of how sound production occurs and is used naturally (Diamond 1983). Testing for sound production in the wild, however, is often conducted without direct observation of sound producers or their behavior and relies on comparison with known sounds for identification or other more circumstantial evidence (Lindseth and Lobel 2018). Identification of unobserved sounds based on comparison with known sounds relies on the existence of comprehensive libraries of sounds, which are rarely complete for a given geographic area, giving rise to frequent calls for developing sound libraries (e.g., Lindseth and Lobel 2018; Luczkovich et al. 2008; Rountree et al. 2006). To identify sound sources more directly, wild studies may incorporate unaided visual observation (e.g., Abbott 1877) or underwater video (e.g., Rountree et al. 2018), among other methods. Even with direct observation, however, it may not be possible to provide conclusive proof of sound source identity if obvious sound production behavior is not evident (e.g., Rountree and Juanes 2010). In addition, fish behavior can be altered by the presence of observers or instruments (e.g., Lindfield et al. 2014). Some of these conundrums can be addressed using multiple modes of observation together with passive acoustic arrays, though these techniques have yet to be regularly implemented (Mouy et al. 2018; Rountree 2008; Rountree et al. 2020a). Similarly, semi-wild studies may aid in isolating the species and sound production behavior of interest while still reducing acoustic distortions and observer effects (e.g., Kaparang et al. 1999), but misidentifications are nonetheless still possible if another soniferous species is nearby (Moulton 1956; Fish and Mowbray 1970; Sprague and Luczkovich 2001). Because of the benefits and downsides of any individual fish sound production study method, testing in a variety of environments and scenarios is necessary to comprehensively describe the soniferous behavior of a fish species.

Despite the value in varied testing for sound production, these practices were not universal in the studies surveyed. For species tested within individual references, only 41 of the 450 investigations found in the review tested for active sound production behavior in more than one environment among captivity, semi-wild,

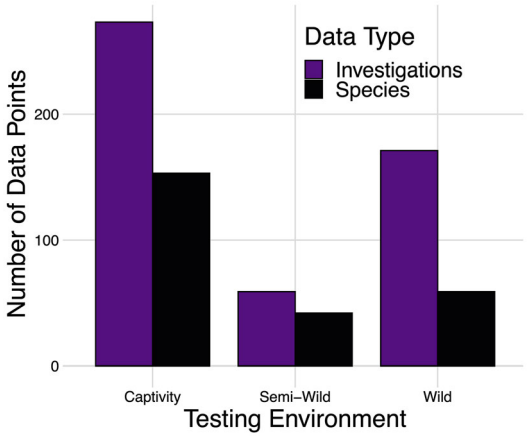

**Fig. 3** The number of investigations (i.e., individual auditory documentations of actively soniferous behavior by a species in a reference) and the number of species tested in each environment

and wild. Twenty-two investigations had at least one unclear or unreported testing environment, further complicating the reproducibility or comprehension of their research. Additionally, of the 186 species covered in this review, only 46 species were documented actively producing sounds in more than one environment, with captivity being the most common method among investigations and species, followed by wild, then semi-wild (Fig. 3). The field could therefore greatly increase its current rate of usage of multiple testing environments.

When possible, studies should utilize multiple testing environments to overcome the weaknesses of any individual approach (Diamond 1983) and to describe fish soniferous behavior more extensively (e.g., Bertucci et al. 2021; Fish and Mowbray 1970). As declaring a fish species unable to produce active sounds is challenging, the testing of multiple environments could also aid in determining the likelihood of soniferous behavior overall or at least in certain situations. The establishment of recommended fish sound production testing guidelines would further aid researchers in standardizing practices across studies and justifying the need for multiple testing environments in funding applications.

## Sound Visualizations

As the human ear may not be able to sufficiently perceive and differentiate between underwater sounds, bioacousticians commonly use visualizations to identify and compare sounds more effectively (Jones et al. 2020). There are many methods used to visualize sounds and soundscapes, but this review only focused on three: oscillograms, spectrograms, and power spectra. Oscillograms, also known as waveforms, show relative or absolute amplitude changes of sound over time. Spectrograms show frequency changes over time, with relative or absolute amplitude represented with a color or darkness scale. Power spectra, in contrast, summarize a time-varying sound by the relative or absolute amplitude of a range of frequencies. All have multiple

possible uses for fish sound production research. For example, oscillograms can be used to distinguish between complex sounds, such as pulse trains, more easily (e.g., McIver et al. 2014), spectrograms can be helpful in partitioning individual fish sounds (e.g., Carriço et al. 2020), and power spectra can be used to find acoustic metrics like peak frequency (e.g., Tu et al. 2018).

Despite the diverse uses of different methods of sound visualizations, they are not always included when discussing fish sounds in scientific publications. Among the 450 investigations reviewed for marine, subtropical soniferous fishes, 227 included at least one oscillogram, 244 included at least one spectrogram, 97 included at least one power spectrum, and 145 had none of the three sound visualizations. The investigations included in the review considered a total of 186 species for sound production. Of these, only 43 species had all three types of visualizations to illustrate their sounds, while 41 species had none of the three sound visualization types. Though the use of sound visualizations has increased similarly to the increase in fish sound production publications (Fig. 4a), the relative inclusion of sound visualizations in investigations per year has remained largely unchanged in recent decades,

**Fig. 4** (**a**) The number of investigations (i.e., individual auditory documentations of actively soniferous behavior by a species in a reference) per year; and (**b**) the percentage of investigations per year that included an oscillogram, spectrogram, or power spectrum

with any of the visualizations only occasionally provided in all references for a particular year (Fig. 4b). As data were not collected on whether visualizations were provided for each sound type produced by a particular species in a reference, the provisioning of sound visualizations could be even lower.

The inclusion of oscillograms, spectrograms, and power spectra in addition to representative recordings, when feasible, would facilitate knowledge sharing in scientific publications on fish sound production. For example, Fish and Mowbray 1970 provided spectrograms, oscillograms, and recordings for many of the soniferous behaviors of the fish species they studied – a lot of which are still used by researchers as a helpful identification guide and regional inventory of fish sound production to the current day (Looby et al. 2022a, b; Rountree et al. 2002). With the increasing use and availability of supplementary material, online data repositories, and other electronic options for figures and other files associated with publications, any feasibility barriers to including representative sound visualizations and recordings to accompany studies of fish sound production are substantially reduced. Researchers describing soniferous fish behavior should therefore be encouraged to include recordings and multiple types of sound visualizations to improve the applicability and understanding of their work.

## Concurrence with Previous Work

This publication is not the first to recognize these or other challenges related to fish sound production research. For example, Rountree et al. (2019) conducted a similar review of freshwater, North American fish sound production research that included 84 studies on 87 fish species, which highlighted the need for standardized sound nomenclature. They also found that of the species included in their review, 34% lacked any statistical description of sound characteristics, which are similarly crucial as visualizations for identifying and describing fish sounds. The comparable findings of research trends in both freshwater (Rountree et al. 2019) and marine systems (herein) highlight systemic gaps in research priorities, methodologies, and reporting patterns. Other works discuss issues that are not covered by this review, such as publications calling for the continued development of standardized acoustical analysis protocols (e.g., Gibb et al. 2019), comprehensive recording libraries (e.g., Parsons et al. 2022), or the consideration of particle motion in addition to acoustic pressure (e.g., Nedelec et al. 2016). There have also been innovative solutions proposed to some of the challenges in fish sound production research, such as synchronous video and audio recordings to validate sound producer identities in the wild (Lobel 1992; Mouy et al. 2018), ecosystem-level ocean observatories to integrate acoustic and other remote sensing technologies (Rountree et al. 2020a), or the establishment of online data and recording repositories (e.g., Looby et al. 2022b). This review of select challenges will hopefully contribute to the wider discourse on how to continue improving research into fish sound production.

## Recommendations for Future Work

1. Wide-reaching research surveys (e.g., Fish and Mowbray 1970) and community science initiatives (e.g., FrogID 2022) are needed to examine greater numbers of possibly soniferous fish species. As more data on soniferous species are collected and synthesized, then meta-analyses, ancestral state reconstructions, and other reviews and analyses can more effectively describe patterns and the scale of fish sound production globally (e.g., Looby et al. 2022a; Parmentier et al. 2021; Rice et al. 2022).
2. Standardized sound descriptors (e.g., Jones et al. 2020) should be developed and applied by the research community to promote effective communication and comparisons among fish sounds. Such a system would hopefully be able to provide technical information about the sound, such as its duration and frequency, while still being accessible to the wider public.
3. When practicable, fish species should be examined for sound production in multiple types of testing environments (e.g., both in the lab and in the field) and other conditions (e.g., at varying times of day) to ensure comprehensive documentation and understanding of their soniferous behavior (e.g., Bertucci et al. 2021).
4. Recordings and multiple types of sound visualizations should be provided in the main-text, supplementary files, and/or supporting data repositories when describing fish sound production in scientific publications (e.g., Fish and Mowbray 1970) to better facilitate the ability of researchers to understand and learn from each other's work.

## Conclusion

Contemporary scientific research into fish sounds, their ecological uses, and potential applications with PAM has been ongoing for almost 150 years, with thousands of fish species thought to use active and passive sounds for signaling and communication (Kasumyan 2008; Looby et al. 2022a; Rice et al. 2022). The systematized review data compiled here represent four general areas to ameliorate the efficiency and consistency of research into fish sound production. While the rate of studies on fish sound production has been increasing to the present day, the number of soniferous species documented per reference has decreased and the current rate of soniferous species discovery remains insufficient to describe the thousands of soniferous species thought to exist (Fig. 1). There are dozens of sound descriptors applied inconsistently for describing sound production (Fig. 2), generating confusion in the literature and limiting syntheses that could document trends in sound production across fish species. Fishes are not regularly tested in multiple environments (Fig. 3) despite widespread acknowledgment of the influence testing environment may have on sound production and behavior. Additionally, sound visualizations that are helpful for identifying and

describing sounds are variably provided (Fig. 4) despite their differing utilities. Advancements in these areas would greatly improve the ability to document, describe, and synthesize fish sounds for a wider variety of uses and studies.

**Abstract**

Rapid changes in the global distribution of walleye pollock (*Gadus chalcogrammus*) due to climate change have raised concerns of potential negative interactions with other Arctic and North Pacific fishes, particularly with the Arctic cod (*Boreogadus saida*). Since both walleye pollock and Arctic cod are known to be soniferous, passive acoustic monitoring (PAM) surveys can be used to document changes in the temporal and spatial distributions of the two species. However, PAM requires a detailed knowledge of the sound characteristics of each species. Therefore, this chapter presents the first quantitative description of walleye pollock sounds to enable future PAM surveys. Over 6000 sounds attributed to walleye pollock were detected in 69 h of recordings in April 2018 at the Hatfield Marine Science Center (Oregon). Walleye pollock sounds averaged 95 ms in duration, with a peak frequency

of 83 Hz ($n = 635$). Sounds were classified into four types of grunts, based on frequency structure: broadband, low-frequency, mid-frequency, and two-frequency. A comparison with published data for Arctic cod suggests that the two species can be distinguished by the sound duration, peak frequency, and pulse rate of their calls.

## Introduction

Walleye pollock (*Gadus chalcogrammus*) is a widespread bentho-pelagic fish species that ranges from the coasts of Korea, Japan, and California in the North Pacific to Norway in the North Atlantic (Orlov et al. 2021). Walleye pollock is the second most extensively fished species in the world, with global annual catches over three million tons between 2015 and 2019 (FAO 2021). In addition, it plays a key role in the ecosystem as a prey for numerous marine mammals and birds and as a predator of zooplankton and fish (Springer 1992; Gaichas and Francis 2008; Hirota et al. 2014; Park et al. 2018).

Walleye pollock health and survival is tightly linked to zooplankton productivity, which is impacted by fluctuations in temperature (Kimmel et al. 2018). Rising ocean temperatures have caused a shift northward of walleye pollock distribution in the Northeast Pacific (Kotwicki et al. 2005; O'Leary et al. 2020), and this could in turn displace other fish populations (Fossheim et al. 2015; Stevenson and Lauth 2019), including Arctic cod (*Boreogadus saida*) (Koenker et al. 2018; Steiner et al. 2019). This concern warrants further monitoring of both species.

Methods to survey walleye pollock distribution include trawling and active acoustics (Honkalehto et al. 2011), which can be invasive. For example, the use of echosounders can elicit behavioral responses in cetaceans (e.g., Cholewiak et al. 2017; Burnham et al. 2022) and some fishes (e.g., Mann et al. 2005), while trawling physically disturbs seabed habitats and can cause declines in organism abundance and biomass (e.g., Pitcher et al. 2022). Here, the use of passive acoustic monitoring (PAM) is proposed as a non-invasive way to monitor walleye pollock populations. Sounds produced by Arctic cod have already been described (Riera et al. 2018), but very little is known about walleye pollock sounds (Park et al. 1994). Park et al. (1994) described soniferous behavior during reproduction but provide limited quantification of sound acoustic properties. They later described the sonic muscles and sound production mechanism of the species (Park et al. 1995). Herein, the sounds produced by walleye pollock are quantitatively described, so that they can be identified in PAM recordings and distinguished from the sounds produced by other gadids that co-occur in the same habitat.

## Methods

### Data Collection

Passive acoustic recordings were collected in April 2018 in a tank at the Hatfield Marine Science Center (Newport, OR) using a SoundTrap ST300 STD (Standard, Ocean Instruments, Auckland, New Zealand) on a continuous duty cycle at 96 kHz (16 bit). The circular tank was 4.5 m in diameter, 1.3 m high, and contained approximately 30 walleye pollock of mixed sexes, including some gravid females. These fish were wild caught by beach seine as age 0 in 2016. Water temperatures were kept between 8.0 °C and 8.4 °C. Salinity remained between ~30 and 32 PPT by pumping water at a high tide from Yaquina Bay into a large reservoir upstream of the holding tanks. The recorder was deployed at 2 pm on April 16 and recovered at 11 am on April 19, which yielded 69 h of acoustic data (almost three full 24-h periods).

### Data Post-Processing

The recordings were amplified by adding 30 dB. They were then analyzed with Raven Pro 1.5 acoustic software (Center for Conservation Bioacoustics 2014) by aurally and visually inspecting each spectrogram (10,500 FFT, Hann window, 85% overlap). Several parameters of frequency, duration, and energy were measured for sounds with good signal-to-noise ratios. Percentiles of each measurement are reported as they are more robust against measurement bias (Charif et al. 2010). The frequency measurements included the lowest, highest, peak, and center frequencies, the 5th (F. 5%) and 95th (F. 95%) percentile frequencies, and the first (Q1) and third (Q3) frequency quartiles (Charif et al. 2010).

The peak frequency is the lowest frequency at which maximum power occurs within the signal. The center frequency divides the sound into two frequency intervals of equal energy. F. 5% is the frequency that divides the selection into two frequency intervals containing 5% of the energy at the bottom and 95% of the energy at the top, while F. 95% is the frequency that divides the signal into two frequency intervals containing 95% of the energy at the bottom and 5% of the energy at the top. Q1 is the frequency that divides the sound into two frequency intervals containing 25% and 75% of the energy, while Q3 divides the sound between 75% and 25%. The interquartile (IQR) bandwidth is the difference between Q3 and Q1, while the 90% bandwidth is the difference between F. 5% and F. 95% frequencies.

Other measurements include energy, aggregate, and average entropy (see Charif et al. 2010, for calculation details). Energy is the total energy in the sound (within frequency bounds). Aggregate entropy is a measure of the disorder in a sound based on the distribution of energy throughout the sound. Higher entropy values correspond to greater disorder in the sound, whereas a pure tone with energy in only one frequency would have zero entropy. Average entropy is an average of the entropy calculated for each time interval within the sound.

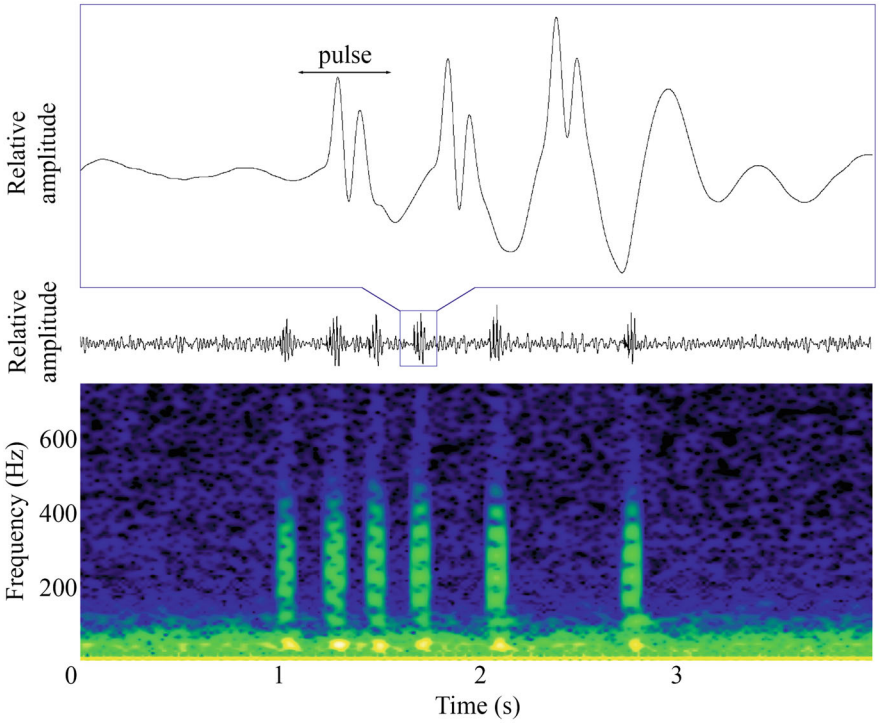

**Fig. 1** Waveform (top) and spectrogram (bottom) of a broadband grunt train produced by walleye pollock (*Gadus chalcogrammus*) recorded at the Hatfield Marine Science Center (10,500 FFT Hann window with 85% overlap). The top panel is an expansion of the fourth grunt in the middle panel, delineated with a box, to show the structure of each pulse

Given their similarity with Arctic cod vocalizations (Riera et al. 2018), walleye pollock sounds were referred to as grunts. Data were analyzed twice: first to count the sounds and then to select the best examples for detailed measurement.

A bandpass filter corresponding to the specific frequency range of each grunt was applied in order to obtain the number of pulses per grunt. As defined in Riera et al. (2018), a pulse is the unit that gets repeated in the amplitude-modulated oscillations that make out a grunt (see Fig. 1).

## Statistical Analysis

Canonical discrimination analysis (CDA) and analysis of variance (ANOVA) were used to test for multivariate and univariate differences in acoustic parameters among the four most common sound types. A stepwise discriminant analysis was used to reduce the number of input variables to CDA (Pielou 1984; Harris 2001; SAS Institute, Inc. 2012). The CDA tests whether the sound types exhibit significant

multivariate differences and, if so, which acoustic parameters contribute the most to the observed differences. All input variables were log transformed prior to analyses.

## Results

Walleye pollock were found to produce sounds as single grunts or trains of grunts. Although not quantified, sounds were produced much more frequently at night than during the day. A total of 6173 individual grunts and trains of grunts were found in the 69 h of recordings. Of these, 635 grunts were selected for detailed measurements from 168 grunt trains (Table 1).

The duration of walleye pollock grunts ranged between 29 and 340 ms (average of 95 ± 1.5 SE), and their frequency ranged from 14 to 838 Hz, with an average peak frequency of 83 ± 1.6 (Table 1). Trains averaged 4 grunts and 1.1 s duration (range 1–41 grunts, Table 1). Pulse structure was measured in 584 grunts, with an average of 5 pulses/grunt (range 2–20) and an average pulse rate of 57 pulses/s (Table 1).

Four types of walleye pollock grunts were distinguished based on frequency structure, which were named broadband ($n$ = 451), low-frequency ($n$ = 15), mid-frequency ($n$ = 95), and two-frequency ($n$ = 66) (Table 2). However, the disproportionate occurrence of the sound types was partially a result of selecting only the best sounds for measurement. Broadband grunts showed one strong energy band at the lower end of their frequency range and displayed harmonics up to 838 Hz (average bandwidth 558 ± 4.4 Hz; Fig. 1; Table 2). Low-frequency grunts presented

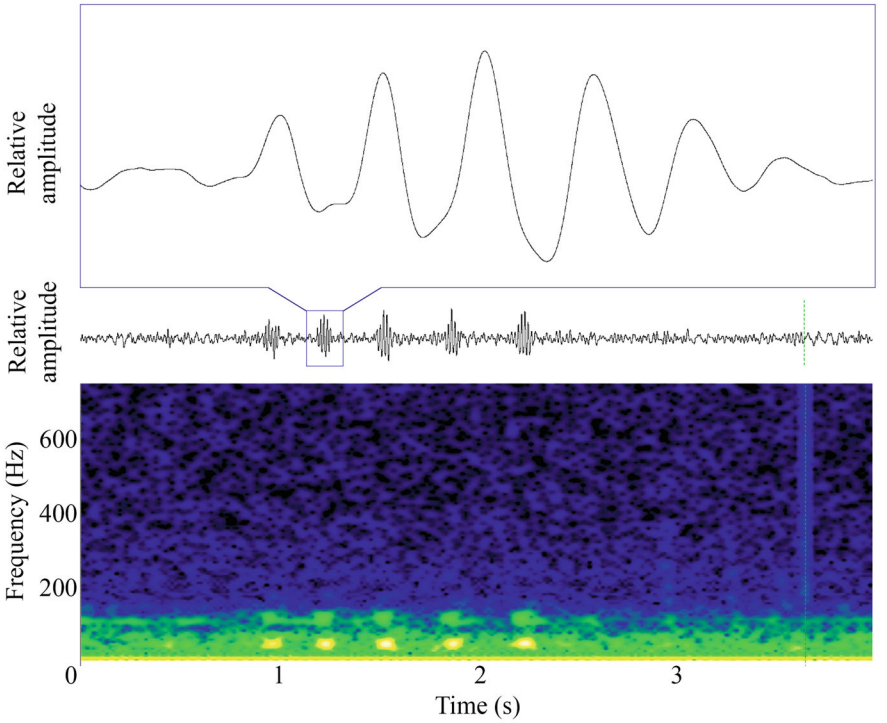

**Fig. 2** Waveform (top) and spectrogram (bottom) of a low-frequency grunt train produced by walleye pollock (*Gadus chalcogrammus*) recorded at the Hatfield Marine Science Center (10,500 FFT Hann window with 85% overlap). The top panel is an expansion of the second grunt in the middle panel, delineated with a box, to show the structure of each pulse

one strong energy band at the lower end of their frequency range, but fewer harmonics, with an average high frequency of 232 ± 23.0 Hz (Fig. 2; Table 2). Mid-frequency grunts were similar to low-frequency grunts, with an average high frequency of 238 ± 5.6 Hz, but had a wider 90% bandwidth (66 vs. 51 Hz, respectively; Fig. 3; Table 2). Two-frequency grunts looked like a combination of low- and mid-frequency grunts: with two strong energy bands and few harmonics (Fig. 4; Table 2).

Pulses tended to have a double peak structure, but differed among the four sound types. The first peak had a higher amplitude than the second peak for the broadband (Fig. 1) and mid-frequency (Fig. 3) type grunts, but the two-frequency grunts exhibited the opposite pattern (Fig. 4). Low-frequency grunts were most different, exhibiting a single peak pulse structure (Fig. 2). However, mid-frequency grunts tended to have pulses of varying structures; beginning with pulses with two peaks similar to broadband grunts, but transitioning to single peaks like the low-frequency grunts.

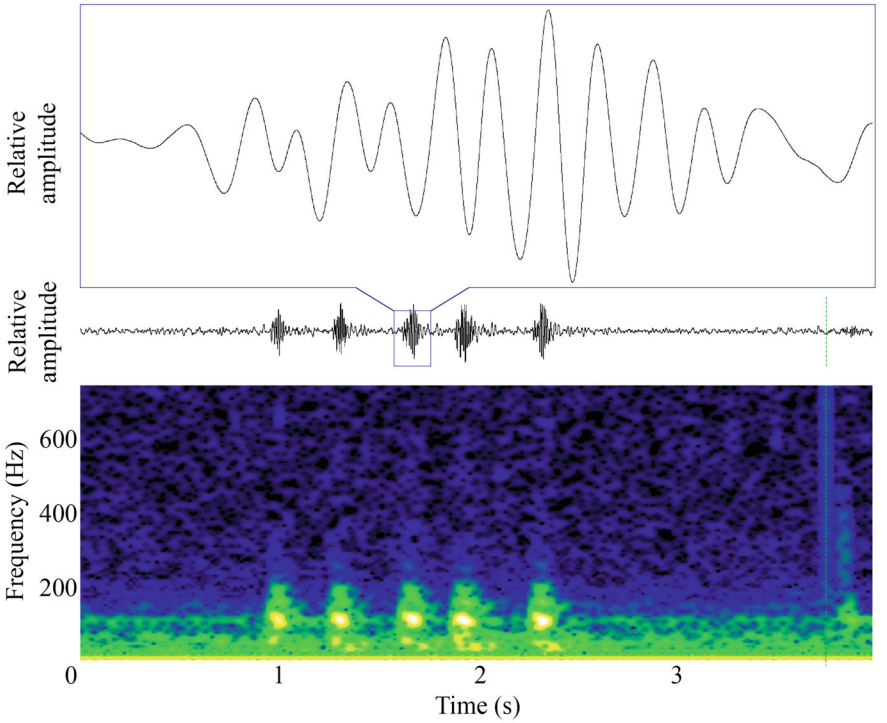

**Fig. 3** Waveform (top) and spectrogram (bottom) of a mid-frequency grunt train produced by walleye pollock (*Gadus chalcogrammus*) recorded at the Hatfield Marine Science Center (10,500 FFT Hann window with 85% overlap). The top panel is an expansion of the third grunt in the middle panel, delineated with a box, to show the structure of each pulse

Twelve variables were selected for input into the CDA analysis, which resulted in a strong discrimination among the four sound types ($p < 0.0001$; Table 3; Fig. 5). The eight variables that contributed the most to the group discrimination are shown as vectors drawn from the origin with lengths proportional to the variable's contribution to the group separation and direction indicating the variable's relative contribution to each canonical. The first two canonicals were significant ($p < 0.001$) and account for 98% of the variance. The four sound types are separated most strongly on the first canonical, which is driven largely by sound frequency composition. Sound types with lower frequencies (low-, mid-, and two-frequency types) cluster on the left, while the broadband type with higher-frequency content clusters to the right. The second canonical is driven most strongly by the sound energy content (positive) and frequency content (negative) and separates the mid- from the two-frequency sound types, with the low-frequency type intermediate. The low- and two-frequency types are most similar.

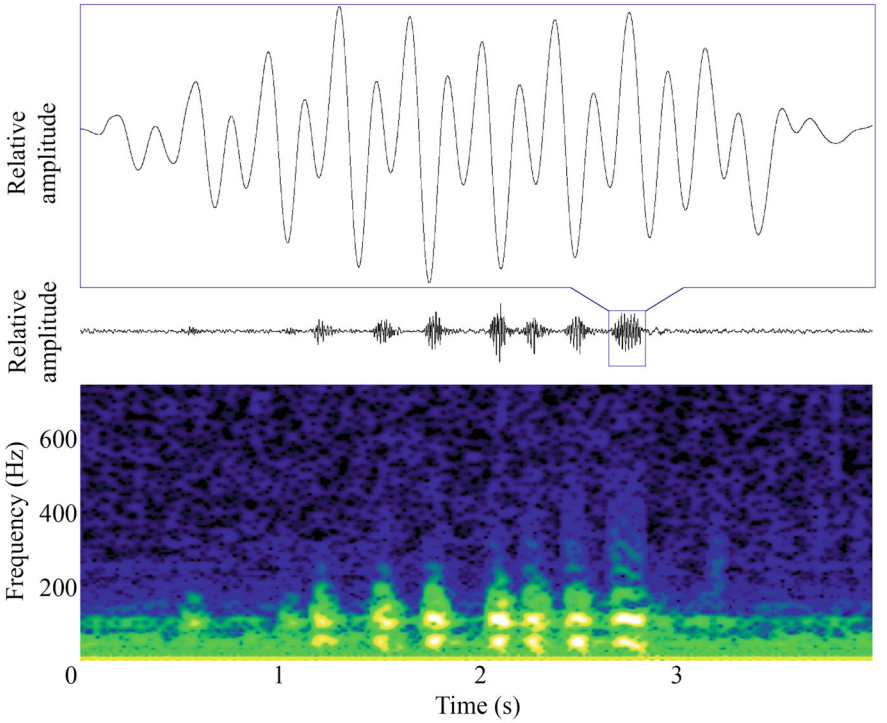

**Fig. 4** Waveform (top) and spectrogram (bottom) of a two-frequency grunt train produced by walleye pollock (*Gadus chalcogrammus*) recorded at the Hatfield Marine Science Center (10,500 FFT Hann window with 85% overlap). The top panel is an expansion of the last grunt in the middle panel, delineated with a box, to show the structure of each pulse

## Discussion

Walleye pollock produced at least four different types of sounds based on their frequency and pulse structures. Park et al. (1994) similarly reported four types of sounds, but presented only limited information on sound characteristics. They reported a high frequency of 800 Hz, similar to the 838 Hz maximum frequency reported herein. Park et al. (1994) highlighted four behavioral states in which sound production occurred: threatening, attacking, courting, and mating, each with a distinct associated sound type. Unfortunately, this study lacks visual observations of behavior, but the broadband grunts described here (Fig. 1) strongly resemble the spectrogram of aggressive-attacking calls presented in the Park et al. (1994) study. The other three types of grunts reported here had lower frequencies, similar to the courting and mating calls reported by Park et al. (1994), but more data are need to confirm the associated behaviors.

**Table 3** Canonical coefficients for all 12 variables input into a canonical discrimination analysis (CDA) among 4 types of sounds produced by walleye pollock based on transformed sound measurements (see Fig. 5). Pearson correlation coefficients (*$p < 0.05$; ***$p < 0.001$) of measurement variables with each canonical axis indicate variables that contributed the greatest to the discrimination among groups. Code = label for vector plotted in Fig. 5 indicating the relative contribution of each variable to the discrimination

Walleye pollock are being found in locations further North than their previously known range (e.g., Orlov et al. 2021), which means they now share a habitat with other Arctic gadids such as Arctic cod (*Boreogadus saida*). Being able to distinguish the two species acoustically would mean that PAM surveys can be used to help monitor these ecosystem-wide shifts and potential inter-species competition for habitat. In addition to Arctic cod, there are six other species of gadids that co-occur with walleye pollock in some areas of their range, such as Pacific cod (*Gadus macrocephalus*), saffron cod (*Eleginus gracilis*), Pacific tomcod (*Microgadus proximus*), Greenland cod (*Gadus ogac*), Atlantic cod (*Gadus morhua*), and polar cod (*Arctogadus glacialis*). Of these, Arctic cod (Riera et al. 2018) and Atlantic cod (Hernandez et al. 2013) are the only species with confirmed sound production. Pacific cod is the only other species that has been examined for sound production, but it has been found neither to possess sonic muscles (Hawkins and Rasmussen 1978) nor to produce sounds (Sakurai and Hattori 1996). Hawkins and Rasmussen (1978) did not find evidence of sonic muscles for saffron cod and Pacific tomcod, suggesting they are not soniferous, but direct studies of their behavior are needed to confirm that supposition. To date, the other two species (Greenland and polar cod) with distributions overlapping with walleye pollock have not been examined for sound production (Looby et al. 2022a, b).

A comparison between the walleye pollock sounds presented here and those previously described for other gadid species suggests clear differences that can be

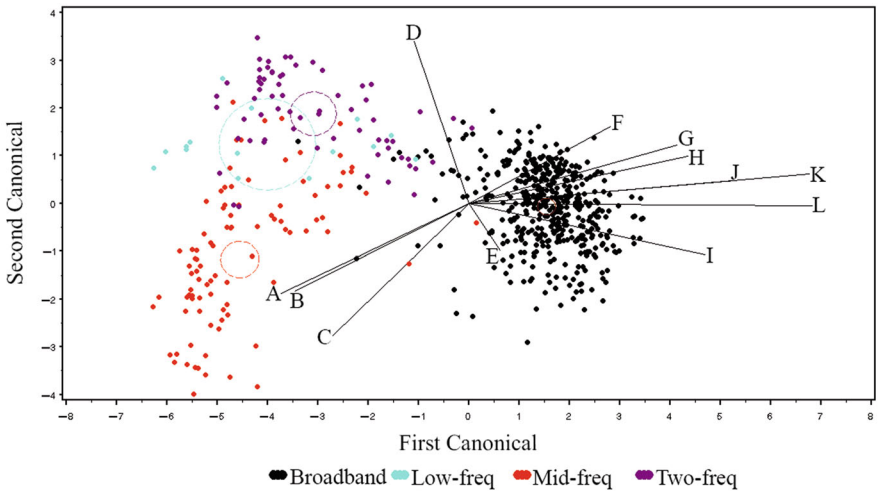

**Fig. 5** Comparison of acoustic properties of four sound types exhibited by walleye pollock: broadband (black), low-frequency (teal), mid-frequency (red), and two-frequency (purple). Canonical discrimination analysis of walleye pollock sound types for selected variables (see Table 3 for canonical statistics). Colored circles represent the 99th confidence interval for the group mean canonical. The nine variables most strongly influencing the group discrimination are shown as vectors drawn from the origin with lengths proportional to the variable's contribution to group separation and direction indicating the variable's relative contribution to each canonical. These variables are as follows: (A) fifth percentile frequency (F. 5%), (B) peak frequency, (C) low frequency, (D) energy, (E) third quartile frequency (Q3), (F) interquartile (IQR) bandwidth, (G) aggregate entropy, (H) average entropy, (I) 95th percentile frequency (F. 95%), (J) 90% bandwidth, (K) bandwidth, and (L) high frequency

used to distinguish among species where they occur together. The main difference between walleye pollock and Arctic cod grunts is the occurrence of grunt trains in the former, whereas Arctic cod are only known to produce single grunts (Fig. 6). The duration of walleye pollock grunts is shorter (average 95 ± 1.5 ms) than that of Arctic cod grunts (average 289 ± 13 ms) and is composed of fewer pulses (5 vs. 9, Table 1). The duration of grunts is still longer for Arctic cod when compared to the different types of walleye pollock grunts separately (Table 2). Although it was not possible to directly measure the fundamental frequency of either walleye pollock or Arctic cod due to high levels of low-frequency noise in the holding facilities, Arctic cod had a higher peak frequency (Table 1), but likely had a much lower fundamental frequency based on its pulse rate (30 vs. 57 pulses/s). Published data for Atlantic cod (Hernandez et al. 2013) suggest it is more similar to Arctic cod with a fundamental frequency of 50 Hz, duration of 168 ms, and average of 9 pulses/grunt.

Successful identification of underwater sounds to fish species supplies valuable proof of presence. In addition, being able to attribute specific sounds to a behavioral context can indicate the importance of a given habitat to the species (Rountree et al. 2006). This study confirms previous observations of sound production by walleye pollock during the spawning period and provides detailed data on their acoustic

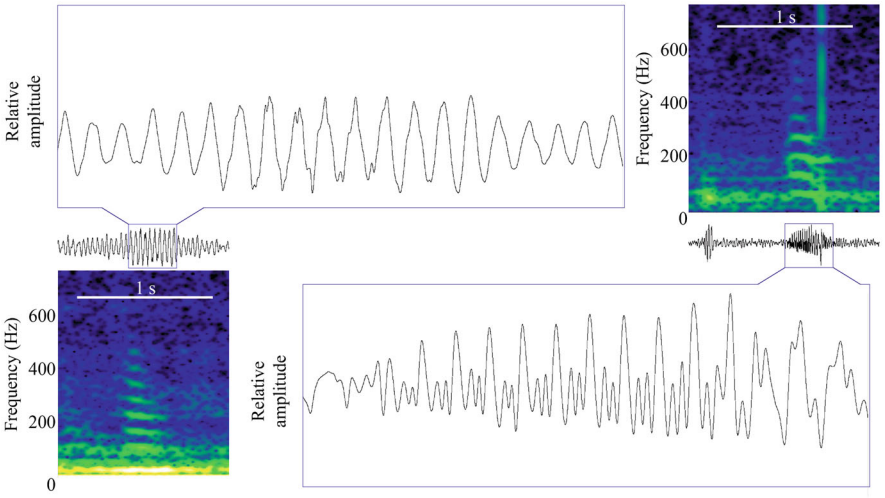

**Fig. 6** Waveform and spectrogram of Arctic cod grunts (*Boreogadus saida*) recorded at the Hatfield Marine Science Center (left) and University of British Columbia (right) (10,500 FFT Hann window with 85% overlap). The waveforms are further zoomed in to show the detail of the pulses. These grunts were quantitatively described in Riera et al. (2018)

characteristics, which will enable future PAM surveys for the species. More year-round studies will reveal whether sound production is exclusive to the reproductive period or if it also occurs at other times. Further observations with video recordings could help attribute each of the different sound types to specific behaviors. Knowing the behavioral context of different sounds could help identify important habitat for the species, for example, if reproductive grunts are reliably detected in certain locations, they might become protected at certain times of the year.

The number of existing long-term PAM datasets from the Arctic is rapidly increasing (Chou et al. 2019; Pine et al. 2020; Halliday et al. 2021), with corresponding fish sounds that have yet to be positively attributed to species. This quantitative description of walleye pollock grunts will help increase the number of fish sounds identified to species in existing recordings, as well as inform future studies with a focus on gadid presence, movement, and important habitats. However, additional studies are needed to describe sound production by other gadids in the region to ensure against false attribution of sound to either Arctic cod or walleye pollock and further enable PAM studies of interactions among all soniferous gadids in the region.

**Acknowledgments** The authors would like to thank our collaborators at the Hatfield Marine Science Center: Ben Laurel and Chris Magel. Thanks are also due to Annika Heimrich for her assistance in data collection and Lucas Agagnier for his contribution to data analysis. We are grateful to MERIDIAN for their support. Funding was provided by DFO Contribution Agreements, an NSERC Discovery grant, CFI and BCKDF equipment grants, and the Liber Ero Foundation. The authors also thank the AN2022 conference sponsors for providing travel support and the opportunity to present these findings.

**Abstract**

Fish sound production is taxonomically and geographically widespread. Produced actively or passively, acoustic contributions of fishes to aquatic soundscapes support a myriad of con- and hetero-specific interactions. Despite the ecological importance of fish sounds, the field of bioacoustics historically lacked a global inventory of fish species known to produce sound. FishSounds launched in 2021, cataloging examinations of active and passive sound production by 1185 fish species from 837 references, as well as 239 exemplary audio recordings. In April 2022, FishSounds released Version 1.1 to expand the website's data and improve its functionality. This new version updated the core dataset to include work published up until the end of the year 2021, adding 30 species, 25 recordings, and 85 references. It also added text to note the original species names used by the authors, updated all taxonomy data to FishBase version 02/2022, and included a webpage highlighting other resources that might be of interest to users. Additionally, FishSounds Educate launched a series of interactive lectures, classroom workshops, and field labs for primary, secondary, and university students. Future FishSounds versions will prioritize streamlining the data submission process, improving the user experience, and using bioacoustics to increase ocean literacy.

## Introduction

Sound is widely used for information dissemination and acquisition by aquatic taxa (Ladich 2000; Duarte et al. 2021). Acoustic signals travel faster and farther in aquatic environments than in air, often reaching greater distances than other sensory cues (Staaterman and Paris 2014; Ladich and Winkler 2017). Because of the unique benefits of sound as a sensory cue in underwater ecosystems, many fish lineages have undergone convergent evolution to increase their physiological capacity to perceive and produce sounds for communication and the assessment of habitats, resources, and threats (Ladich 2000; Kasumyan 2009). Consequently, fish sounds can be recorded passively for the purposes of ecological monitoring and fisheries management (Lindseth and Lobel 2018). Passive acoustic recording allows fish populations to be studied remotely, thereby reducing reliance on invasive sampling methods, increasing the potential spatial and temporal coverage of research efforts, and documenting novel contributions to aquatic soundscapes (Rountree et al. 2006; Rountree and Juanes 2017).

The prevalence of sound production among fish remains indeterminate despite considerable advancements in bioacoustics and global interest in how noise pollution impacts fishes (Cox et al. 2018; Duarte et al. 2021). Although there have been numerous efforts to catalogue soniferous fish species, these endeavors have been constrained spatially (Fish and Mowbray 1970; Rountree et al. 2019) or taxonomically (Colleye et al. 2011). Furthermore, currently published reviews synthesizing information on sound production in fishes lack explicit data collection methodology and reporting (Kaatz et al. 2017) or have primarily qualitative descriptions (Kasumyan 2009). Consequently, bioacousticians have identified the need to determine the prevalence of soniferous fishes and develop a comprehensive and updateable list of fish species that have been examined for sound production (Gannon 2008; Linke et al. 2018; Lindseth and Lobel 2018; Rountree et al. 2019).

To rectify this widely recognized constraint, the FishSounds project was launched (Looby et al. 2021, 2022b, 2023). To do so, it established an international collaboration between researchers and website developers from six organizations – the University of Victoria, the University of Florida, Dalhousie University, Simon Fraser University, Universidade de São Paulo, and the Marine Environmental Research Infrastructure for Data Integration and Application Network (MERIDIAN). This collaboration applied a cross-disciplinary approach, combining expertise in fish ecology, bioacoustics, and data management to the consolidation, management, and application of fish acoustics. The FishSounds project focuses on three primary objectives: (1) conduct a global, systematized review to catalogue the fish species that have been examined for sound production, (2) construct a comprehensive web portal amalgamating acoustic recordings and published information on fish sound production, which allows researchers to contribute observations and search archived examinations by taxa, sound characteristics, or reference, and (3) disseminate this information to acousticians, conservation managers, and the general public. This conference proceeding outlines the progress on these objectives, focusing on the release of FishSounds Version 1.1 as part of ongoing efforts to expand the website's

data and improve its functionality and launching FishSounds Educate as an avenue for increasing ocean literacy.

## FishSounds Version 1.1

The release of FishSounds Version 1.1 on 28 April 2022 included several extensive data and recording updates, improvements to the user experience, and additions to the web portal (Fig. 1). These updates are summarized below. Additional information on each development can also be found on the FishSounds.net website, as well as highlighted in tweets from the Twitter account (@FishSoundsWeb). When applicable, any changes made to the website are reflected in the Borealis data repository, which is versioned and archived (Looby et al. 2021).

### Data and Recording Updates

The most significant change to the website featured an update of the core dataset on literature documenting known soniferous fish species. Following the methods in Looby et al. (2022a), the updated FishSounds dataset includes any references published by the end of December 2021. This update surveyed 625 new references for potential relevance. From these references, 85 examined a fish species for sound

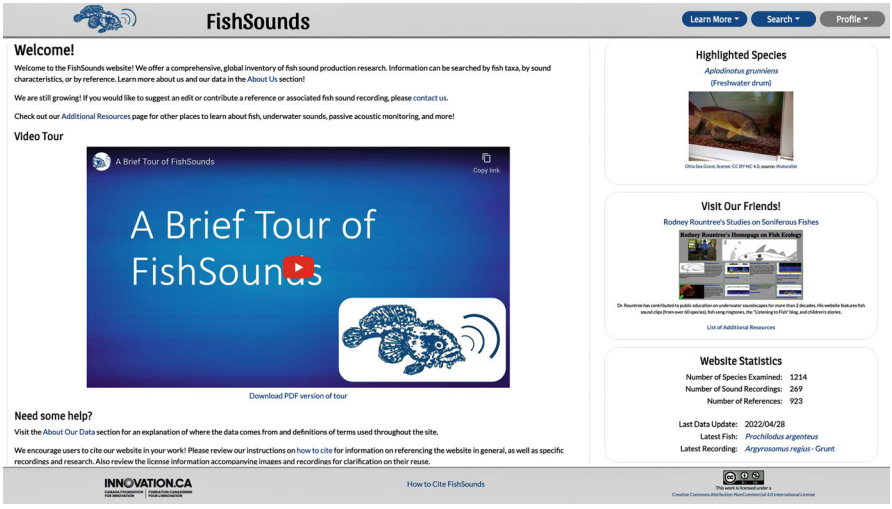

**Fig. 1** FishSounds Version 1.1 home page. The latest version of FishSounds includes the addition of 30 species, 25 recordings and 85 references, updated taxonomic information, and a web page highlighting other resources that might be of interest to users. As a result of this update, FishSounds now catalogues records for 1214 species examined across 923 references and allows users to search archived examinations by taxa, sound characteristics, or reference

production, 30 of which were new species not yet included on the website. Several of the new literature additions included work that had been published in the year since the initial Looby et al. (2021) review was completed (e.g., Parmentier et al. 2022) as well as studies that the original review had missed (e.g., Lowe and Skelton 2008). With the inclusion of these additional examinations, the website now catalogues records for 1214 species examined across 923 references, which were identified by a literature review that now spans over 3000 references.

In addition to updating the soniferous fish diversity data, 25 new recordings were added to Version 1.1 of the FishSounds website. These included several additional recordings linked to the SOUNDS table on FishBase (Kaschner 2012; Froese and Pauly 2022). Contributors generously donated new recordings, such as clips of grunt and pulse sounds produced by the meagre (*Argyrosomus regius*) that were recorded as part of Viera et al. (2019) (Fig. 2). FishSounds now provides a total of 269 recordings, making it one of the largest global repositories for fish sounds that currently exists.

The fish species information listed on FishSounds was updated as part of Version 1.1. FishSounds provides general information on fish species, such as taxonomy or distribution, taken from FishBase using the R package rfishbase (Boettiger et al. 2012; Froese and Pauly 2022). The latest update included data from the FishBase data version released in February 2022, which incorporated information from Nelson et al. (2016), among other taxonomic authorities. Changes to the FishBase data also included recognizing eight taxonomic classes instead of six, 600 families instead of 590, and well-defined suborders of Perciformes at uplifted rank orders (Bailly 2021). Numerous alterations to groupings, species, and scientific names were also included

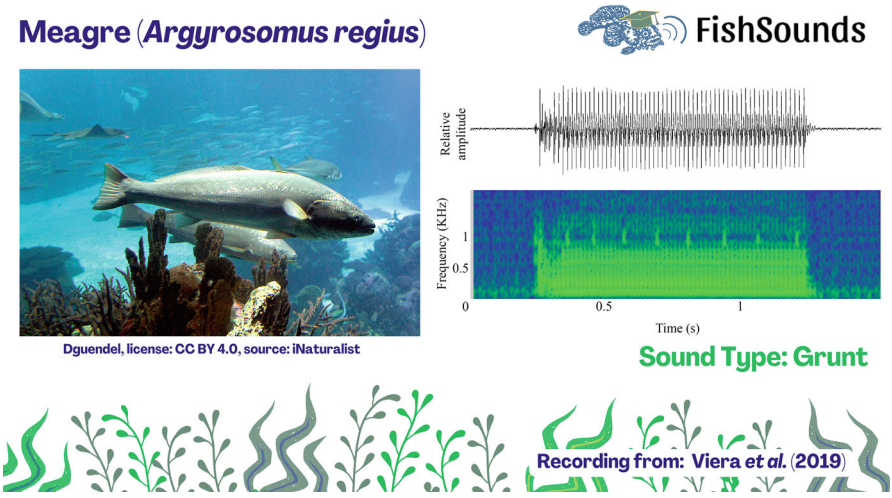

**Fig. 2** An image of the meagre (*Argyrosomus regius*) alongside a waveform and spectrogram of a representative example of its grunt sound as displayed on FishSounds (Looby et al. 2022b). Waveform and spectrogram created with permission from Viera et al. (2019). (Fish image used with permission from Dguendel (2022), license: CC BY 4.0, source iNaturalist)

in this FishBase update (Bailly 2021). Since the release of FishSounds Version 1.1, FishBase has changed to a June 2022 version, which will be integrated into FishSounds in its next data update. Incorporating the latest versions of FishBase data will ensure that FishSounds more accurately reflects contemporary thinking on fish nomenclature and taxonomy.

## Improvements to User Experience

FishSounds Version 1.1 added information to improve the user experience and website functionality. The most substantial addition included in this update was the provision of the species names originally used by the authors for the sound production examinations on the website. This will help users locate information within references for species names that have changed since their publication. For example, the scrawled cowfish was listed with the scientific name *Lactophrys quadricornis* in Fish and Mowbray (1970) but is currently listed on FishSounds as *Acanthostracion quadricornis* based on the latest FishBase classification (Froese and Pauly 2022); users may have previously had a hard time locating information on the species from its original reference because of the change. With the FishSounds Version 1.1, nomenclature previously used and currently accepted is now listed on the associated Reference Details page. The inclusion of changes in taxonomic classification will also improve the long-term sustainability of the FishSounds data, allowing it to adapt to ever-evolving fish nomenclature and making users aware of any reclassifications.

Editor's notes have also been added to the FishSounds website. Each note is indicated with a blue "" symbol and can be used by the FishSounds editors to denote potential contradictions in the literature or other notes of potential interest. For example, there is a so-called "chatter" sound that was misattributed in Fish and Mowbray (1970) to be produced by *Cynoscion regalis* (Sprague and Luczkovich 2001). Therefore, next to the Fish and Mowbray (1970) reference on the *C. regalis* species page, there is an editorial note that reads: "The chatter sound reported to be produced by this species was later shown to be produced by *Ophidion marginatum*." These editor notes will detail contradictions or corrections from the literature with more nuance than was possible during the Looby et al. (2022b) data collection.

FishSounds Version 1.1 also includes several additional features to increase users' awareness and use of external resources, web pages, and other bioacoustics repositories. All DOI numbers listed on the website, including those associated with each reference, are now hyperlinked to the source (e.g., published article). The inclusion of hyperlinks will more effectively encourage users to navigate from FishSounds to the original data sources. An "Additional Resources" page was also added to help users explore other related websites that may be of interest, such as the Ocean Networks SoundCloud or the Macaulay Library at the Cornell Lab of Ornithology, which also host impressive repositories of fish sounds and other recordings. A panel was added to the FishSounds homepage to further highlight

websites from the Additional Resources page (Fig. 1). These improvements will foster a sense of community among similar acoustics and fish websites while encouraging users to explore original research and related projects.

## Additional Changes

The FishSounds Version 1.1. update implemented other website alterations to ensure cohesion across the associated FishSounds datasets and increase data transparency. Several of the terms used to describe aspects of the references were altered during this process. For example, the term "physiological examination" was switched to "morphophysiological examination" to more accurately describe studies examining the morphological (i.e., relating to structures) and/or the physiological (i.e., relating to functions) aspects of fish sound production. Distinguishing morphophysiological examinations is also consistent with Looby et al. (2022b), which is the foundation of the FishSounds website. Other terms had their definitions clarified in the Website Definitions provided on the About page, such as the "*** frequency" term used in the acoustic measurements tables to describe the frequency that divides the spectral content above and below the percentage or quartile reported in the measurement, represented by the three asterisks. All data definitions are listed in a searchable table that allows users to easily navigate the myriad of definitions used in bioacoustics and on the website. Future FishSounds versions will continue to revise terminology based on user feedback. Other changes were made throughout the website as needed. These included listing additional citations for recording credits, adding new fish images that had been donated, and updating the website acknowledgments to include new recording contributors and research assistants, whose support is greatly appreciated. There is also an updated list of presentations and publications that have occurred since the initial website launch (e.g., Parsons et al. 2022; Looby et al. 2022a, 2023). Finally, the citation to be used when crediting FishSounds has been updated to 2022 instead of 2021 and Version 1.1 instead of 1.0.

## User Engagement with FishSounds

FishSounds has had success in garnering users and engagement. On 28 October 2022, FishSounds celebrated its 1-year anniversary (Fig. 3). Since launching, FishSounds has had over 13,000 users and 64,000 page views, with its highest user counts from the USA, Canada, and then Europe (Google Analytics 2022). The most viewed fish species on the website were the Bocon toadfish (*Amphichthys cryptocentrus*) and haddock (*Melanogrammus aeglefinus*) – fitting as the FishSounds logo is a toadfish. The FishSounds Twitter account (@FishSoundsWeb), which regularly highlights species and references from the website and shares other relevant news and papers (e.g., Fig. 4), achieved 690 followers and over 100,000 tweet impressions by December 2022 (Fig. 3).

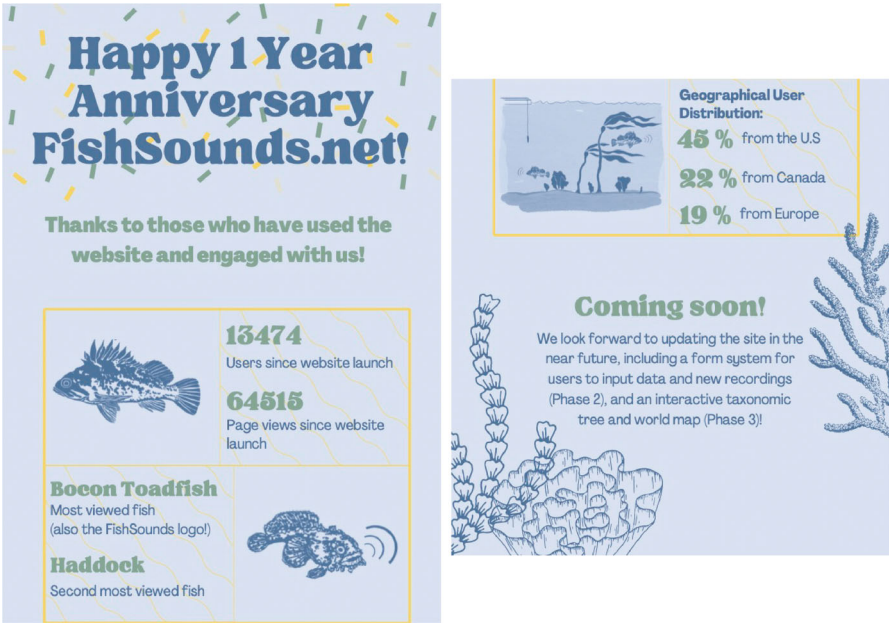

**Fig. 3** Image shared in celebration of the 1-year anniversary of FishSounds on the FishSounds Twitter account (@FishSoundsWeb) highlighting some of the website engagement metrics and future plans

## Upcoming Website Versions

Future versions of the FishSounds web portal have been scheduled for 2023. Led by Sarah Vela, these updates will continue to expand the functionality of the web portal and improve the user experience. Planned additions to FishSounds include the development of a form system for users to help contribute to FishSounds directly, an interactive map of fish passive and active sound production, and additional data visualizations. Future updates will also increase the number of species, recordings, and references in the core dataset to include work published in 2022. These data updates will follow the methods developed by Looby et al. (2022a). Version updates scheduled for the latter portion of 2023 and early 2024 will improve the extent to which users can search and download the FishSounds data and integrate a taxonomic tree illustrating passive and active sound production by fish. Future updates are the direct result of community input and aim to address the ever-expanding needs of bioacousticians, marine ecologists, and members of the public interested in fish sounds. Therefore, FishSounds is keen for feedback from the users of the web portal on how future updates can better meet the needs of the community that makes this work possible.

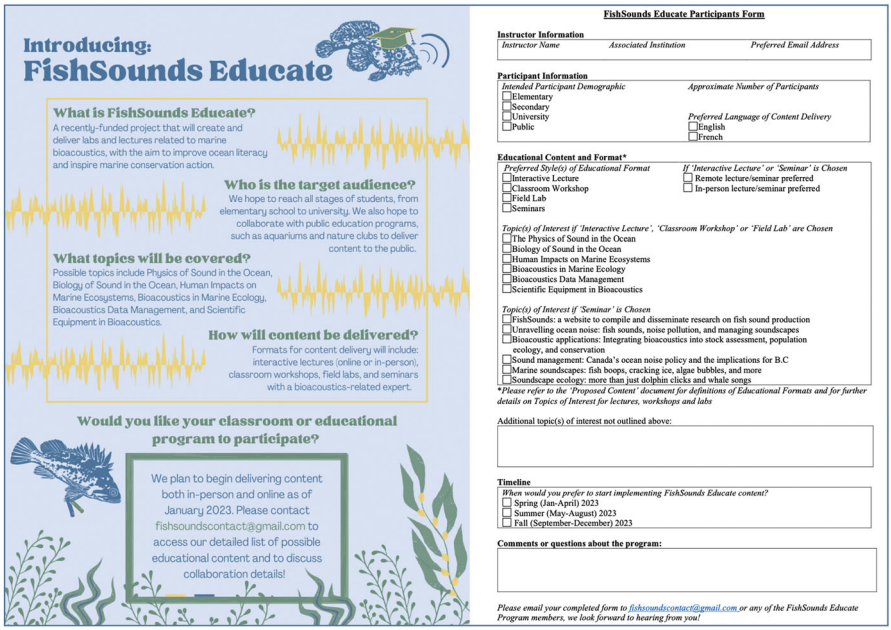

**Fig. 4** FishSounds Educate launch announcement and participation form. To increase ocean literacy in Canada, FishSounds Educate is developing and implementing interactive lectures, classroom workrooms, and field labs for primary, secondary, and university students, as well as seminars for members of the public. Instructors or institutions interested in integrating bioacoustics into their lesson plans should contact the FishSounds team

## FishSounds Educate

FishSounds Educate launched in September 2022 with the aim of increasing awareness of one of the most vital but understudied attributes of marine ecosystems – sound. This ambitious aim will be achieved through four primary objectives: establish educational partnerships, implement FishSounds Educate lectures and labs, disseminate resources equitably, and further develop FishSounds Educate online. The funding for FishSounds Educate was provided by Fisheries and Oceans Canada's Oceans Management Contribution Program, which supports outreach, monitoring, stewardship, and capacity-building initiatives to achieve Canada's commitment to marine conservation targets. The FishSounds team is currently establishing educational partnerships with instructors and institutions from across Canada to ensure that the materials reach a broad audience. Establishing partnerships involves connecting with instructors and institutions that have marine-focused programs (e.g., Bamfield Marine Science Centre), as well as those who have yet to integrate ocean sciences into their lesson plans. FishSounds Educate will implement four types of lesson materials: interactive lectures, classroom workrooms, field labs,

and seminars. Each of these will be developed for primary, secondary, and university students and then will be tailored according to classroom, institution or instructor's objectives, logistical constraints, and format. All FishSounds Educate materials will be available in English and French. FishSounds Educate will provide the training and equipment required for each type of lesson to be conducted, ensuring that participation in the program occurs at no direct cost to the instructor or institution, reducing any potential participation barriers. This will include providing access to software, hydrophones, and other acoustic recorders. FishSounds Educate will continue to support the instructors as they deliver the material or join the instructor either in person or remotely as guest presenters.

FishSounds Educate will be made freely available to the public by developing an education portal on the FishSounds website. This will include all lesson materials, instructional videos, and the information needed to become a FishSounds Educate partner. FishSounds Educate will be continually developed for the project's duration, including forming partnerships with public venues (e.g., aquariums) and non-governmental organizations. Finally, FishSounds Educate will develop the interactive lectures into a monthly seminar series on the importance of ocean noise as a tool for conservation, with the team and the broader research community presenting to academics, educators, and the public.

## Conclusions

FishSounds is one of the first publicly available and interactive web portals consolidating existing information on active and passive sound production by fishes, allowing users to search by taxa, geographical distribution (e.g., region or water body), sound type, or reference. Consequently, the FishSounds web portal provides researchers globally with a comprehensive species-level description of sound production in fish and continually updates these descriptions as the field progresses. This momentous feat was made possible due to the decades of dedicated and innovative research conducted by bioacousticians, whose examinations form the foundation of FishSounds. This web portal addresses multiple barriers restricting the progression of investigations into the ecological importance of aquatic soundscapes and extends FishSounds' utility beyond that of an archive, generating a platform for connecting researchers, facilitating collaborations, and promoting emerging research. FishSounds Version 1.1 represents an important step toward this objective. Expansions of the FishSounds data and recording archive, improvements to the user experience, and increases in the functionality of the web portal are the primary products of this update. These accompaniments coincide with the launch of the ocean literacy project – FishSounds Educate. Future updates will further prioritize increasing researchers' ability to explore and engage with the FishSounds data and foster public outreach opportunities. Despite still being in its infancy, FishSounds has the potential to bolster the field of bioacoustics' ongoing efforts to advance research into soniferous fish diversity, passive acoustic monitoring, and human

impacts on underwater soundscapes, as well as serve as a public resource for those interested in learning more about fish sounds and underwater soundscapes.

Firth, Scotland, UK. Underwater turbine noise may be important for acoustically sensitive marine mammals to detect turbines and avoid collision, but it may also negatively affect them, as well as fish and invertebrates (e.g., injury, disturbance, and habitat exclusion). The turbines' source levels were determined, and a 3D-noise model predicted the acoustic footprints of the existing and future turbine arrays. Highest noise levels were between 50 and 1000 Hz for both turbines. However, noise levels (25 Hz–25 kHz) recorded from the Andritz turbine were generally lower in amplitude compared to those recorded from the Atlantis turbine. The results show that harbor seals (and probably other marine mammal species) will be able to detect operating tidal turbines at distances that are likely sufficient to avoid collision. The MeyGen project aims to build out to 400 MW in later stages of the project which will increase the predicted noise footprint ranges presented here, with unknown environmental consequences. This highlights the importance of including these results on underwater noise in strategic marine spatial planning of larger tidal turbine arrays.

## Introduction

The United Kingdom (UK) has committed to reaching net zero greenhouse gas emissions by 2045 (Scotland) or 2050 (Wales and England) (Priestley 2019; Scottish Government 2020; Welsh Government 2021). To enable this, clean energy alternatives will have to replace fossil fuel-based energy generation. Tidal stream energy generation will likely play an important part in this transition and could provide an equivalent of 11% of the UK's annual electricity demand (34 TWh/year) (Coles et al. 2021).

As a relatively new renewable energy industry, it is important that tidal stream energy generation is developed sustainably and that next to economic, regulatory, and societal concerns, environmental impacts of large-scale tidal arrays are considered carefully when assessing the viability of future projects. While the primary environmental concerns about tidal stream energy relate to collision risk with turbine rotors and associated injuries (Band et al. 2016; Waggitt and Scott 2014; Wilson et al. 2007), underwater noise generated by devices may also negatively affect many marine animals. Potential impacts include auditory injury, disturbance, acoustic masking, barrier effects, and habitat exclusion (Pine et al. 2019; Polagye et al. 2011). In contrast, underwater noise from tidal turbines may provide an important sensory cue for animals to detect turbines and avoid collisions.

Regarding the potential of habitat exclusion study, results have been mixed and are species and scale dependent. For example, evidence from a single turbine demonstration project suggested no large-scale area avoidance for harbor seals (*Phoca vitulina*) (Sparling et al. 2018). Harbor porpoises (*Phocoena phocoena*) have also been detected within 30 m of an operational tidal stream turbine (Gillespie

et al. 2021); however, porpoises have also been shown to avoid operating turbines at the same site, with interactions with the tidal flow affecting this behavior (Gillespie et al. 2021; Palmer et al. 2021). Additionally, harbor seals have also been shown to avoid operating tidal turbine arrays on spatial scales of a few hundred meters to a few kilometers (Hastie et al. 2018; Onoufriou et al. 2021).

Whether marine mammal behavior observed around tidal energy demonstration projects can be applied across different tidal energy sites with different numbers of devices and in varying habitats is currently unknown. This uncertainty has the potential to delay or curtail licensing of future large-scale array deployments, which may include tens or hundreds of tidal turbines,[1] especially if these are sited in important transitory corridors or close to important foraging sites. To better understand potential effects of tidal arrays of this size, it is therefore important to characterize the spatial and temporal variation in the noise signatures of different types of turbines along with site-specific ambient sound and propagation characteristics of these challenging environments. This study compares the underwater noise signatures of two different types of tidal stream turbines: the Atlantis AR1500 and Andritz Hydro Hammerfest AHH1500 turbines. Both turbines are 1.5 MW three-bladed horizontal axis turbines and were measured, independent of each other, at the MeyGen[1] project site, located in the Pentland Firth, Scotland.

Underwater noise measurements near the operating turbines were used to estimate the turbines' source level and to develop and validate a three-dimensional noise propagation model for each of the turbines. The models for individual turbines were combined and used to predict the spatial extent over which turbine noise is likely to be above average ambient sound for the current array configuration in the study site (1 × Atlantis AR1500 and 3 × Andritz Hydro Hammerfest AHH1500 turbines). This information was then used to assess likely ranges over which turbine arrays may be audible to harbor seals, the marine mammal species of primary conservation concern in this area given their dramatic decline in population size in the project area over the last 20 years (Thompson et al. 2019; NERC Special Committee on Seals 2021[2]). In addition to the currently deployed MeyGen Phase 1 four-turbine array, a range of hypothetical future array scenarios for MeyGen Phase 2, based on information from SIMEC Atlantis Energy, were modelled.

## Methods

### Site Description

The MeyGen project is in the Inner Sound, a channel between the Island of Stroma and the Scottish mainland (Fig. 1); this area has a maximum water depth of 80 m and tidal currents which are among the strongest in the world, frequently exceeding

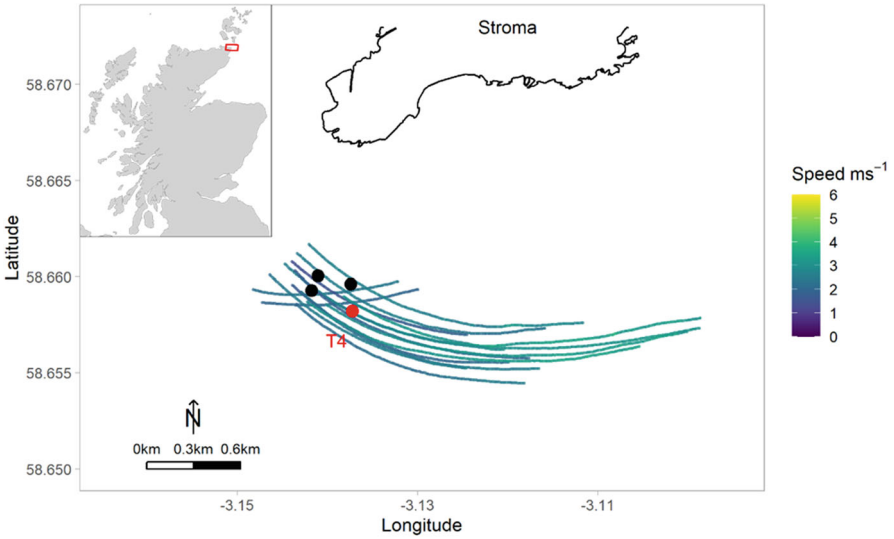

**Fig. 1** Map of the study area in the Inner Sound, showing drifter paths while Atlantis AR 1500 turbine (T4; red dot) was active and monitored (06/08/2018). The other turbines of the Phase 1 array (black dots), which were not deployed at the time of monitoring, are shown for reference. Inset shows study area (red rectangle) in relation to map of Scotland

5 ms$^{-1}$ (Shields et al. 2009). The MeyGen array was installed in 2016 and is currently the largest tidal-stream turbine array (6 MW) in the world, comprising of four 1.5 MW turbines. The MeyGen project aims to build up to 80 MW capacity during Phase 2, with the view of supporting up to 400 MW in later stages of the project[1]. The current four-turbine array contains one Atlantis AR 1500 (T4) and three Andritz Hydro Hammerfest AHH 1500 turbines (T1–3) which are deployed at water depths of about 40–50 m and spaced approximately 200 m apart.

## Sound Measurements

The Atlantis AR1500 turbine T4 and Andritz Hydro Hammerfest AHH 1500 turbine T3 were acoustically monitored on 06/08/2018 and 12–13/04/2021, respectively (Figs. 1 and 2).

To reduce the effects of water flowing over the hydrophone which can introduce flow- or pseudo-noise into sound recordings made in fast flowing waters (e.g., Martin and Popper 2016), three freely moving Lagrangian drifters were used for sound measurements. Each drifter was equipped with an acoustic recorder (RTSYS EA-SDA14) and hydrophone (Reson TC4032 and TC4014; sensitivities TC4032: −162.6 and −169.5 dB re 1 V/1 µPa; and TC4014: −179.9 dB re 1 V/1 µPa), which was suspended approximately 6 m below the surface (Risch et al. 2020; Wilson et al. 2014). The drifters were deployed upstream of the turbine from a

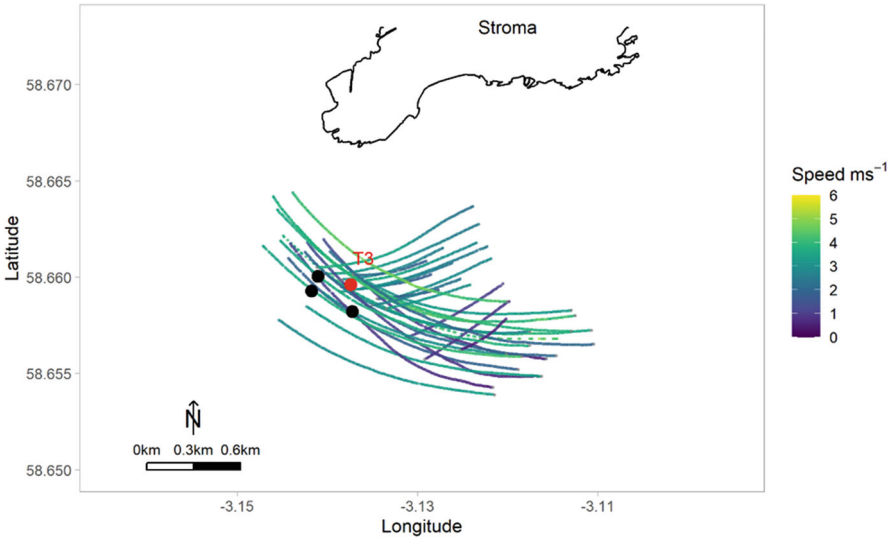

**Fig. 2** Map of the study area in the Inner Sound, showing drifter paths while monitoring the active Andritz Hammerfest AHH 1500 turbine (T3; red dot) (12–13/04/2021). The other turbines (black dots) of the Phase 1 array, which were not deployed at the time of monitoring, are shown for reference

small vessel, which then cut its engines and both the monitoring system and vessel drifted past the turbine. The drifters were then recovered, taken back upstream and redeployed.

Only one turbine was operational during each respective noise monitoring period. The Atlantis turbine was monitored during 15 individual drifts (13 during flood and 2 during ebb tide conditions), at a mean flow speed of 2.6 ms$^{-1}$. The closest point of approach of the drifting hydrophones to the turbine was at a horizontal distance of 7.6 m. The Andritz turbine was monitored over 2 days and 34 individual drifts (17 during flood and 17 during ebb tide conditions), at a mean flow speed of 2.8 ms$^{-1}$. The closest point of approach to the Andritz turbine was recorded at a horizontal distance of 23 m to the turbine.

Recordings were amplified (gain: 14.7 dB) and digitized at a sampling rate of 312,500 Hz with a resolution of 24 bit and the recording chain fully calibrated by the National Physics Laboratory (NPL). Acoustic baseline surveys covering an area of approximately 10 km$^2$ around the turbine locations prior to turbine deployment were carried out in October 2015 and May/June 2016 (Fig. 3; see Risch et al. (2020) for details). During these ambient baseline surveys, a total of 54 individual drifts were performed using 3 drifters (36 during flood and 18 during ebb tide conditions). The mean flow speed for these drifts was 2.7 ms$^{-1}$ (Fig. 3). All acoustic measurements used in this study were recorded at sea states of Beaufort wind force scale 3 or lower. Acoustic spectra were manually screened using RavenPro 1.6.4 (K. Lisa Yang

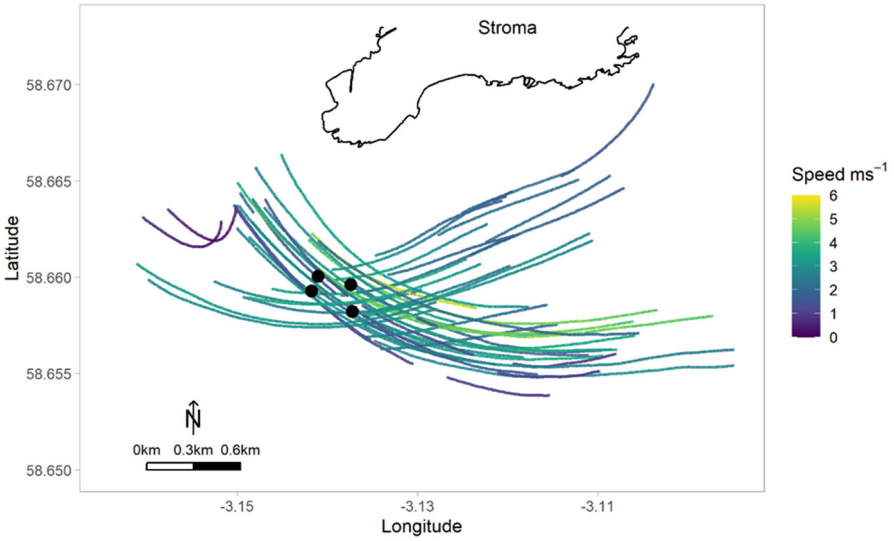

**Fig. 3** Map of the study area in the Inner Sound, showing drifter paths while monitoring ambient sound at the study site before the four turbines were installed (01/10/2015; 24/05/2016; 23–24/06/2016). Phase 1 turbine locations (black dots) are shown for reference

Center for Conservation Bioacoustics at the Cornell Lab of Ornithology 2023) and sections with vessel noise or drifter self-noise were excluded from further analysis.

## Acoustic Analyses

Spectrograms (10–1000 Hz; 10–5000 Hz; 10–40,000 Hz–1-s Hann window and 0% overlap) of the data recorded during each drift were generated and viewed using PAMGuide (Merchant et al. 2015). After initial inspection of the acoustic raw data, sound pressure levels were quantified in one-third octave bands with center frequencies from 25 to 125,000 Hz over a 1-s time window, using the one-third octave level (TOL) function in PAMGuide. Sound measurements were georeferenced, and each transect was divided into 10 m nonoverlapping segments. The median sound pressure level (SPL or TOL; dB re 1 μPa) was then calculated for each third octave band and each 10 m segment. These data were subsequently aggregated by tidal status (e.g., ebb, flood and slack water as assessed based on current directional flow in the field) and turbine rotations per minute (RPM), to evaluate noise level variations with and without operational turbine signals present.

Turbine operational data (RPM) were provided by SIMEC Atlantis Energy and ranged from 3 to 10 rotations per minute for the Atlantis AR1500 turbine (T4) and from 0.5 to 16 rotations per minute for the Andritz AHH1500 turbine (T3). However, the Atlantis turbine was not operating at full power at the time of monitoring, which was carried out during neap tides. Expected RPMs under full operation of the turbine

would be higher and more closely aligned with those of the Andritz turbine (pers. comm. F. Johnson, SIMEC Atlantis Energy).

## Turbine Noise Modelling

### Modelling Approach

A three-dimensional structural acoustic finite element model of the Atlantis AR 1500 and Andritz Hammerfest AHH 1500 tidal turbines was used to derive the source levels for turbine operational noise. The model was developed using the commercially available modelling package COMSOL Multiphysics (Comsol 2023) and has been applied successfully to the development of models of onshore wind turbine noise and tidal energy converters in the past (Carruthers and Marmo 2011). The model produces a three-dimensional sound field, from which source level as a function of angular position from the turbine main axis can be derived.

Estimated turbine source levels were calibrated using the measured acoustic data recorded in situ when the Andritz turbine (T3) was operating with a rotation speed greater than 14 RPM. This rotor speed is close the maximum speed of the Andritz device (maximum recorded RPM: 16.7) and was taken as a proxy for the peak power output. In contrast, the source level for the Atlantis turbine (T4) was derived by calibrating the finite element model to recordings of the Atlantis turbine operating at greater than 8 RPM (maximum recorded RPM: 10). The turbine was not running at full power when sound measurements were taken due to the monitoring taking place during neap tides.

The source levels derived using finite element models were extrapolated into the far-field (up to 9.3 km west of the center of the tidal array and 11.0 km east of the center) using a boundary element method at lower frequencies ($\leq$200 Hz) and a three-dimensional ray trace model at higher frequencies (>250 Hz) to increase computational efficiency. The propagation of noise was modelled at one-third octave frequencies bands from 25 Hz to 25 kHz. The tidal turbines were represented as point sources emitting ranges with a spherical spread. In the ray trace models, 10,000 rays were released from each point representing each turbine; thus, 40,000 rays were used to model the array of four turbines. The rays were allowed to propagate for 15 s, applying a 10 μs time step. Rays were terminated upon leaving the model space. Rays were also terminated when the power become less than $1e^{-20}$ W to improve the numerical efficiency of the model. The water was modelled as saltwater with properties listed in Table 1. The attenuation coefficient of the water was modelled as being frequency dependent based on the method of Ainslie and McColm (1998) and using the properties listed in Table 1.

The water surface was taken to be a perfect reflector with a reflection coefficient of 1. The seabed was modelled as sandy sediment, which is the predominant sediment type in the Inner Sound (e.g., Fairley et al. 2015) using an impedance condition based on a sediment density of 2040 kg/m$^3$ and speed of sound of 1720 ms$^{-1}$ (LeBlanc et al. 1992).

**Table 1** Materials properties of seawater modelled in the Humber Estuary (Ainslie and McColm 1998)

| Material property | Value | Unit |
|---|---|---|
| Speed of sound | 1500 | m/s |
| Density | 1026 | $kg/m^3$ |
| Salinity | 35 | Ppt |
| Temperature | 15 | °C |
| pH | 8 | |

The modelled sound pressure levels presented in this report are calculated assuming maximum power output, as approximated by peak RPM for the Andritz turbine. In contrast, the Atlantis turbine was not fully operational during monitoring, and the noise model of this turbine was calibrated with the available acoustic measurements when the turbine was at peak RPM on the day of monitoring (06/08/2018), which is not equal to peak power for this turbine. Measured and predicted noise levels presented in this report for the Atlantis turbine must therefore be treated with caution.

## Frequency-Weighting of Predicted Noise Levels

Impacts of underwater noise on marine mammals are generally estimated using auditory weighting functions (e.g., National Marine Fisheries Service 2018). Such weighting functions are based on species (or species groups) hearing range and sensitivity, and data on physiological or behavioral responses to noise. Animals are not equally sensitive to all frequencies, and auditory frequency weighting is therefore an important concept for the assessment of audibility and potential impacts of different sources of underwater noise (Tougaard and Dähne 2017). Based on phylogenetic relationships and best available knowledge, marine mammals have been separated into functional hearing groups for which similar auditory weighting functions should be applied (Southall et al. 2007, 2019). The group phocid carnivores in water (PCW) comprises all *Phocidae* in water, including harbor and gray seals. Predicted noise levels presented in this study will be frequency-weighted using the weighting function for this group to focus the analysis of turbine noise on harbor seals, which due to their declining population status (Thompson et al. 2019; NERC Special Committee on Seals 2021[2]) are the most vulnerable marine mammal species inhabiting the MeyGen project area.

## Modelling Turbine Array Scenarios

The first modelling scenario explored in this study focused on the existing four-turbine array (1 × Atlantis and 3 × Andritz turbines) deployed during Phase 1 of the MeyGen project. The noise propagation models for each individual turbine were calibrated with empirical field measurements of both turbines (see above) before integration into a cumulative far-field noise field. The MeyGen project will build up to 80 MW (= 30 turbines) in Phase 2 of the project[1]. Although the specific details of Phase 2 (in terms of turbine numbers, type, and locations) are yet to be finalized, four realistic yet hypothetical future 30-turbine array scenarios were modelled. Scenarios varied in turbine type (all Atlantis vs. all Andritz turbines) and lateral spacing of

turbine blade tips (4-m vs. 16-m). Array layouts were informed by information provided by SIMEC Atlantis Energy.

### Spatial Extent and Signal Detection Ranges

Soundscape measurements carried out in October 2015 and May/June 2016 were used to estimate the audibility of the turbine signal to harbor seals in the context of site-specific ambient sound conditions. In general, a sound signal can be detected by an animal up to the distance where the received sound level matches its hearing threshold at a certain frequency band. However, if the ambient sound in respective frequency bands is higher than the animal's hearing threshold, the maximum detection distance is determined by the distance at which the received sound levels equal ambient sound over a similar frequency range (Madsen et al. 2006). This simple approximation of signal audibility is generally applicable for broadband sounds. It should be noted, however, that due to the shape of their auditory filters, it is likely that harbor seals can detect the discrete tonal frequencies present in the noise produced by tidal stream turbines at a few decibels below ambient sound levels (see: Au 1993; Madsen et al. 2006; Erbe et al. 2015).

For simplicity, in this study, the minimum signal detection distance for harbor seals is assumed to be at the distance where predicted frequency-weighted turbine noise levels match the average ambient sound levels recorded during flood tides. In the Inner Sound, median ambient sound levels under these conditions are in the range of 100–105 dB re 1 μPa at 100 Hz–1 kHz (Risch et al. 2020), which is above the harbor seal hearing threshold at these frequencies (Kastelein et al. 2009). The 100 dB noise contour is therefore used to estimate the turbine signal detection distance for harbor seals. Detection distances are likely larger during periods of decreasing tidal flow when ambient sound levels are generally lower (e.g., Willis et al. 2013) and will vary spatially due to turbulence related variability in underwater sound during different tidal phases (Risch et al. 2020).

## Results

### Turbine Signal Characterization and Comparisons Between Atlantis and Andritz Turbine Sound Signatures

Example spectrograms of the closest drifts to the active Atlantis and Andritz turbines are presented in Fig. 6. Sound from both turbines is clearly discernible over ambient sound levels and reaches its maximum at the closest point of approach (CPA; measured horizontally) to the turbine (CPA Atlantis: 7.6 m; CPA Andritz: 23 m; Fig. 4).

Both turbines showed oscillating tonal signatures below 1 kHz (Fig. 4). Underwater sounds recorded from the Andritz turbine showed less pronounced tonal sounds and harmonic structure, when compared to recorded sounds from the Atlantis turbine. A strong tonal signal at approximately 20 kHz which was recorded from the

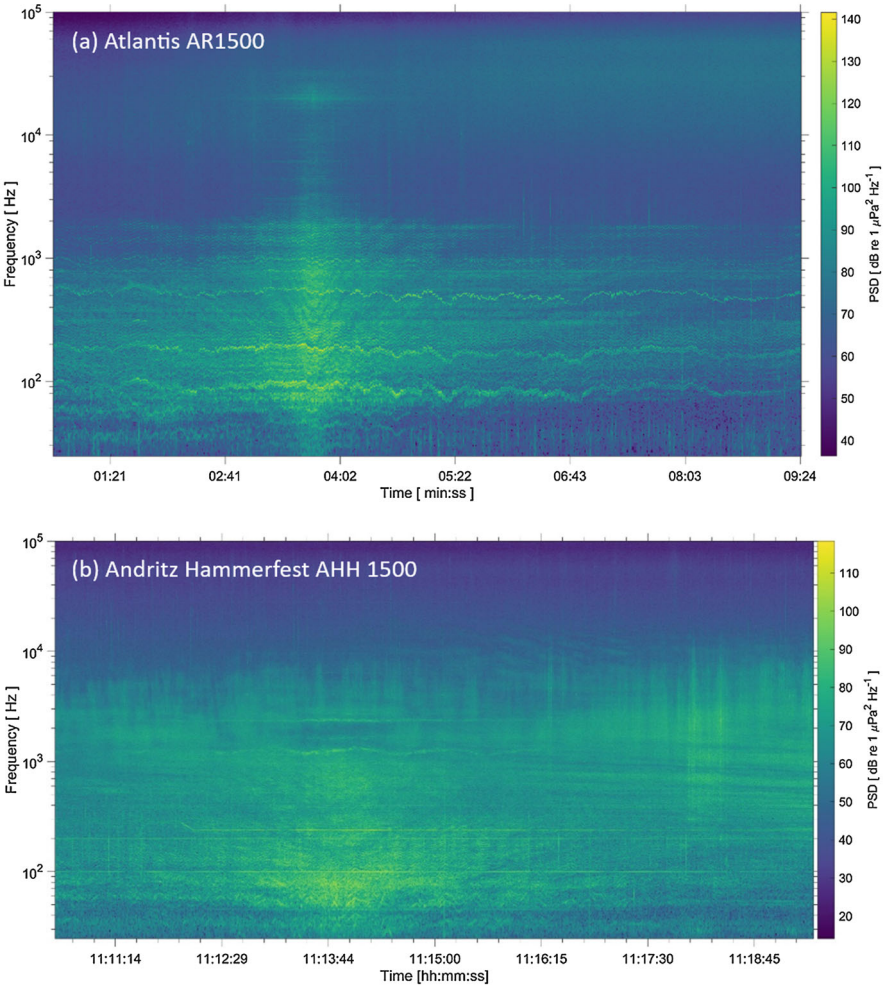

**Fig. 4** Power spectral densities (PSD; dB re 1 $\mu Pa^2 Hz^{-1}$) using a 1 s Hann window and 0% overlap for two of the closest drifts monitoring (**a**) the Atlantis AR1500 turbine (Closest Point of Approach (CPA) = 7.6m) and (**b**) the Andritz AHH1500 turbine (CPA = 23m)

operating Atlantis turbine (Fig. 4a; Risch et al. 2020) was not recorded from the Andritz turbine (Fig. 4b).

Highest broadband noise levels were observed in the lower-frequency range from 100 Hz to 1 kHz for both turbines. When comparing median noise levels, recorded at similar distances and under comparable environmental conditions, noise levels from the Atlantis turbine were generally higher than those measured for the Andritz turbine, particularly in the lower ($\leq$100 Hz) and higher (>1 kHz) frequency ranges (Fig. 5).

For both turbines, sound levels across the full spectrum were approximately 10–20 dB higher when measured within 20–30 m from the active turbines compared

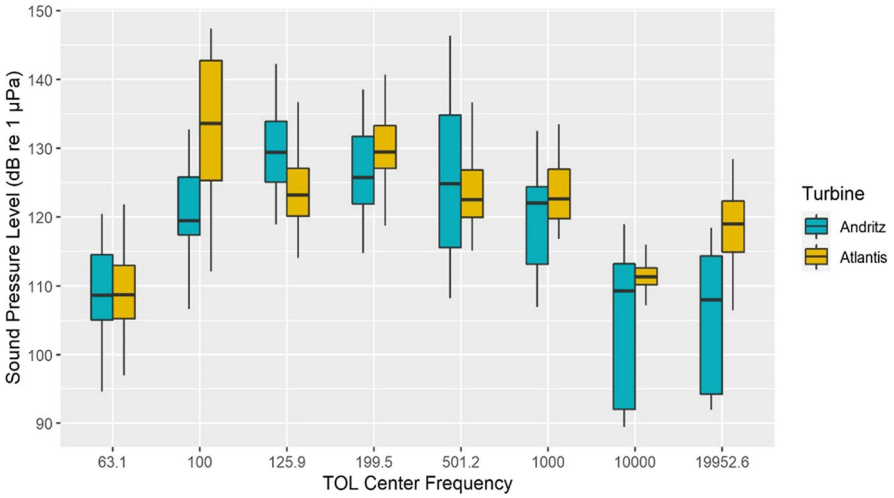

**Fig. 5** Grouped boxplot of one-third octave sound pressure levels (TOL in dB re 1 µPa) measured within 0–100 m from the Andritz Hammerfest AHH1500 (blue) and Atlantis AR 1500 (yellow), respectively. All measurements were taken during flood tide, sea state ≤2 Beaufort and maximum RPM (which differed between turbines and was higher for the Andritz turbine, see section "Methods"). Lower and upper bounds of boxes represent lower and upper quartiles, respectively. Solid lines represent medians, and whiskers indicate furthest data points within 1.5 × interquartile range. TOL center frequencies (x-axis) in Hz

to those measured between 100 and 120 m from it under similar conditions (Figs. 6 and 7). For the Atlantis turbine, median noise levels for frequencies between 100 Hz and 1 kHz were between 125 and 140 dB re 1 µPa, when measured within 20 m from the turbine (Fig. 7a). Measured sound levels for the Andritz turbine were more variable (Figs. 6 and 7), but maximum noise levels for individual one-third octave-bands were in a similar range for both turbines (Fig. 7a).

Sound levels were generally lower when RPM was lower, for both turbines (Figs. 6 and 7). As described above, the Atlantis turbine was not operating at full power during acoustic monitoring of the turbine; maximum observed RPM for this turbine were between 7 and 9 RPM, while for the Andritz turbine, highest recorded rotational speeds were between 14 and 16 RPM. This limitation of the available data set needs to be carefully considered when interpreting the results of this study and the predicted noise levels in subsequent analyses.

## Noise Propagation Modelling and Noise Predictions for Multi-turbine Arrays

Turbine noise level measurements were used to estimate source levels for both turbines and build individual turbine noise propagation models, treating each turbine as a point source. Propagation models were compared to measurements at a range of

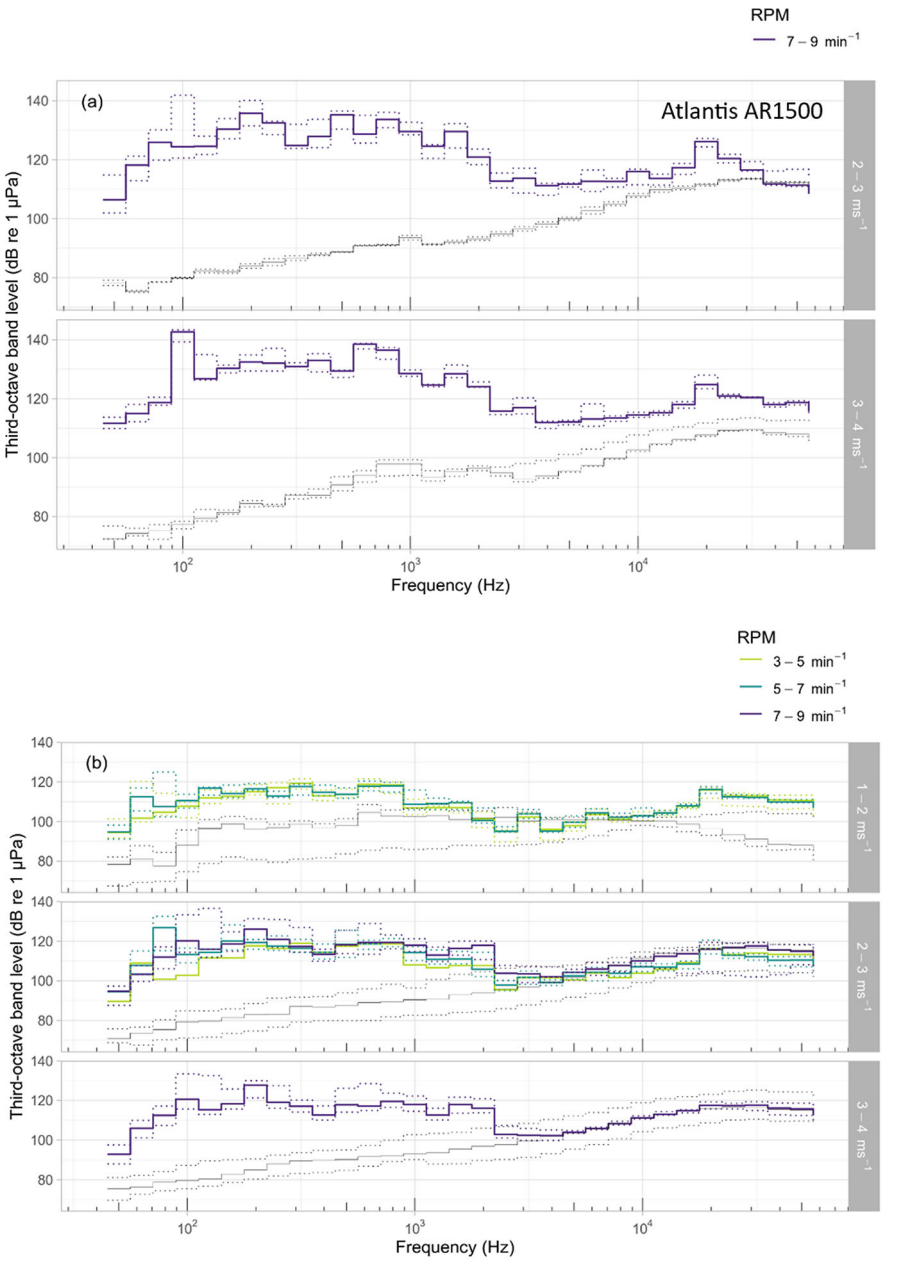

**Fig. 6** Atlantis AR1500: Median one-third octave sound pressure levels (50 Hz–63 kHz; TOL in dB re 1 µPa) (thick lines), and 5th and 95th percentiles (dotted lines), calculated over a 1 s window. Plots are faceted by current speed in $ms^{-1}$, as measured by drifters, and colored by turbine rotational speed in $min^{-1}$ (RPM). All data collected during flood tides and Beaufort 2 or below. (**a**) Data

distances from the operational turbines. Validation results for the Andritz Hammerfest AHH 1500 turbine showed reasonable agreement between measured and modelled data, with most model predictions falling within one stand deviation of the mean measurements at 100 and 1000 m from the turbine.

Cumulative, broadband (25 Hz–25 kHz) turbine noise levels modelled for the currently deployed four-turbine array (1 × Atlantis, 3 × Andritz), assuming maximum power generation,[3] are presented in Fig. 8. The overall larger acoustic footprint for noise generated by the Atlantis turbine is discernible. This difference is likely driven by the additional noise at 20 kHz and higher levels in the lower frequencies (e.g., Figs. 4, 5, 6, and 7). Given average broadband ambient levels of about 100 dB re 1 μPa (Risch et al. 2020), unweighted noise levels for this scenario extend to an area of 1.5 $km^2$ above ambient sound, with a median and maximum radius (calculated from the centroid of the 100 dB contour) of 714 m and 845 m, respectively (Fig. 8a, Table 2). Frequency-weighted (for phocid carnivores in water (PCW); Southall et al. 2019) turbine noise levels for this scenario are above ambient across an area of 0.2 $km^2$ with a median radius of 259 m (Fig. 8b, Table 2).

The MeyGen project will build out to 80 MW (= 30 turbines) in Phase 2 of the project[1]. Four hypothetical but realistic future 30-turbine array scenarios were modelled. Scenarios varied in turbine type (all Atlantis vs. all Andritz turbines) and lateral spacing of turbine blade tips (4-m vs. 16-m). Array layouts were informed by information from SIMEC Atlantis Energy.

Model results for the 30-turbine scenario with all Atlantis AR 1500 turbines for the 4-m array are shown in Table 2. PCW frequency-weighted turbine noise levels are above ambient across an area of 0.8 $km^2$, with a median and maximum radius of 540 m and 657 m, respectively (calculated from the centroid of the 100 dB contour). This compares to an area of 1.0 $km^2$, with a median and maximum radius of 588 m and 824 m, respectively, for the array with 16-m spacing between Atlantis turbines (Table 2).

For a 30-turbine array of all Andritz Hammerfest AHH 1500 turbines, PCW frequency-weighted noise levels of the 4-m spaced arrays are above ambient across an area of 0.3 $km^2$, with a median and maximum radius of 330 m and 434 m, respectively (Table 2). The area of turbine noise above ambient sound for the 16-m array is 0.4 $km^2$, with a median radius of 356 m and a maximum radius of 669 m from the centroid of the 100 dB contour (Table 2).

**Fig. 6** (continued) recorded between 0 m and 20 m and (**b**) between 100 m and 120 m from the operational turbine. Gray solid lines are median ambient one-third octave band levels collected under similar conditions and across the same spatial range. Gray dotted lines indicate 5th and 95th percentiles of ambient noise levels

[3] The Atlantis turbine was not fully operational yet at the time of monitoring (pers. comm. F. Johnson, SIMEC Atlantis Energy), which will affect measured and predicted noise levels.

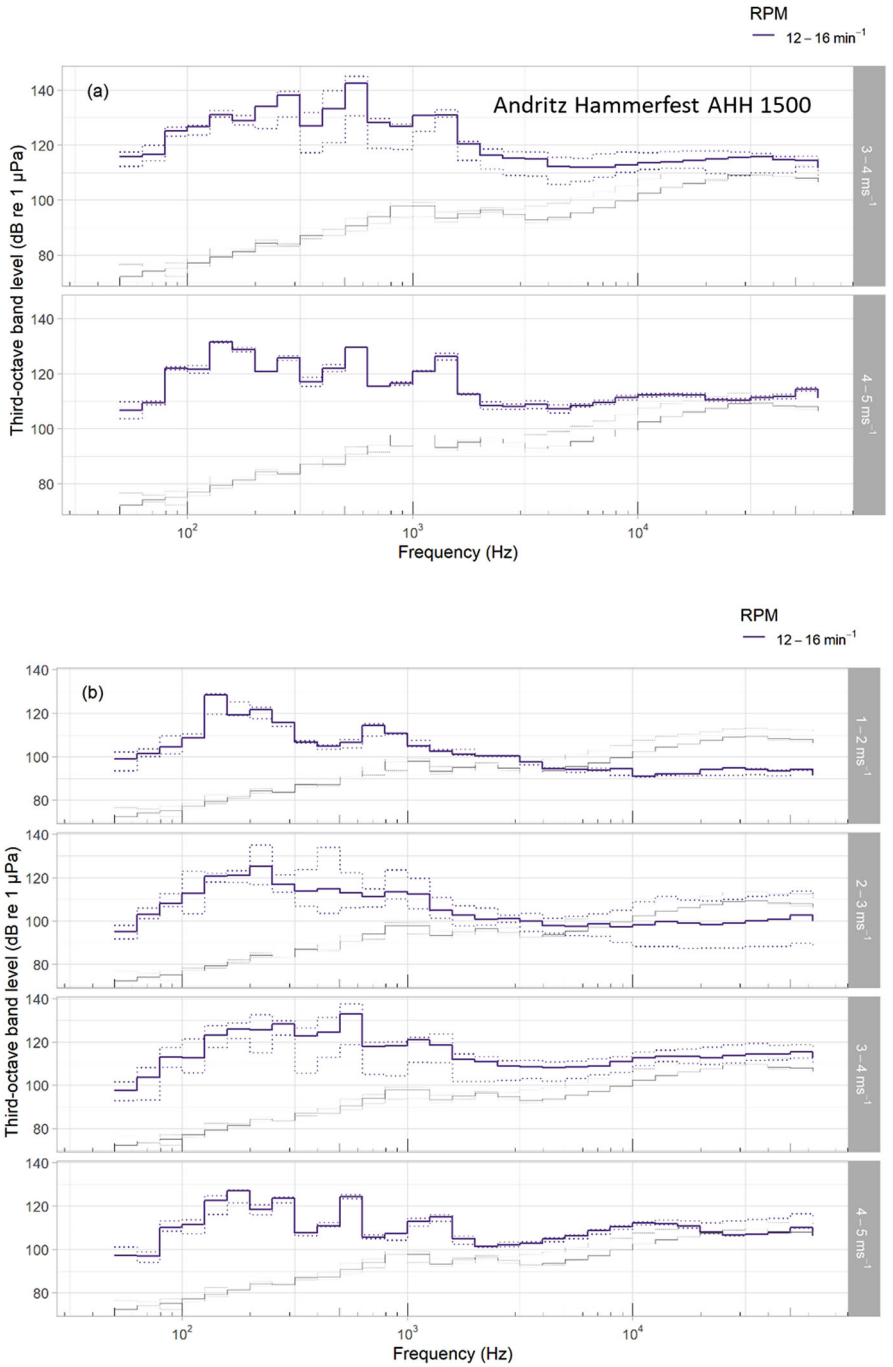

**Fig. 7** Andritz AHH1500 turbine: Median one-third octave sound pressure levels (50 Hz–63 kHz; TOL in dB re 1 µPa) (thick lines), and 5th and 95th percentiles (dotted lines), calculated over a 1 s

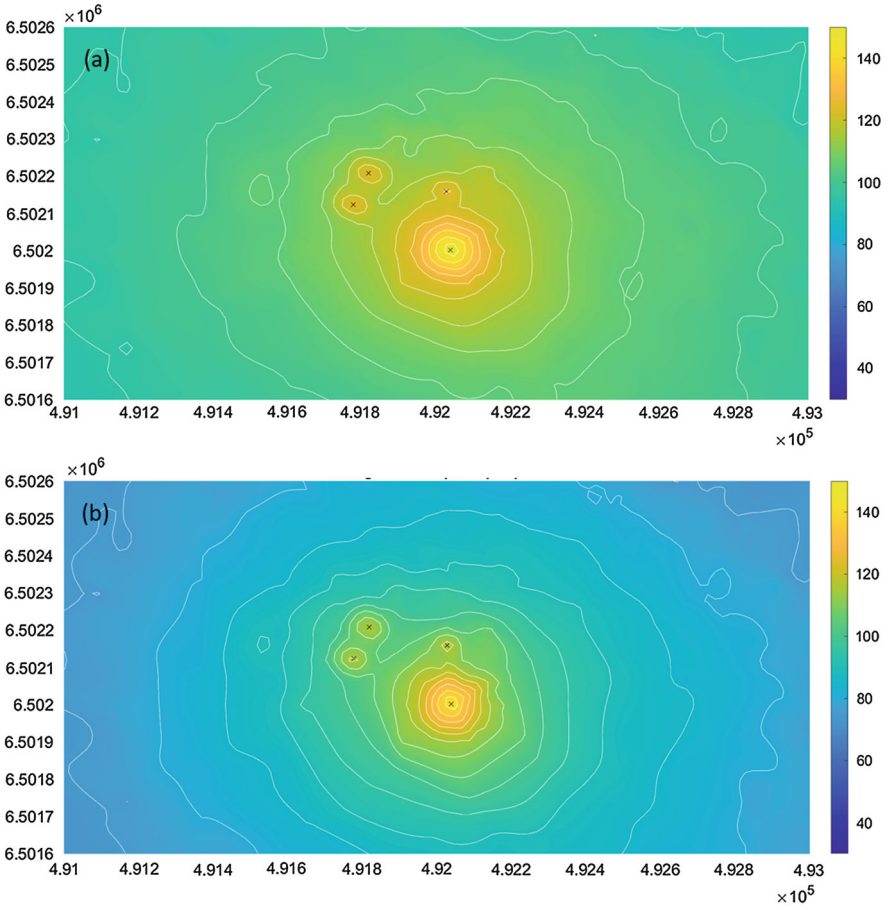

**Fig. 8** (**a**) Unweighted and (**b**) phocid carnivores in water (PCW) weighted sound pressure level map (25 Hz–25 kHz) for MeyGen Phase 1: four-turbine array (1 × Atlantis AR 1500, 3 × Andritz Hammerfest AHH 1500). Scale: one-third octave sound pressure level (dB re 1 μPa)

When comparing cumulative noise levels of the 4-m Atlantis vs. Andritz turbine arrays, the louder Atlantis array extends the area over which weighted received levels are above ambient sound by 0.5 $km^2$ in area and 223 m maximum radius compared to the Andritz array (Table 2). When spacing individual turbines by 16-m

**Fig. 7** (continued) window. Plots are faceted by current speed in $ms^{-1}$ (as measured by drifters) and colored by turbine rotational speed in $min^{-1}$ (RPM). All data collected during flood tides and Beaufort 2 or below. (**a**) Data recorded between 0 m and 30 m and (**b**) between 100 m and 120 m from the operational turbine. | **30 turbines; 16-m lateral spacing (Andritz); PCW weighted** | 0.4 | 669 | 356 |

between rotor tips, the difference between the Atlantis and the Andritz arrays is 0.6 $km^2$ in area and 155 m in maximum radius from the centroid of the 100 dB contour (Table 2).

## Discussion

This study characterized the underwater sound characteristics of two types of tidal stream turbines, the Atlantis AR1500 and Andritz Hammerfest AHH1500 turbines. The peak frequencies of both measured turbines were between 100 Hz and 1 kHz. Both turbines produce a similar oscillating tonal signal with a fundamental frequency of about 100 Hz, although oscillations were more clearly discernible in the signal of the Atlantis turbine. Harmonics were also more pronounced for this turbine.

Underwater noise produced by tidal stream turbines is typically related to the mechanical vibration in the machinery; it is created by imbalances of the rotating components, including the teeth in the gearbox encountering each other (referred to as *gear meshing*) and electromagnetic interaction between the spinning poles and stationary stators in the generator (referred to as *cogging forces*). Rotational imbalances often occur at very low frequencies (<50 Hz), while gear meshing and electromagnetic interactions tend to occur at low to moderate frequencies (50 Hz–2 kHz) (B. Marmo, *pers. comm.*). All these sources occur in discrete frequency bands related to the rotational speed of each component, which likely creates the tonal signatures observed here and in other studies of operational horizontal axis tidal-stream turbines (Lossent et al. 2018; Schmitt et al. 2015). It has also been shown that sound levels vary in relation to operational mode of turbines (e.g., constant spinning, free-wheeling, and braking) (Schmitt et al. 2015). In the current study, only rotational state of the turbines was known and compared against recorded turbine noise levels. In future acoustic studies, it would be useful to

record turbine noise during different operational states to assess relative changes in noise levels throughout the tidal cycle. When interpreting results from this study, the relatively low rotational speed of the Atlantis turbine, when the current recordings were made, needs to be considered, as noise levels can be expected to be higher when the turbine is operating at higher rotational speeds (Risch et al. 2020). Fundamentally, predicted noise levels for scenarios including this turbine type are an approximation and should be adjusted once new data collected from a turbine of this type operating at full speed become available.

With these caveats in mind, results from this study showed that within 100 m from the operating turbine, median noise levels in the peak one-third octave band (centered at 100 Hz) measured from the Andritz turbine (120 dB re 1 μPa) were about 10 dB lower than those for the Atlantis turbine (133 dB re 1 μPa) (Fig. 5). These noise levels are higher than those reported for operational noise from offshore wind turbines of comparable size (1.5 MW) recorded at the same distance (102–112 dB re 1 μPa; see Tougaard et al. 2020). This is expected, as in the case of tidal turbines all noise sources are fully submerged, whereas wind turbines produce airborne noise, some of which is carried underwater via the turbine tower. Turbine noise levels are slightly lower than those recorded from a passing ship (130–140 dB re 1 μPa; Hermannsen et al. 2014; Tougaard et al. 2020). However, compared to a passing ship, the contribution of tidal turbines to the local soundscape is more constant, albeit variable depending on tidal state (Risch et al. 2020).

When comparing median noise levels, recorded at similar distances and under comparable environmental conditions, levels from the Atlantis turbine were generally higher than those measured for the Andritz turbine (Fig. 5). Further, a 20 kHz tone was detected when monitoring the Atlantis turbine (see Fig. 4 and Risch et al. 2020) but was not present in the recordings of the Andritz turbine. The origin of this component of the signal is currently unknown. However, it is most likely produced by electromagnetic interactions inside the turbine, as it is recorded only when the turbine is generating power and not during times of slack water when the turbine is not generating (Gillespie et al. 2020).

Predicted noise levels in the subsequent array modelling exercises are dominated by the contribution of the louder Atlantis turbine (Fig. 8). There are many possible causes of the difference in noise levels, including differences in the way the drivetrains are coupled to their support structures (B. Marmo, *pers. comm.*). However, more data collected under various operational states of both turbines would help to elucidate further causes for the observed differences as well as their relative impact on the noise footprint of future turbine arrays.

Recordings of both turbine types were used to calibrate and validate the turbine source levels, and noise propagation modelling, using available peak RPM as a proxy for peak power generation. Modelled broadband (25 Hz–25 kHz) noise levels for all four turbines of the MeyGen Phase 1 array at peak power resulted in an acoustic spatial footprint of 1.5 $km^2$ (maximum radius: 845 m) above average ambient sound. This area was 0.2 $km^2$ (maximum radius: 334 m) when noise levels were weighted for best hearing of seals in water using recommended auditory weighting functions for this species group (Phocid Carnivores in Water (PCW):

National Marine Fisheries Service 2018, Southall et al. 2019). These findings imply that the operating turbine array is detectable to harbor seals over a range of at least 300 m. However, given the tonal components of the Atlantis turbine signal, animals are likely able to detect the turbines at larger distances, since tonal signals can be detected at received levels a few dB below ambient sound levels (e.g., Au 1993; Madsen et al. 2006; Erbe et al. 2015). Detection distances will also be influenced by changing ambient sound levels across the tidal cycle, with quieter periods during slack water and minimum tidal currents likely providing conditions for better signal propagation (e.g., Carter 2013; Willis et al. 2013). Localized turbulence (e.g., standing waves, boils, and downwellings) also contribute to a dynamic variation in the acoustic soundscape and may also influence detection distances of tidal turbines (Bassett et al. 2014; Willis et al. 2013). Possible avoidance of turbine arrays or other behavioral changes might also be extended to larger areas under quieter ambient sound conditions.

Overall, these data show that harbor seals (and likely other marine mammal species, such as gray seals, harbor porpoises, and delphinids) will be able to detect operating tidal turbines at distances that are likely sufficient to avoid collision. This aligns with previous studies of animal behavior around tidal stream turbines which showed that both harbor seals (Hastie et al. 2018; Joy et al. 2018; Onoufriou et al. 2021) and harbor porpoises (Sparling et al. 2018; Tollit et al. 2019; Gillespie et al. 2021; Palmer et al. 2021) avoid operating tidal turbines on spatial scales of a few hundred meters to a few kilometers.

Regarding the potential of habitat exclusion, evidence from a single turbine demonstration project suggested no large-scale area avoidance for harbor seals (Sparling et al. 2018). On the other hand, the species has also been shown to avoid operating tidal turbines on spatial scales of a few hundred meters to a few kilometers (Hastie et al. 2018; Onoufriou et al. 2021). Results from the current study show that the noise footprint of turbine arrays depends on turbine type, array size, and spacing of individual turbines, which will also affect avoidance distances. In addition, environmental factors (width of channel, number of entrances, flow speed, etc.) and individual and population level behavioral differences could also contribute to differences in avoidance between sites.

Comparing predicted noise levels of the MeyGen Phase 2, 30-turbine array scenarios of all Atlantis and all Andritz turbines showed radial differences in frequency-weighted sound levels (above ambient sound) of 233 and 155 m for the array with 4-m and 16-m spacings between turbine blade tips, respectively (Table 2). Due to their smaller size, noise levels in the center of the 4-m arrays are about 2 dB higher than in the 16-m arrays (Table 2). However, given that the two array sizes are still relatively similar in size (about 1.5 difference in overall array size), the noise fields of these (realistic) Meygen array scenarios are similar when compared at a few kilometers distance from the array center (Table 2).

Despite relatively small differences in noise extent between the 4-m and 16-m 30 turbine arrays compared here, results from this study demonstrate that, in general, it can be expected that the noise field of arrays with larger spacing between individual turbines will result in larger overall noise footprints, which might increase

behavioral response distances and the likelihood of habitat loss even in highly dynamic tidal environments that show comparatively high ambient noise levels (Risch et al. 2020). This is of particular importance, given that after the second phase of the MeyGen project, which will build the array out to the consented 86 MW (about 30 turbines added to the existing 4), the view is to support 400 MW in later stages of the project.

Results from this study extend an earlier acoustic study of the Atlantis turbine (Risch et al. 2020) by adding information about operational noise of the Andritz Hammerfest AHH 1500 turbine deployed at the same location. This allowed for comparisons between the turbine types and array configurations with different spacing between individual turbines which highlighted the importance of taking turbine type, array size, and configuration into account when predicting the spatial extent of underwater noise produced by tidal stream energy generation. Specifically, results from this study showed that different tidal stream turbines produce different noise signatures that vary with turbine rotational speed, which in turn is influenced by tidal current speed. This type of knowledge is vital when considering mitigation of collision risk as well as potential for avoidance, barrier effects, or large-scale habitat exclusion (e.g., Hastie et al. 2018; Gillespie et al. 2021; Palmer et al. 2021). In future, these data could be combined with locations of harbor seals tagged with GPS tags in the project area to relate observed behavioral responses to received noise levels, to then develop noise response functions, which may further inform current collision risk models (Onoufriou et al. 2021).

## Conclusion

In conclusion, this study highlighted the importance of considering cumulative noise effects of increasingly larger tidal turbine arrays. The current four-turbine array is likely detectable for harbor seals across an area of 0.2 $km^2$ (radius: 334 m). A 30-turbine (86 MW) array of all Atlantis turbines increased the area to 0.8 $km^2$ (radius: 657 m). An identical array of Andritz turbines creates a noise footprint of 0.3 $km^2$ (radius: 434 m). The MeyGen project aims to build out to 400 MW in later stages of the project which will increase these predicted ranges. We recommend that these results are included in regional strategic environmental impact assessments, which should also include other sources of noise nearby (e.g., the presence of shipping lanes).

**Acknowledgments** The ambient noise data collection for this project was supported by funding from the EU FP7REGPOT program for the MERIKA project (2014–2017) awarded to the University of the Highlands and Islands (UHI) under Grant Agreement No. 315925. The project received additional funds from the Scottish Government and UHI's Knowledge Exchange Challenge Fund to support collection of operational turbine sound data and manuscript preparation. We thank Erica Cruz from WavEC, the crews of the Environmental Research Institute's (ERI) RV Aurora and Marine Scotland's RV Scotia [trip 0816S; partly funded by the KTP project (No. 1010381/KTP9812) between Aberdeen University and MeyGent Ltd.], as well as personnel from Aberdeen University and the Sea Mammal Research Unit (SMRU) of the University of St Andrews for

fieldwork support. Many thanks to Cara Donovan, Daniel Coles, and Frasier Johnson from MeyGen and Simec Atlantis Energy for sharing turbine operational data and their encouragement and support throughout the study.

**Abstract**

The nature of underwater sound generated by floating offshore wind turbines (OWTs) is of increasing interest to the renewable energy industry. This chapter presents the findings from the measurements of the first operational floating OWF, HYWIND Scotland.

Two acoustic recorders were deployed for 4 months: one at a control site and one within the OWF. Continuous tonal sounds associated with the turbine operations and transient sounds originating from the moorings were identified. The characteristics of the latter and the relevant implications for impact assessment are described. A kurtosis analysis of the sounds from the moorings of the HYWIND turbines indicated that the signals were more non-impulsive than impulsive. Directional analysis of the acoustic data revealed that different types of sounds (i.e., creaks, snaps, rattles) were generated from each of the three monitored turbines despite these having the same design. The loudness of their signals also varied according to the source. These findings show the importance of collecting in-field measurements to inform impact assessment studies. Due to the variability of these signals, characteristics from mooring noise are difficult to predict in underwater noise modeling studies.

## Introduction

Understanding the nature of underwater sound from floating offshore wind turbines (OWTs) is a topic of increasing interest in the renewable energy industry. There are ambitious plans to develop large floating offshore wind farms (OWFs) around the world. OWFs up to 54 GW are currently proposed for construction. Each will be required to submit detailed impact assessment studies that estimate the effects of sound on marine life, among other effects.

Sound emissions from fixed-structure OWTs, such as monopiles, have been extensively measured and evaluated during installation and operation. Fixed-structure OWTs are appropriate for water depths up to ~60 m; however, in deeper locations, other approaches are planned, with a leading design being floating foundations secured to the seabed with mooring lines. No public literature is available on measurements from floating foundations because only a few have been installed to date.

HYWIND Scotland is the world's first operational floating OWF and comprises five wind turbine generators (WTGs) for a total installed capacity of 30 MW. Each

**Fig. 1** Diagram of the HYWIND Scotland WTG. (Source: Equinor ASA)

WTG is mounted on a spar buoy/pillar moored to the seabed by a ballasted catenary system employing three mooring cables (Fig. 1).

JASCO conducted a sound source characterization (SSC) study for Equinor (previously Statoil) in 2011 on a similar mooring system deployed as part of the HYWIND DEMO system off the coast of Stavanger, Norway. Those measurements led to the identification of tonal and transient sounds (e.g., snapping and clicking) generated by the turbine; the latter may be associated with the mooring system (Martin et al. 2011).

The focus of this chapter is to present an operational noise profile for the HYWIND Scotland system, describing the characteristics of the sound signals associated with the moorings of these systems and discussing the implications for their impact on marine fauna.

## Sound from Operational OWTs

Underwater sound from any type of wind turbine in operation originates in the moving mechanical parts in the nacelle, almost exclusively with energy emitted at low frequencies below 1 kHz and typically with strong tonal elements at the frequencies corresponding to the rotation of the gears and their harmonics

(Pangerc et al. 2016). Noise is transmitted through the tower and radiates into the water from the submerged section. The underwater operational sound levels might therefore depend on the type of foundation, but this has not been demonstrated by the studies conducted to date (Tougaard et al. 2020). Two factors that influence the sound level are the turbine size and the wind strength. As the size of blades increases, the mechanical forces acting on the gears and bearings also increase, resulting in higher noise levels; the same is true for an increase in wind speed (Tougaard et al. 2020). The underwater sound levels emitted by operational turbines have the potential to impact marine fauna, particularly when considering the sound fields generated by several turbines within a wind farm (Stöber and Thomsen 2021).

With regard to floating WTGs, additional potential sources of underwater sound have been identified (Martin et al. 2011). These include the mooring systems and equipment that may be project specific (this may vary according to the float solution chosen), such as pumps that may be used to ballast semi-submersible platforms. As these elements are project specific, predicting their sound signature and associated levels may be difficult to predict, especially in the environmental impact assessments when the detailed design may not have been defined. For this reason, collecting in-field measurements to characterize the signals emitted by the WTGs once installed as full-scale systems is useful.

Sound emissions associated with ballasting pumps are expected to be of a continuous nature, given that they use the same type of propellers as ballasting ships. These will also generate low-frequency tones according to their dimensions and rotational speed specifications; however, little literature is available that studied this specific component as it is not a ship's main source of underwater radiated noise (URN). Nevertheless, the pumps are activated when the wind changes directions; therefore, depending on the volume of water to be transferred, they are active for a few minutes when such an event occurs, rather than pumping constantly.

The sound emissions from the moorings of floating turbines are comparable to chains and catenaries regularly used for offshore moorings, for instance, for ocean buoys collecting long-term data. While it is common knowledge that such moorings generate sound as they move vertically and horizontally in the water column with the movement of waves, current, and tide, their signature has not been described in the literature. Typically, this source is referred to in the available literature as an "undesired" source because studies are dedicated to characterizing anthropogenic activities and mooring noise is not the target of the investigation. Moorings on buoys dedicated to acoustic monitoring are therefore designed to be as quiet as possible to ensure that this source does not impact the quality of the data by masking the target source(s) or clipping the recordings (Robinson et al. 2014). Sounds from moorings are transient, but they can occur very regularly throughout a mooring's deployment. Therefore, characterizing and assessing the potential impacts of these elements requires further investigation. Transient noises (at ~23 second intervals) with $L_{0\text{-}p}$ greater than 160 dB re 1 μPa likely related to tension releases in the moorings from floating WTGs were described for the HYWIND demo project (Martin et al. 2011), which was a single, small-scale, floating turbine installed offshore of Norway.

## Acoustic Data Collection

All underwater sound data was measured using JASCO's Autonomous Multichannel Acoustic Recorders (AMARs). One recorder (an AMAR G4) was positioned in the west-northwest area of the HYWIND site (Fig. 3). This recorder was 642 m from the turbine HS-1.

A second recorder (an AMAR G3 with a single omnidirectional hydrophone) was deployed approximately 13 km from the HYWIND site to collect "control" data for ambient sound.

## Recording Specifications

Both AMARs were fitted with GeoSpectrum Technologies Inc.'s omni-directional hydrophones (i.e., M36-V35-100 with a nominal sensitivity of −165 dBV/μPa with pre-amplification). Flow noise minimization was achieved by using an acoustically transparent shroud around the hydrophone cade.

The four hydrophones of the HYWIND mooring were mounted in an orthogonal arrangement with a nominal 50 cm spacing to allow the time of arrivals from different directions to be determined (Fig. 2). Precise measurements of the relative distance between hydrophones were taken and used as inputs for the directional calculations.

The AMARs recorded continuously at a 64,000 Hz sample rate to return a recorded bandwidth of 10–32,000 Hz. The recording channels had a 24-bit resolution with a spectral noise floor of 32 dB re 1 $\mu Pa^2$/Hz and a nominal ceiling of 165 dB re 1 μPa. Acoustic data were stored on 13 × 512 GB flash memory cards for each instrument. JASCO field staff calibrated the AMARs before deploying and after retrieving them. Calibrations were performed using a pistonphone type 42 AC precision sound source (G.R.A.S. Sound & Vibration A/S). At both sites, the AMARs logged data 24 h per day from 21 October 2020 to 24 January 2021 (Table 1). Approximately 6.6 TB of data were collected.

## Acoustic Data Analysis

The acoustic analysis methods and the terminology used were in accordance with ISO 18,405:2017 (ISO 2017).

The bearing angles of each hydrophone were calculated based on their relative distances and positions with respect to each wind turbine (Table 2). The correct orientation of the array was further confirmed by correlating the bearings obtained from the analysis of the signature of the vessel used for deploying and retrieving the recorders, *SWATH 1* with actual bearings calculated from the positions of the vessel's GPS track log.

The orthogonal hydrophone array allowed for the spatial discrimination of bearing and elevation of detected sound. Such data was stored for individual events

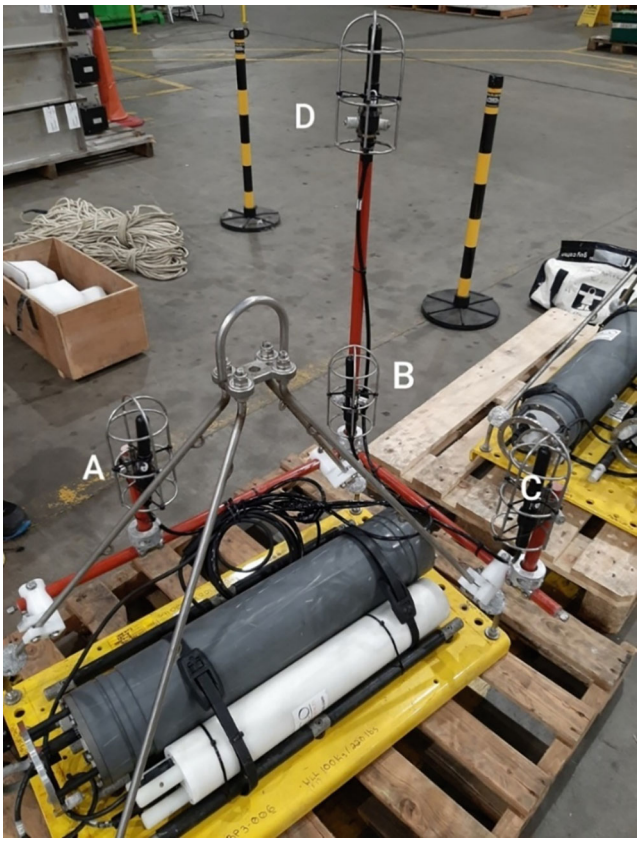

**Fig. 2** Photo of the HYWIND equipment before it was deployed. The assembly includes an AMAR G4 (white tube) fixed on a baseplate, a battery back (gray tube), and the four hydrophones mounted on a fiberglass frame (red tubes)

for later analysis. The bearing to each time/frequency cell is color coded and displayed using directograms (Fig. 3); this type of image shows the direction of a sound source relative to the array. The radial resolution obtained was 22.5 degrees. The color wheel represents sound originating from different directions. For instance, sound propagating from the north of the AMAR would be presented in a shade of red, while from the south would be colored in light blue.

Impulses were detected using a Teager-Kaiser energy detector (Kaiser 1990, Kandia and Stylianou 2006). Two distinct tonal continuous sounds below 100 Hz were identified during the analysis; these were identified as part of the floating turbines' signature. Both tones would affect the performance of the impulse detector and were therefore filtered out of the transient signals analysis. For the latter, a high-pass filter was applied (stop band $f = 85$ Hz, passband $f = 100$ Hz). A 100 ms energy time series was obtained by filtering the squared time series, then summing over a 100 ms window, and then dividing by the number of samples in the window. The

time series was divided by its mean value for each 20-s long data buffer that was passed to the Teager-Kaiser operator (Kaiser 1990, Kandia and Stylianou 2006). Normalizing this buffer by its mean value allowed for the use of a fixed threshold that was independent of the absolute magnitude of the raw time-series data. A detection threshold of 15 was chosen for the Teager-Kaiser operator. The detector

was set with a 1.0 s "lock-out" after each strike was detected; this minimized false alarms on multipath arrivals.

## Kurtosis Estimation

Understanding whether signals are impulsive or non-impulsive is important when selecting which hearing threshold shift regulatory criteria to apply (NMFS 2018). In recent years, kurtosis has been suggested as an objective metric to determine the impulsiveness of a sound source (Martin et al. 2020, Müller et al. 2020). Kurtosis was therefore calculated for the evaluation of the broadband transient signals identified in the recordings to determine the most appropriate applicable criteria for impact assessment.

Kurtosis ($\beta$) is defined as the ratio of the fourth moment to the squared second moment of the instantaneous sound pressure:

$$\beta = \frac{\frac{1}{N}\sum_{N}(p_i - \bar{p})^4}{\left[\frac{1}{N}\sum_{N}(p_i - \bar{p})^2\right]^2} \quad (1)$$

where the $i$th sample of the instantaneous sound pressure is $p_i$, the sound pressure's arithmetic mean is $\bar{p}$, and the number of data samples in the analysis window that affects the resulting value for kurtosis is $N$. As Martin et al. (2020) suggest, this project applied a 60 s analysis window. A kurtosis value of 3 represents random Gaussian noise. When deciding if a soundscape is impulsive to help determine whether an impulsive or non-impulsive hearing threshold shift threshold is exceeded, kurtosis value of 40 is used as the threshold (NFMS 2018). A kurtosis value of approximately 3 also represents wind-driven underwater ambient sound.

## Acoustic Modeling

Sound propagation modeling was performed for two purposes: to compute the source level of the sounds emitted from the turbines (i.e., back-propagation) and then to forward propagate the source levels to determine sound levels as a function of distances from the turbines. The modeling assumed that a point source could represent the turbine spar (cylinder shaped). The reported nominal draft of the spar was 78 m, with the point source being modeled at the mid-point (i.e., source depth of 39 m).

JASCO's Marine Operations Noise Model (MONM)(Austin and Chapman 2011), which is based on the parabolic equation (Collins 1998), was used for low-frequency propagation (less than 1 kHz) combined with BELLHOP for frequencies above 1 kHz.

Decidecade bands in the range 10 Hz–25 kHz were modeled. The algorithm developed by Harrison and Harrison (1995) was used to consider sounds across each frequency band (as opposed to individual frequencies). This algorithm uses a

range-dependent smoothing factor to simulate a frequency smearing in frequency, eliminating peaks and troughs in the sound field.

### HS-2 Source Levels Estimation

Source levels ($L_s$) were estimated for a single turbine (i.e., HS-2, the dominant in terms of received levels among the three turbines) according to:

$$L_S = L_p + N_{PL}. \quad (2)$$

where $L_s$ is the source level, $L_p$ is the sound pressure level (1 min), and $N_{PL}$ is the propagation loss, as per (ISO 2017) terminology.

It is only possible to back-propagate the sound levels recorded at the HYWIND monitoring station. As such, the full frequency spectra from 10 Hz to 25 kHz were included. In the low frequencies (i.e., below 100 Hz), the sound signature of the wind turbine also included the tonal components (peaking around 24 and 75 Hz) that are associated with the electrical power generation and other unknown mechanical sources within the turbines. These are not described in detail in this publication.

The source levels presented may be overestimated when the difference in sound levels between the Control and Hywind Scotland sites at specific frequency bands is small. This is because the ambient sound in that frequency band would be back-propagated.

Figure 4 shows the propagation loss ($N_{PL}$) calculated

The source levels calculated for the turbines at the different wind speeds are shown in Fig. 5 for the median (50th percentile) sound levels and Fig. 6 for the 5th percentile sound levels. For each analyzed wind speed, Table 3 shows the broadband back-propagated source levels in the 5th, 25th, 50th, 75th, and 5th percentiles.

There was a trend of increased sound levels with increased wind speed, as well as changes in the spectral characteristics. Noticeable peaks appeared at 20–25 Hz, 40 Hz, and 63–80 Hz and also at 1.0–1.25 kHz, especially at 20 knots and with the addition of a peak at 200–250 Hz at 25 knots (Burns et al. 2022).

## Results

Analyzing the acoustic data revealed a substantial amount of mooring noise. Several energy peaks were observed between 100 and 400 Hz. These appear to be associated with the regular transient sounds of the HYWIND mooring system components. The sounds are described as “snaps,” “creaks,” and “rattles.” These generally broadband transients occur irregularly, and their duration also varied, with typical durations between 0.2 and 1.0 s.

The transient sounds from the moorings are broadband, repetitive, and considerably less impulsive. These sounds are three types, described as “bangs,” “creaks,” and “rattles” during aural analysis. Aural analysis reveals that an action of tension

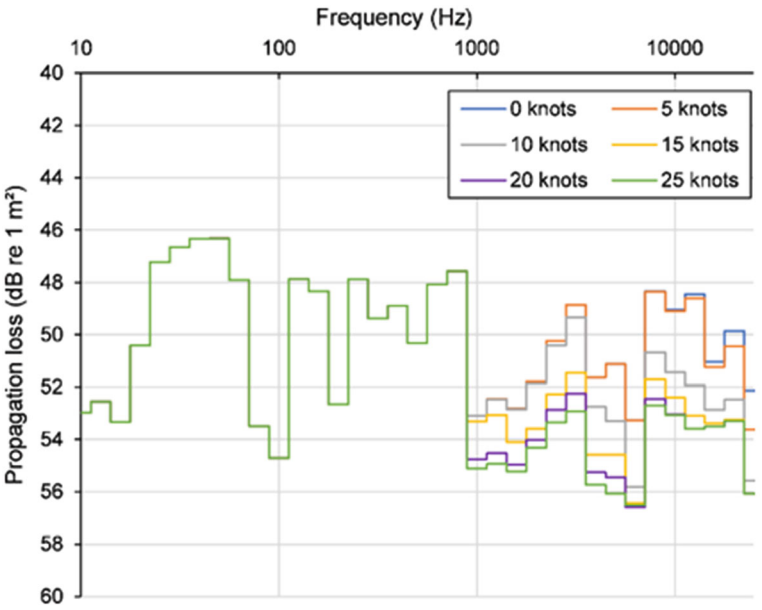

**Fig. 4** Propagation loss between the point source midway down the spar and the HYWIND recorder (880 m distance) for varying wind conditions. The propagation loss for bands below 1 kHz was calculated using the parabolic equation model that does not account for sea surface roughness (i.e., variation with wind speed). | 25 | 162.1 | 164.9 | 167.2 | 169.3 | 172.0 |

release occurs in many of these noises. The rapid onset combined with the significant intensity of the sound visible in the spectrograms supports this.

In a 20-min segment recorded on 1 January 2021, human analysists manually annotated over 300 detections (Fig. 7). The audible broadband mooring transients shown on the directogram in Fig. 7 are consistently colored blue, pink, or green. This indicates that there were three, discrete, separate sources. The directions of HS-1 (eastward), HS-4 (south-westward), and HS-2 (north-westward) correspond exactly to the direction of the blue, pink, and green sectors on the color wheel. HS-1 and HS-4 are clearly generating less mooring noise than HS-2.

The transients originating from relatively small bearing clusters, aligned with HS-1, HS-2, and HS-4, were each acoustically different and distinct. There were also similar sound pressure levels for each cluster, which indicates a consistent source

generation and distance (Figs. 8, 9, 10, and 11). The same type of mooring movement, such as surfaces rubbing under tension, appears to be generating the sounds. Most transient sounds are a repetition of staccato sounds; however, this mooring noise appears to have unique spectral and temporal identities for each turbine.

The low-frequency "bang" sound (green in Fig. 8) was associated with HS-1. The quietest of the three sounds, the bang was dominated by the lowest frequencies

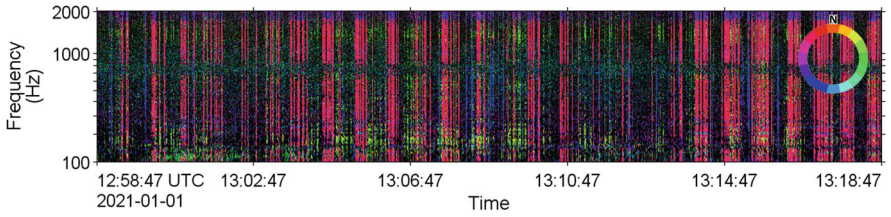

**Fig. 7** Directogram of 20 min of data during winds greater than 20 knots on 1 January 2021

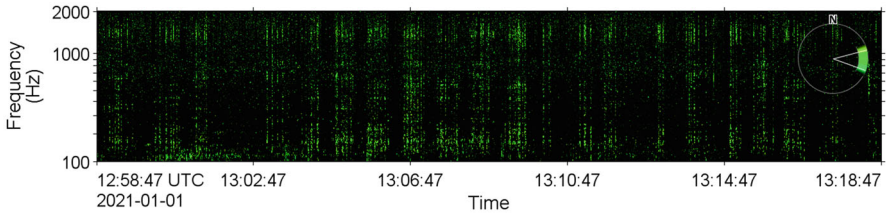

**Fig. 8** Directogram showing only transients received from the direction of HS-1

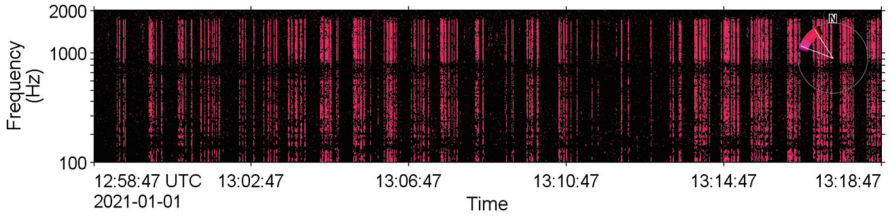

**Fig. 9** Directogram showing only transients received from the direction of HS-2

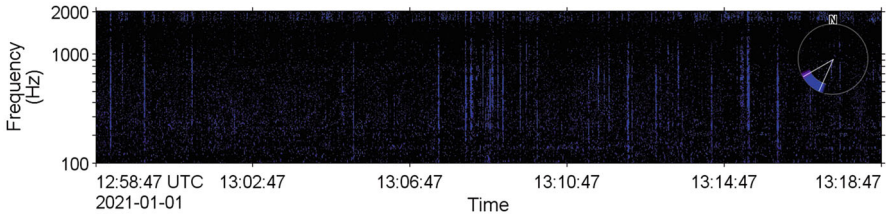

**Fig. 10** Directogram showing only transients received from HS-4 turbine

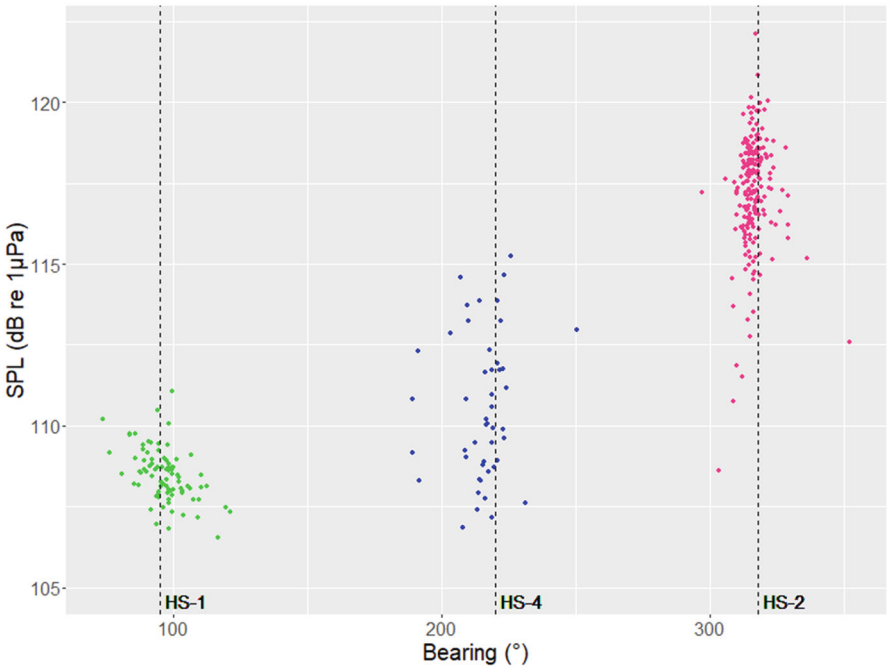

**Fig. 11** Plot of the transient bearing from the AMAR against sound pressure level (SPL) for 20 min on 1 January 2021. HS-1 "bang" transients (green), HS-2 "creak" transients (pink), and HS-4 "rattle" transients (blue). (Burns et al. 2022).

(<250 Hz). While these bangs were usually the shortest-duration sounds, they could, however, last for more than 2.5 s, with occasional instances of prolonged reverberation. This bang was not always audible because of masking by other sounds (or potentially by other ambient sounds).

HS-2 generated a "creak" transient (red in Fig. 9). This had the highest SPL and masked the other two sounds when their occurrence overlapped. The duration of individual sounds was around 0.4 s, with some up to 1.5 s. This sound often had frequencies absent from the 700–900 Hz band.

HS-4 was associated with a "rattle" type sound (blue in Fig. 10). The duration of individual events varied from approximately 0.5 to 1.0 s. It sounded like a repeated tapping noise, with variable numbers of taps. The blue sounds had most of their energy in the 200–800 Hz band.

The variability in bearings versus received SPL for each transient sound type is presented in Fig. 11; this shows that the mooring noise levels differed for each HYWIND turbine and that the sound originated close to the bearing of the pillars. This indicates that the noise was restricted to the mooring components close to or at the pillar, rather than along the mooring chains. It is unclear why one mooring might be noisier than another when both experience the similar dynamic stresses.

The occurrence of mooring transients showed a positive correlation with wind speed but that was non-statistically significant. At higher wind speeds, the amount of mooring noise increased and substantially contributed to the wind farm's overall noise signature.

There was a stronger correlation between the occurrence of transient sounds and significant wave heights. This positive correlation may be due to a greater influence of waves, rather than wind speed, in causing the structure to heave, which therefore caused the mooring system to heave more.

The different transient sounds caused by the mooring were not mutually exclusive, and the data commonly showed combinations of different types of noise. This finding is consistent with the discovery that each HYWIND system seems to produce a unique type of mooring noise.

## Impulsiveness Analysis

A qualitative assessment of the impulses indicated that they tended to be on the order of 1 s long (Ainslie et al. 2021) and that multiple sub-pulses and/or tones were presented within the pulse. The pulses' peak pressures and rise times are clearly identifiable from the background but not as much as usual pile driving or seismic airgun impulses.

The detected impulses had interquartile durations of 1.3–1.7 s, which is longer than the conventional way an "impulse" is defined. As expected, a greater number of impulse detections at higher wind speeds at HYWIND were found by the detector; this was not replicated at the Control site (Fig. 12). As expected, the number of impulse detections at HYWIND decreased with increasing wind speed; above 100 Hz more wind-driven noise is present, which made detecting the impulses a more difficult task. One output of the impulse detector is the per-impulse sound exposure level in decidecade bands, and in Fig. 13 the mean, median, and 90th percentile of these are shown. Figure 14 shows auditory frequency weightings from

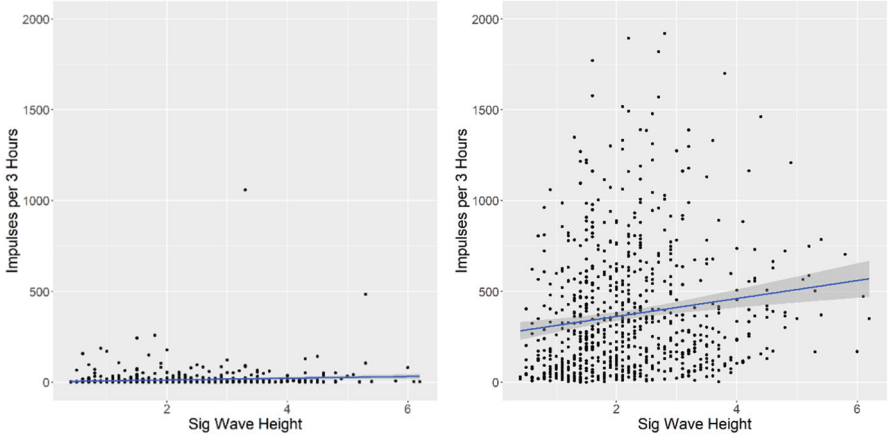

**Fig. 12** Scatterplot of the number of impulse detections per 3 h versus the significant wave heights at (left) the Control site and (right) HYWIND. (Burns et al. 2022)

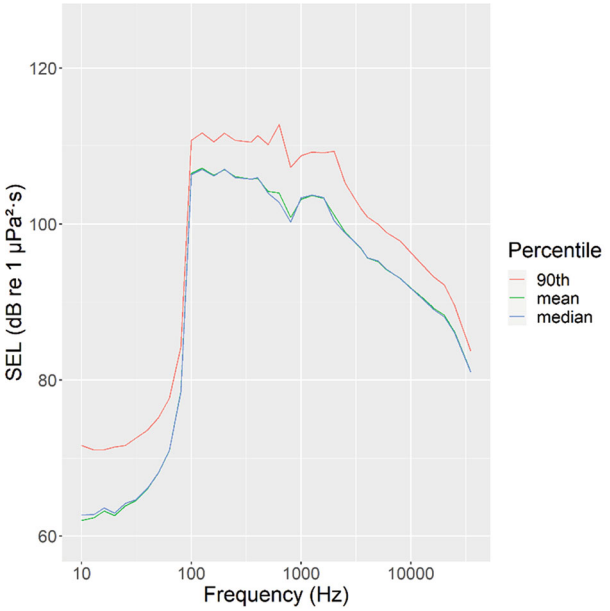

**Fig. 13** The decidecade sound exposure levels (SEL) of the impulses detected at HYWIND in the mean, median, and 90th percentile compared with the decidecade center frequencies

the NMFS (2018) were applied to the decidecade SEL to determine the daily SEL. The impulsive SEL weighted high-frequency cetaceans were mostly 6 dB below the total daily SEL as shown Fig. 15, and they were commonly more than 10 dB below the total. The observation that there were more impulses at the HYWIND site (e.g., Fig. 12) is supported by comparing the kurtosis at HYWIND and the Control site, as shown in Fig. 16. However, highly impulsive minutes ($\beta > 40$) were exceptionally rare at both HYWIND and the Control site. This kind of kurtosis distribution from a sound source is an excellent example of how applying a kurtosis-weighted SEL to predict hearing threshold shifts is valuable for regulatory applications (Zhao et al. 2010, see ▶ Chap. 81, "Impulsive or Non-impulsive: Determining Hearing Loss Thresholds for Marine Mammals," by Zeddies et al.).

Use of the non-impulsive threshold from NMFS (2018) is recommended because minutes with a high kurtosis occurred relatively infrequently, the length of the impulses, and the impulsive SEL being 6 dB or higher below the total SEL. That is, the Temporary Threshold Shift (TTS) for high-frequency cetaceans (porpoise) would be 153 dB re 1 $\mu Pa^2s$.

## Marine Mammal Impact Modeling

Marine mammal impact modeling was performed using the same methods as the back-propagation; however, individual point sources representing the five turbines were modeled over 360° of radial transects. This provided a full three-dimensional

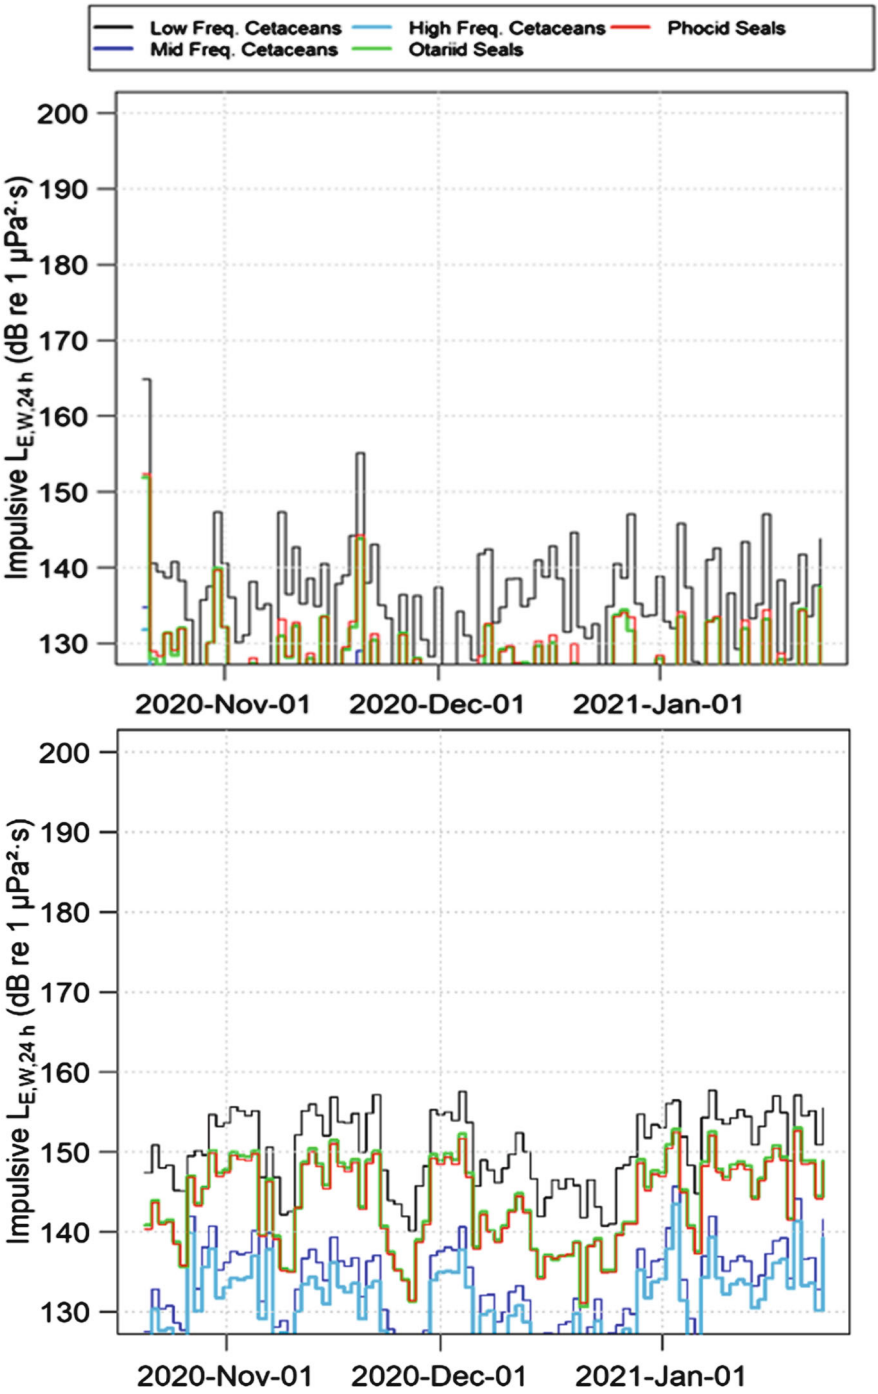

**Fig. 14** Daily auditory frequency weighted sound exposure level (SEL) for the transient events detected at (top) the Control site and (bottom) HYWIND

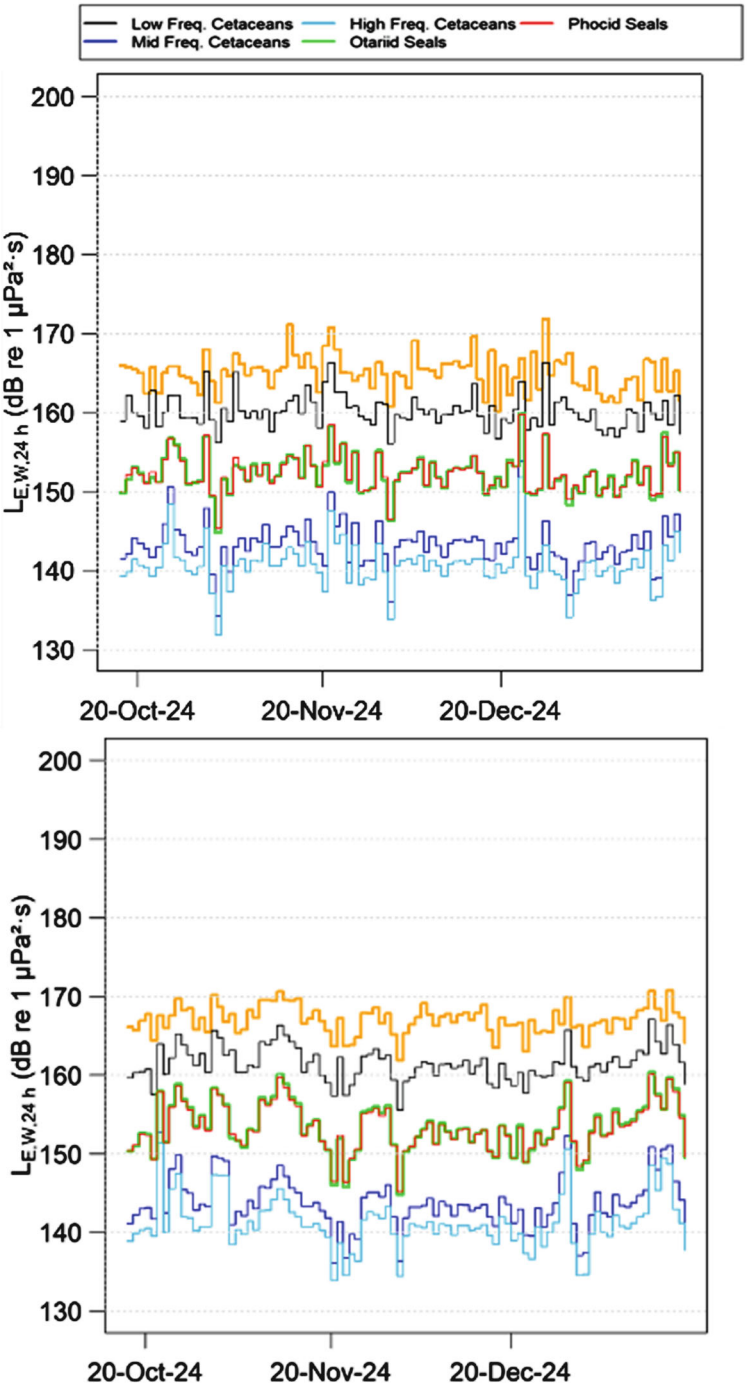

**Fig. 15** Daily auditory frequency weighted sound exposure level (SEL) for full days at (top) the Control site and (bottom) HYWIND

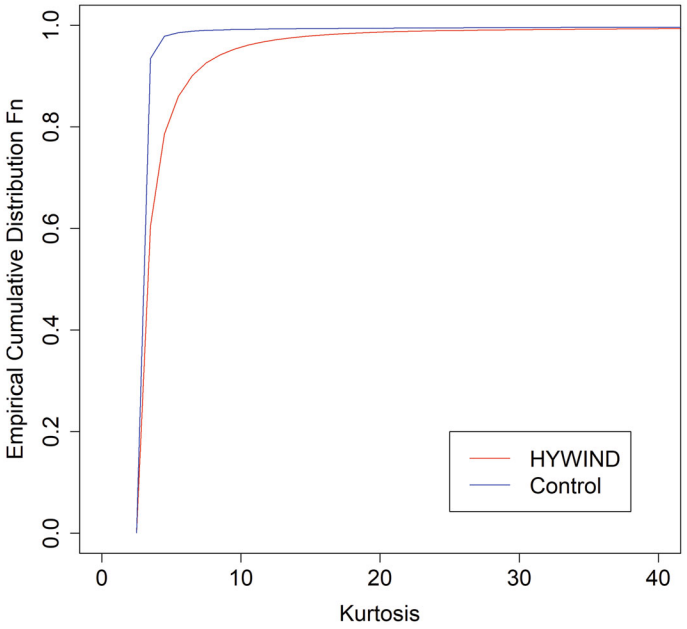

**Fig. 16** Empirical cumulative distribution functions for the 1-min kurtosis at the Control and HYWIND sites

(3-D) sound field. Maps of sound fields indicate the areas exposed to sound at certain levels. Figures 17 and 18 show examples representing the SPL for the 10-knot 50th-percentile and the 25-knot 95th-percentile sound fields, respectively.

The predicted levels for given conditions over the wider area, as well as the Southall et al. (2019) recommended maximum distances to impact thresholds, can be estimated by the model. In Table 4, the modeled weighted received SEL over 24 h for the considered auditory groups are shown, again presuming a constant windspeed of 15 knots, for the median and 75th percentile cases. In Table 5, the maximum modeled distances from the nearest turbine to the calculated isopleths associated with auditory impacts are shown, assuming a 24-h exposure at a 15-knot wind speed and taking the median and 75th percentile cases (i.e., sound levels that are constant over a 24 h).

Over 24 h, sound levels were dominated by the highest levels within the recorded timespan. This means that the modeled, 24-h, 75th percentile sound level matches the recorded daily sound level more closely than the 50th percentile level. The average result skews toward the higher sound levels when sound levels are averaged over a longer timespan (e.g., over 24 h).

The maximum distances to the recommended TTS-onset sound levels for the auditory groups of interest (see Table 5) are those for receivers that are stationary for

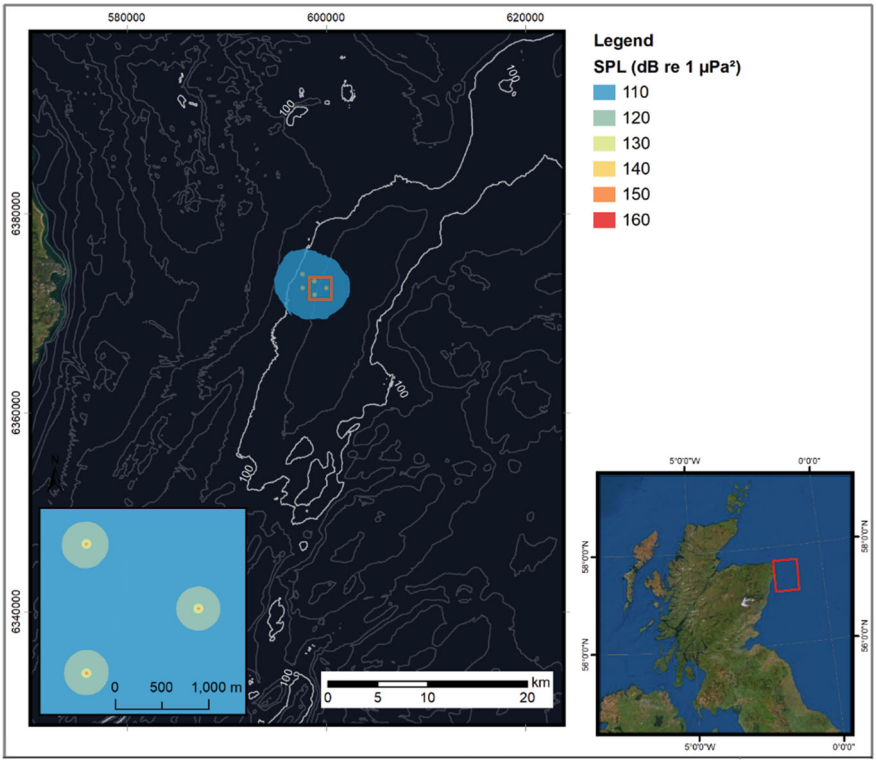

**Fig. 17** The radiated sound field modeled at the HYWIND site. The model assumed a 10-knot wind speed for the 50th percentile source levels. Datum WGS84 projection UTM30N

the exposure duration at the depth at which the sound level is at its loudest. The maximum distance to the TTS isopleth for the cases analyzed, when considering the 75th percentile, is for the very high-frequency cetacean hearing group at an 80-m maximum distance. Sound levels were highly variable, so the exact distances vary.

## Conclusions

The AMAR located at the HYWIND site was approximately equidistant from the three monitored turbines and it was situated to isolate HS-1 to the east. This set up allowed for an uncontaminated directional analysis of one HYWIND Scotland system.

A substantial contribution to the overall noise field from the wind farm was found to be constituted by several transient sounds thought to be associated with the mooring system. Despite the design of the mooring system being identical for

Unlike the HYWIND demonstration system recordings from 2011, there was little evidence of highly impulsive, "snap" noises (Martin et al. 2011). However, there was a much great amount of transient noise from moorings. This mooring noise had distinct characteristics related to individual HYWIND systems. At HS-1, "bang" was produced, at HS-2 there was a "creak," and at there was HS-4 a "rattle." The directional processing of the AMAR array data showed that each type of sound was clearly connected with each system. Wave height positively correlated with occurrence. As wave height increased, there was a substantial corresponding increase in the contribution of the transient sounds to the overall sound signature of the wind farm.

A quantitative analysis of the impulsiveness of the HYWIND soundscape applied an impulse detector and studied the distribution of the per-minute kurtosis. Summing the SEL of all detected impulses showed that the impulsive SEL was generally less than 6 dB below the daily total SEL. The mean timespan of the impulses was ~1.5 s, longer than the 1.0 s interval typically used to identify impulses to assess the effects of sound on hearing. The soundscape at the Control site had a lower kurtosis than at HYWIND; however, the kurtosis value for HYWIND was too low to be considered impulsive. Therefore, non-impulsive TTS SEL thresholds should be used to assess noise from wind farm.

The impulses per hour rate more positively correlated with wave height than with wind speed. A subjective aural analysis of these noises suggests a slightly lower rate of tension release in this particular mooring design; however, there is currently no quantifiable method with which to confirm this. Directional analysis of noise from the HS1, HS2, and HS4 moorings revealed that the noise came from mooring components at or from somewhere near the pillar itself. No available evidence suggests that the mooring noise was generated from the mooring system away from the bridle connection points on the HYWIND spar. This finding is reasonable since the most substantial movement in the mooring system likely occurs that at the points where the chains are connected around the pillar because anchor chains fall

through a ballasted catenary to the ocean floor and then sinks in the soil a distance away from the anchor. When analyzing mooring noise occurrence with wind speed only a limited correlation was found, but when comparing it with wave height a more direct relationship was identified. This result suggests that the dominant environmental factor influencing movement and associated mooring component friction in the floating structure is wave height.

The NMFS (2018) thresholds for temporary hearing thresholds shifts caused by non-impulsive sounds were applied to evaluate the possible effects on marine mammals by noise at HYWIND. The threshold for TTS was never exceeded and the daily marine mammal weighted SEL at both sites were very similar.

**Abstract**

The knowledge of the noise characteristics stemming from recreational boats is scarce, and the amount of studies is too small to draw any conclusions on impact and recommend any measures. To close this gap, it is necessary to measure the underwater radiated noise (URN) from boats and estimate their source level. This chapter aims to describe the development of a methodology for source-level estimations of recreational boats based on classification society's guidelines and test it in field trials. Three boats with different engine, propeller, and fuel types, including one electric motor, were used. Parameters such as speed, measurement depth, distance, and propagation loss estimations are varied, aiming to study their effect on the estimated source level. By combining the GPS position of the boats and sound data from a hydrophone system, successful measurements of the boats' radiated noise were conducted, and their source levels were estimated. The source spectra of all boats showed clear tones, stemming from the rotational frequencies of the engines and propellers. Finally, a measurement guideline was developed for estimation of the source level from recreational boats that can be used for comparison with published scientific studies and environmental impact studies and as input to source models.

Recreational boat · URN · Source level · Measurement methodology

## Introduction

Underwater radiated noise (URN) from a recreational boat is generated by the rotation of the propeller and associated cavitation, the firing sequence of the engine(s), other moving parts of the propulsion system, and the release of subsurface exhausts (Matzner et al. 2010; Erbe 2013; Erbe et al. 2016 etc.). Measurements or modeling of the propagation loss makes source-level estimations possible. The magnitude and frequency content of the source level define the acoustic signature, which depend on how the sound is generated, engine type (inboard and outboard), number of cylinders, propeller type and type of craft, and its load (Matzner et al. 2010; Erbe et al. 2016; Parsons et al. 2021). There are numerous variations and combinations of these parameters, making general conclusions of the acoustic signature a challenge.

The large quantity of recreational boats in shallow water archipelagos has the potential to pollute sensitive biological areas with high levels of underwater noise, resulting in an environmental issue that urgently needs to be assessed (Jain-Schlaepfer et al. 2018; Magnhagen et al. 2017; van der Knaap et al. 2022). In contrast to commercial ships, the knowledge of noise characteristics from recreational boats is lacking, and, at present, there is little evidence to draw any firm conclusions on an environmental impact and even less to recommend any measures.

The boat engine noise is commonly characterized by both broadband and narrowband (tonal) components below approximately 500 Hz. These tones are speed dependent and relate to the number of propeller blades, gear design, revolution per minute (RPM), and other engine characteristics (Matzner et al. 2010; Pollara et al. 2017). Propellers are known to produce amplitude-modulated noise through cavitation mostly noted below 500 Hz (Pollara et al. 2017). The cavitation mainly depends on propeller design, speed, and maintenance of the propeller, e.g., a damaged propeller can induce more cavitation than an undamaged one.

Electric motors are considered quieter underwater than gasoline and diesel engines, but at the time of writing, there were no published studies of URN from recreational boats with electric motors. However, for larger commercial vessels, there are measurements showing electrical ships being less noisy than conventional ships (Parsons et al. 2020).

The chapter describes four overall goals: (1) to develop a methodology for source-level estimation of recreational boats based on existing guidelines for commercial ships; (2) to test it in field trials; (3) to study the effect on the source-level estimation of boat speed, measurement depth, direction, and measurement distance; and (4) to develop a measurement guideline for the source-level estimation for recreational boats based on the experiences from the measurements. This chapter is based on Svedendahl et al. (2021), and more details and results can be found therein.

The described approach is based on the guidelines of the classification society Bureau Veritas (2018) with the aim of testing the efficiency of such methods for use on recreational vessels in shallow water. It is recognized that the methods themselves and the meaning of some key terms (e.g., source level, propagation loss, and radiated noise level) may differ from those adopted by recent ISO standards such as ISO 18405 and ISO 17208 parts 1 and 2. However, in the absence of an ISO standard on measuring ship noise in shallow water (ISO 17208-3 being at only Committee Draft stage), and for consistency with the approaches in the classification society guidance, the terminology and basic methodology used in this chapter and indicated in the text where adaptations has been made.

The work described in this chapter was funded by Vinnova, Sweden's Innovation Agency, together with the Swedish Transport Agency, which in turn was supported from the Swedish Agency for Marin and Water Management grant 11.1.

## Standardization of Measurement and Data Analysis

### Current Status of Standardization

Currently, no measurement standard exists for recreational boats. There are several different standards (ANSI 2009; ISO 2016, 2019) and classification societies (Det Norske Veritas AS 2011; Bureau Veritas 2018, etc.) for measurement and estimation of the source level or radiated noise level of commercial ships. The classification societies also have notations to classify a ship as "silent" in various categories

depending on ship class. The guidelines have different kinds of grades, representing different levels of accuracy in terms of the estimated source level (Ainslie et al. 2022). However, none of these guidelines or notations applies to recreational boats. These boats are smaller and have less powerful engines, which most likely result in lower source levels. It is challenging to follow the measurement geometry of the guidelines and class notations. For example, many guidelines limit the minimum measurement distance to a few hundred meters, which could decrease the signal-to-noise ratio of the measurement of a more silent and smaller recreational boat. With shorter measurement distances, the length of the measurement track will be affected, as well as the post-processing of data, as some guidelines divide the measurement into time segments corresponding to a certain distance covered by the boat.

In all above-referenced methodologies for the estimation of a vessel's source level, there are uncertainties at different levels related to the measurements, equipment, and signal processing. The level of uncertainties in a source-level estimation can be divided into different grades. The American National Standards Institute (ANSI) offers three grades of measurement, each with a stated applicability, test methodology, system uncertainty, and repeatability of the measurement. The grades have different requirements on the hydrophone system, ranging accuracy, minimum number of runs per vessel, and methodology to estimate the propagation loss. The propagation loss estimation can range from elaborated numerical modeling to simple laws, e.g., $20 \log_{10}(R)$ (ANSI 2009), where $R$ is the distance between the source and the receiving hydrophone.

## Designing Measurement Geometry and Overview of the Trial Area Environment

To get a rough estimation of the uncertainty of the proposed methodology, two field campaigns were scheduled for two occasions with different sound speed profiles but at the same location. The measurements in this chapter were performed in partial compliance with the shallow water ship URN measurement guidelines of Bureau Veritas (Bureau Veritas 2018), as well as with consideration of the above-mentioned guidelines and notations. Deviations in the measurement setup in terms of measurement depth, distance, and boat speed were introduced to determine a suitable method to estimate the source level from small boats in shallow water.

The trial site Djupviken (N59°3′28.4″, E18°6′52.6″) is located in the southern part of the Stockholm archipelago in eastern Sweden. The area is a shallow water bay (<50 m depth), with muddy sediments, and in general a flat topography in the middle of the bay (Fig. 1, left).

For the sound measurements, a four-channel instrument, an RTsys, SDA014, was used. The system had four hydrophones located at different depths constituting a vertical line array (Fig. 1, right). The array of hydrophones was mounted on a vertical rig with a bottom weight of 20 kg at 30 m depth and a subsurface buoy at 5 m depth in order to keep the array vertical as well as minimizing the influence from surface waves. Data were recorded with a sampling speed of 78,125 Hz, 24-bit, and stored internally on a SD card and a hard drive.

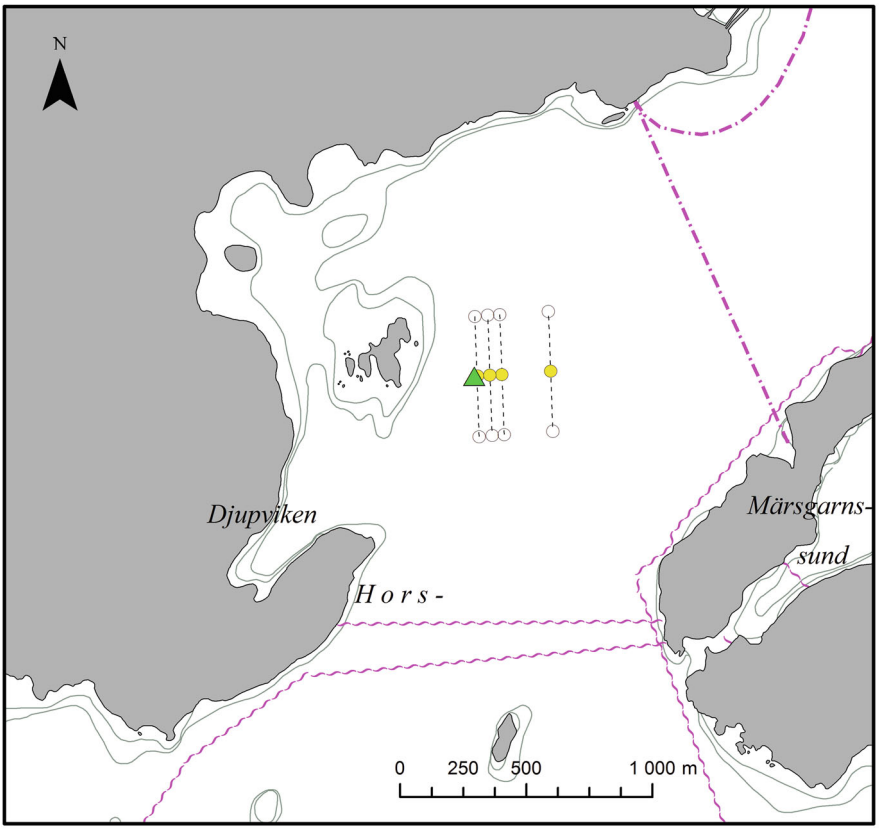

**Fig. 1** Left: The seabed topography of the test site Djupviken on the Swedish east coast south of Stockholm with the test track marked. Right: Sketch of the RTSys array setup and suspension in the water. A 100-m-long cable connected the array to the measurement platform. Hydrophones where (**a**) Reson TC4032, (**b**, **c**) HTI-96-MIN, and (**d**) CO.L.MAR GP090

Salinity, temperature, and sound speed in the water column were measured three times each day with a Sound Velocity Profiler, SWiFT SVP, from Valeport. The sound speed profile of the first measurement campaign 2019-12-04 was almost constant, varying from 1434 m/s at the surface to 1436 m/s at the seabed. During the second campaign 2020-06-24, the situation was different, with a thermocline at 17–20 m depth with speeds spanning from 1440 to 1490 m/s. Propagation loss measurements were only conducted on 2020-06-23, with similar characteristics in the sound speed profile as during the measurement campaign conducted on 2020-06-24.

Propagation loss for the trial area was measured by emitting acoustic pulses at a number of locations in the vicinity to the boat tracks. The receiving equipment was the same as for the sound measurements. The measurements were performed using a workboat, which was set drifting with the current across the boat tracks, while a handheld GPS receiver continuously recorded the positions for each transmission.

The transmitter, of type LL-1424HP, was suspended from a boat at a depth of 5 m. In addition, an active (with internal preamplifier) reference hydrophone of type Neptune D/70/H was positioned at the same depth and 6 m horizontal distance from the transmitter. The complete reference hydrophone system was calibrated a priori down to 100 Hz. Linear frequency-modulated pulses, spanning 100 Hz to 12 kHz, were used during the propagation loss measurements. By match-filtering the received signal with appropriate segments of the emitted signal, the sound pressure level in a given frequency band was obtained. Under the assumption of spherical spreading from the source to the reference hydrophone, the source level was estimated. In other words, the calibrated reference hydrophone was used to determine the SL of the source, and the propagation loss was then calculated using the difference of the SL and the received levels of the RTsys in the specified frequency bands.

Several surface buoys were used to mark the closest point of approach (CPA) to the sensors, indicating the distances 10, 50, 100, and 300 m (Fig. 1). The distance of 100 and 300 m was selected based on the measurement geometry found in the guidelines for commercial ships, but the 10 and 50 m distance was added due to the smaller size of the recreational boats studied here.

The start and end of the track were marked with virtual waypoints in a GPS receiver in order for the boat to keep a straight course. Each track ran in parallel to each other and with the CPA to the RTsys position in the center of the track. The length of the track was 500 meters where the water depth varied between 30 and 40 m.

One run was quantified as a completed passage at a fixed speed between the virtual waypoints marking the start and end, passing the CPA buoys. The boats performed several runs for the speeds 5, 10, and 20 knots. Occasionally a run had to be repeated when other vessels passed the area, increasing the ambient noise above the background level and as a result disturbing the recordings.

Three different kinds of boats were used in this trial, an open boat with a four-stroke outboard petrol engine, Örnvik 540; a day cruiser with an inboard diesel engine, Targa 23, and finally a day cruiser with an electric inboard engine, Eelex 8000, which was a prototype with an experimental hull and propeller (Table 1). The boats were built in 1988, 1997, and 2019, respectively.

The signals from the hydrophones were processed in several sequential steps, based on the guidelines from Bureau Veritas (Bureau Veritas 2018), but with some adjustments to better fit the recreational boat measurements. The guidelines treat the boat in question as an omnidirectional source, i.e., the sound pressure levels measured in different directions from the boat are treated equally and averaged to form the final source level of the boat. The signal processing steps, which are described in detail in Section Measurement Guideline for Recreational Boats (p. 218–223), can be summarized as follows:

1. Combine GPS and hydrophone data.
2. Divide each run into 19 dataset time segments, each of which equivalent to 50 m and thus dependent on the boat speed (see Fig. 2).
3. Calculate PSD from each of the 19 time segments.
4. Convert to 1/3 octave bands (optional).

**Table 1** Overview of the test boats and their technical specifications

| Boat type | Length (m) | Draught (m) | Weight (kg) | Fuel | Engine type | Engine power (hp/kW) | Propulsion |
|---|---|---|---|---|---|---|---|
| Örnvik 540 | 5.4 | 0.4 | 300 + 108 (engine) | Petrol | Outboard, Yamaha, four cylinders (year 1999) | 50 hp/37 kW | Single prop, four blades |
| Targa 23 | 7.6 | 0.9 | 2300 | Diesel | Inboard, Volvo Penta AD31P-A, six cylinders | 150 hp/110 kW | Duo prop, three + four blades |
| Eelex 8000 | 8 | 0.8 | 2600 | Electric | Inboard, electric | 300 hp/225 kW | Single prop, four blades |

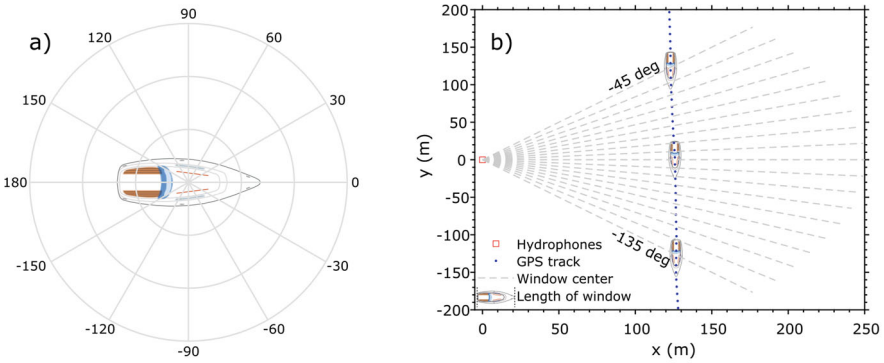

**Fig. 2** The boat angle and data window definitions. (**a**) The boat angle is defined from the source center to the hydrophone(s) and, therefore, (**b**) varies as the boat passes through the measurement area. In this case, a southbound route yields negative angles, while a northbound route results in positive angles. The center of each data window is given by the angles $\pm 45^\circ$ to $\pm 135^\circ$ in $5^\circ$ steps, and the width is 50 m, as indicated by the boat sketch length

5. Correct for background in each window.
6. Correct for propagation loss in each window.
7. Combine the windows into one PSD for the entire run.
8. Combine multiple hydrophone channels (if applicable).
9. Combine multiple runs (if applicable).

## Factors Influencing Estimated Source Levels

Some of the measurement parameters that could influence the estimated source levels include the distance between the boat and the hydrophones, the boat speed, portside/starboard facing the hydrophones or other directional effects, the depth and location of the hydrophones, the PL estimation, and the boat GPS location precision.

### Measurement Depth

The depth position of the hydrophone(s) can lead to a relative change in the measured sound pressure levels but can also make each hydrophone more or less sensitive to other sources. Studying a specific boat run during the measurement campaign, the measured total levels varied from top to bottom with as much as 4 dB, with tonal components varying up to 7 dB. One reason for the observed difference might be the sound speed profile, as the sound speed was causing refraction toward the bottom. The deepest positioned hydrophone also shows higher sound pressure levels.

During the measurement campaigns, it was also noted that a hydrophone closer to the water surface was possibly more influenced by the measurement platform, reflections from floating buoys, waves, and other sound sources located near the

surface. For a hydrophone located near the seabed, other effects can influence the result. It is therefore a good practice not to be closer than 1 m from the seabed (Jensen et al. 2011; Gassmann et al. 2017; ITTC 2017).

## Boat Speed

The boat speed is a parameter that affects the source level. As the speed increases, cavitation may occur at or near the boat propeller leading to increased source levels. A naïve assumption may be that increased boat speed directly leads to increased source levels. However, the noise from the propeller depends largely on the propeller design and condition (see section "Boat-Radiated Noise" for more results).

## Propagation Loss Estimation

One of the largest sources of error in source-level measurements is the propagation loss (PL) of acoustic waves traveling from the source to the receiver. One approach is to measure PL with calibrated sources and receivers. This is, for practical reasons, not always possible. Another approach is to use the boats under investigation to measure and retrieve information on the PL. Another alternative is to numerically model PL based on known parameters of the bottom layer(s) and sound speed profile. Often, the same measurement location is used repeatedly, and knowledge of the expected PL can be gained with time.

Each of the classification society's guidelines for noise measurements of larger vessels has a slightly different approach to handle the estimation of PL, as seen in Table 2.

In short, there are different approaches, each with different pros and cons in terms of time, resources, and accuracy. A measurement will always contain some level of error or uncertainty, but the results may still describe the actual situation better compared to modeling efforts that use some more or less known inputs fottr the final PL estimation. Building knowledge about the measurement area is important, but the underwater acoustic environment can nonetheless change with time.

**Table 2** Propagation loss (PL) estimation methods for different classification guidelines. R is the distance between the source and the receiver

| **Society classification** | Det Norske Veritas Silent-E (2010) | Bureau Veritas URN (2018) | American Bureau of Shipping (2018) | Registro Italiano Navale Dolphin (2016) | Lloyd's Register ShipRight (2018) |
|---|---|---|---|---|---|
| **TL estimation method** | $18log_{10}(R)$ | Acoustic modeling methods | $20\log_{10}(R)$ | $20\log_{10}(R)$ | Measured or modeled TL in shallow waters and $20\log_{10}(R)$ in deep water |

Since modeling PL was not applicable during these measurements, PL measurements were conducted based on two methods: (1) using a known sound source to generate sound at different positions and distances from the receiving hydrophones and (2) to use the boat runs themselves as a source:

1. PL can be measured by drifting through the measurement area with a known calibrated source (as described in section "Designing Measurement Geometry and Overview of the Trial Area Environment"), which creates known sound levels that are measured by the hydrophone(s). The difference between source levels and received levels is then used to estimate PL using GPS location data (Fig. 3). Only data in the far-field regime of the reference hydrophone were evaluated, resulting in a conservative limit of measured data to frequencies above ~500 Hz. Considering all the data points, the average $A$ estimate was 19.8 ± 1.8, 18.4 ± 3.7, 20.0 ± 2.2, and 18.1 ± 3.2 for channels A–D, respectively.
2. PL formulas can also be fitted to measurements of the boats during the noise measurement campaign of the recreational boats. This approach is more uncertain, as the directivity and stability of the source are unknown, but the approach is

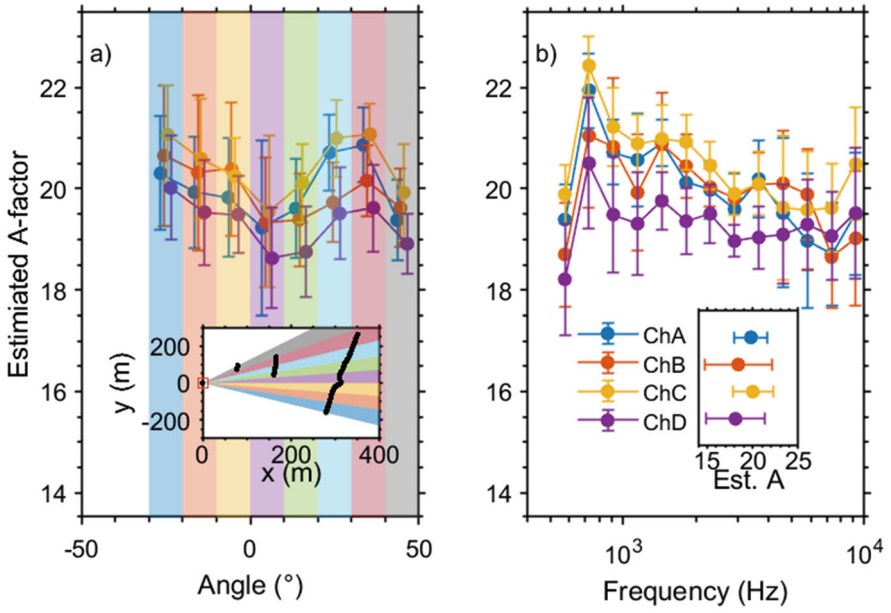

**Fig. 3** Direct measurement results of propagation loss (PL). Using a known source, the PL is calculated and fitted to a $PL = A \cdot log_{10}(R)$ formula in (**a**) an angle range and (**b**) 1/3 octave bands (base 2). The colors of the color-shaded areas in (**a**) correspond to different angle ranges indicated in the inset, where the position of the source throughout the measurement campaign (black) with respect to the hydrophones (red square) define the angle. The inset in (**b**) shows the average estimation of $A$ for the four hydrophone channels, for all source positions and including 1/3 octave bands above 500 Hz

efficient in time and resources. If similar measurement tracks are used during the measurement campaign, the runs can be treated individually and then combined to increase the precision of the track PL estimate (Fig. 4). Different tracks, at different CPA, can yield different PL estimates depending on the bottom layers, water depth, and sound speed profile. In the specific case illustrated in Fig. 4, a simple $PL = A \cdot log_{10}(R)$ formula was used to fit A. The parameter A was found to increase with distance for the four characteristic tracks with CPA 20, 70, 100, and 300 m. Note that the results are vastly different from the measured PL in Fig. 3 which may be due to the nature of the source. The boat was a broadband source and had an unknown three-dimensional directivity. It is possible that tracks with small CPA detect noise that is not detectable at larger distances. Along those lines, it may very well be the data shown in Fig. 3 are not a true PL estimation, but rather an indication of the directivity of the boat itself.

As can be seen in Fig. 5, the distance-dependent PL estimates based on the measurement tracks perform rather well overall, but in some frequency bands, it results in 2–4 dB separation of the source levels from tracks at small and large CPA. Around 20 Hz there is a clear tone in the 310 m CPA data, which is more smeared out in the 120 m CPA case, yielding ~8 dB difference, likely due to other factors than the propagation loss compensation. The PL estimates based on a known source were

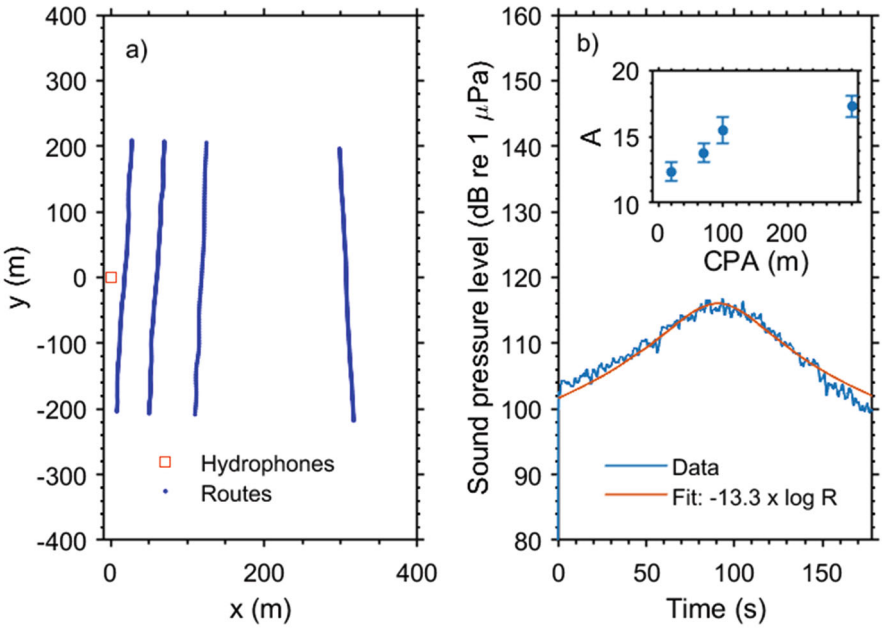

**Fig. 4** CPA-dependent propagation loss (PL) model measurement. (**a**) Runs conducted at different CPA and (**b**) example of the measured sound pressure level (channel A) for one run fitted to a $PL = A \cdot log_{10}(R)$ formula. The inset in (**b**) shows the average values of A, as retrieved from 26 runs for channel A. The error bars correspond to the data included in the analysis only

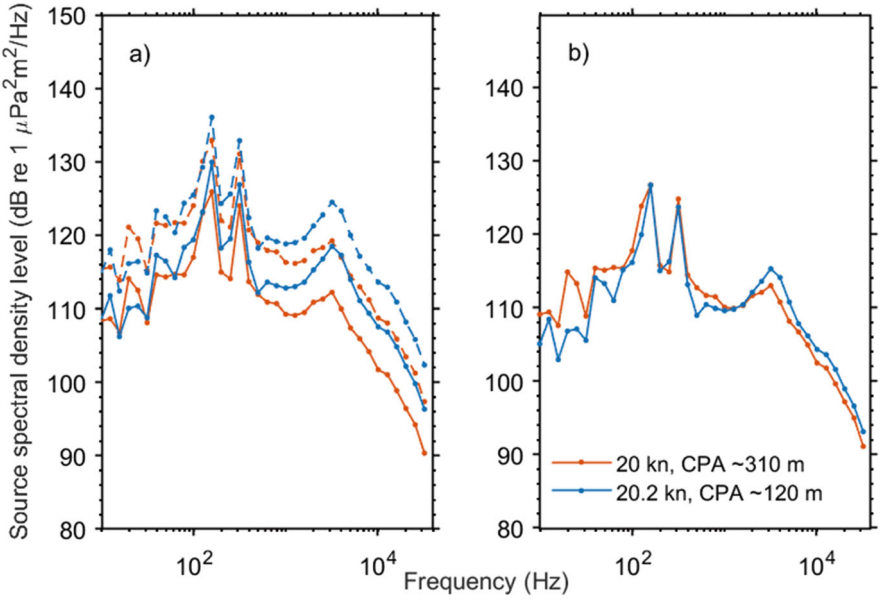

**Fig. 5** Example of propagation loss (PL) implementations. Two runs at similar speeds, but at a CPA of 310 (red) and 120 m (blue) is compared using (**a**) a flat PL = $19.8\log_{10}(R)$ (solid) and PL = $17\log_{10}(R)$ formula (dashed) used throughout the measurement area and (**b**) a distance varying PL model, as described in Fig. 4

performed 1 day before the boat measurements and showed a relatively small distance variation in the fitted PL estimation. The estimates based on a known source varied ±0.8 dB, compared to ±2.5 dB for the measurements based on boat routes. As a conclusion in line with these results, it is important to conduct routes with different CPA to verify the PL model used.

## Distance and GPS Precision

As described above, the amplitude of the sound decreases further from the source, resulting in negligible (relative to the background) sound levels far from the source. It is therefore important to be sure that the signal-to-background level is large enough for the measurement to be successful. For example, the measurements at CPA = 300 m were, on average, 4.5 times more likely to have data points below the background level as compared with CPA = 100 m measurements.

However, there are several factors that come into play when selecting at what distance to undertake the URN measurement. When PL is not very well known, the estimated source-level error becomes larger the further away (see Fig. 2). For example,

assuming $PL = 17 \cdot log_{10}(R)$, when it actually should be $PL = 20 \cdot log_{10}(R)$, results in 6 dB error at 100 m distance.

Finally, the GPS precision may influence the position error. Generally, today's GPS transceivers have a precision of a few meters. Such errors will have a larger impact at close range. At 100 m distance, the effect is significantly smaller compared to the PL-error estimates.

## Starboard/Portside Runs and Directivity

Depending on the design of the hull and propeller(s), the boat constitutes a directional source. For a complete coverage of angles between the hydrophone and the boat, it is important to include both starboard and portside runs. Capturing directivity in a measurement implies that the runs should be long enough such that a large boat-to-hydrophone angle is both obtained and measured accurately.

In other words, the boat should not be too far from the hydrophones both due to signal-to-background limitations but also in order to maintain feasible run times. A 500-m-long track results in a maximum distance of 270 m to the hydrophones and about $\pm 70^\circ$ in angle for 100 m CPA. Increasing the covered angles to $\pm 80^\circ$ would be equivalent to 1200-m-long tracks, that is, more than double the distance for a limited amount of data.

From the directivity in Fig. 6, the sound pressure levels were observed to drop at angles far from the CPA (located at $\pm 90^\circ$). The results suggest that the main angles to take into account indeed are within the $\pm$ (45°–135°) range.

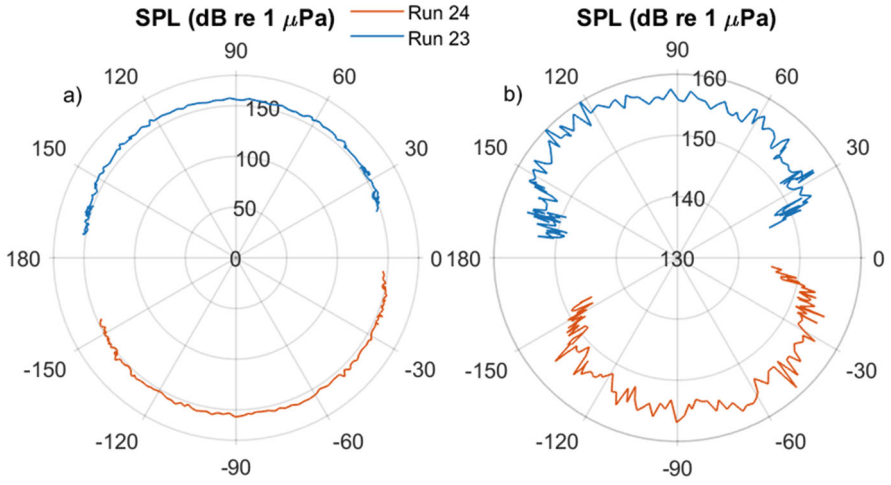

**Fig. 6** Directivity of Eelex 8000, with the origin at (**a**) 0 dB and (**b**) 130 dB. See Fig. 2 for angle definition

## Boat-Radiated Noise

### Source-Level Comparisons of Trial Boats

The three boats constitute a set with different engine, propeller, and fuel types. It is therefore interesting to compare their source levels, as shown in Fig. 7 and Fig. 8. At 5 kn, Örnvik 540 has the highest levels, both in maximum tone levels, found in the narrow band spectrum and in the 1/3 octave spectrum (base 2). In the range 60–200 Hz, this boat is louder than the other two. Furthermore, Eelex 8000 stands out as the quieter at lower frequencies but experiencing higher levels at higher frequencies.

The situation is different at 20 kn, however, where Targa 23 overall seems as the boat with slightly higher levels except for the strong tones near 40 Hz of the Örnvik 540 (Fig. 8). However, the 1/3 octave band (base 2) spectra indicate that the three boats are relatively comparable throughout the measurement frequency range.

At 5 kn, Eelex 8000 has lower levels up to ~600 Hz but was noisier above 4 kHz. The opposite trend was found for 20 kn, where the levels were comparable for the three boats up to 1 kHz, but then Eelex 8000 was quieter, resulting in a lower overall sound pressure level. The calculated source levels were difficult to compare to other studies due to the lack of standardization but are in the same range as other published studies (Erbe et al. 2016; Matzner et al. 2010).

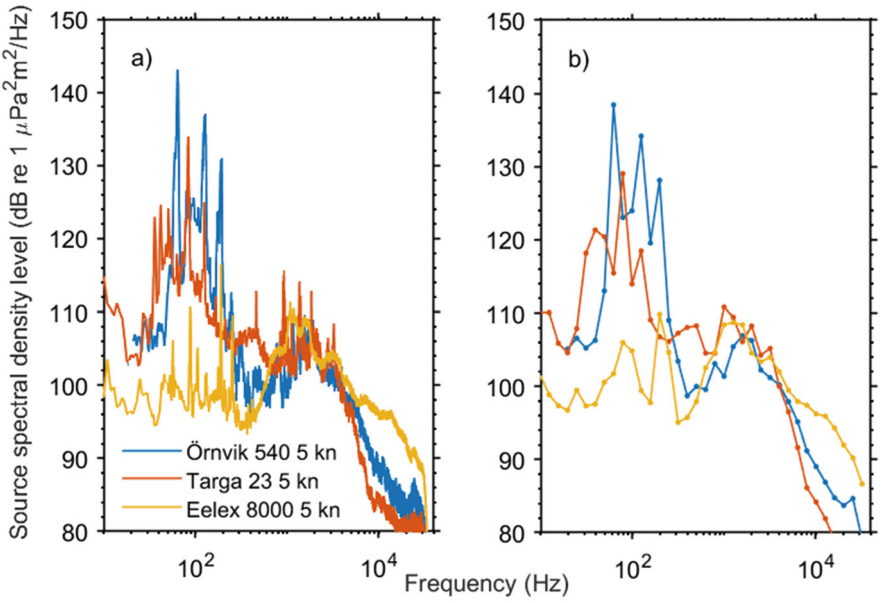

**Fig. 7** Comparison of the source level of three recreational boats at 5 kn. (**a**) Narrow band and (**b**) 1/3 octave band spectra (base 2)

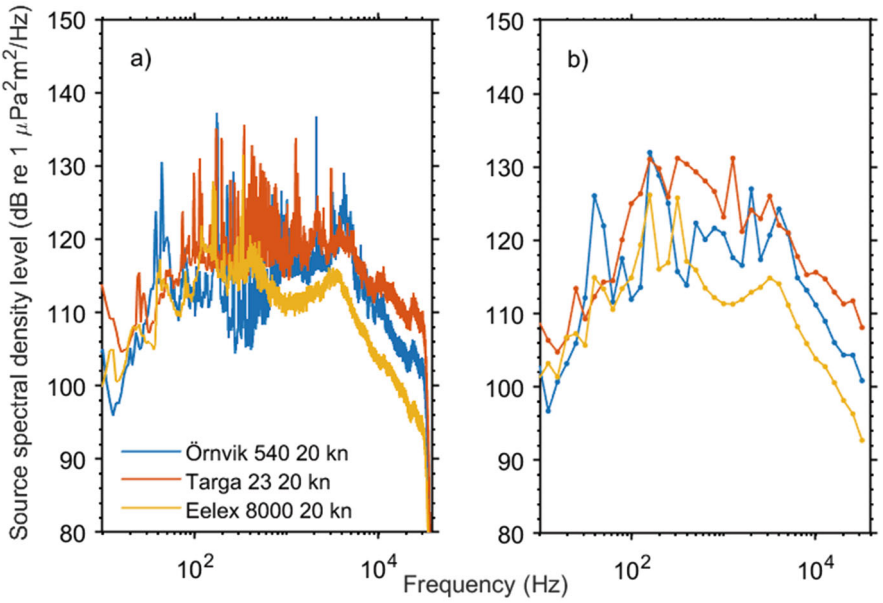

**Fig. 8** Comparison of the source level of three recreational boats at 20 kn. (**a**) Narrow band (1 Hz) and (**b**) 1/3 octave band spectra (base 2)

The broadband source levels for the boats (10 Hz–30 kHz), calculated from narrow band spectra, for 5, respectively, 20 knots were for Örnvik 148 and 158 dB re 1 μPa·m, for Targa 23 145 and 161 dB re 1 μPa·m, and for the Eelex 8000 144 and 153 dB re 1 μPa·m.

## Uncertainties in Source-Level Estimations

As described in section "Source-Level Comparisons of Trial Boats," there are several terms that add up to the measurement uncertainty. The sound pressure level (SPL) measured from an omnidirectional source with source level (SL) is expressed as:

$$SPL = 20\log_{10}(a) - R_r = SL - PL + NL, \tag{1}$$

where $a$ is the measured voltage amplitude of the hydrophone, $R_r$ is the hydrophone sensitivity, $PL$ is the propagation loss, and $NL$ is the background noise level. Assuming that $NL$ is small, eq. (1) is rewritten as

$$SL = 20\log_{10}(a) - R_r + PL. \tag{2}$$

Thus, there are uncertainties introduced in all terms: the measured amplitude, the hydrophone sensitivity calibration, and the propagation loss. Here it is noted that the

post-processing method used herein, specifically the averaging of spectra in different time-segments, treats the boat as an omnidirectional source. This may not be the case, which could introduce additional uncertainty, if the directionality is not fully captured by the measurement geometry. The assumption is commonly used in ship radiation models found in the literature. The close to symmetric curve in the right pane of Fig. 4 suggests that a point source assumption is accurate, at least for the broadband source level.

The measured amplitude error is typically lower than the other terms, and the uncertainty in $R_r$ is most often written in the calibration report, typically around 0.7–0.5 dB, and varies with frequency. The main measurement uncertainty, as mentioned in sections "Propagation Loss Estimation" and "Distance and GPS Precision," is *PL* estimation errors. In this report, this uncertainty has been partly handled by measuring the *PL* using a controlled source. To further estimate *PL* errors, more elaborate methods such as seismic exploration including sediment sampling combined with inverse estimation of the sediment properties could be employed. This is however a laborious task and beyond the scope of this report.

The narrow band *PL* is typically rapidly oscillating function of both frequency and range. For broadband signals, the *PL* can however often be approximated with reasonable accuracy as $PL = A \cdot log_{10}(R)$ where $A$ is constant. Even though there is no formal upper limit on $A$, it typically has a value between 10 and 20. For example, the broadband *PL* estimate in Fig. 3 suggests $A$ is around 19 with a standard deviation of ~3, when combining all channels and source positions in the measurement area. The standard deviation of the $A$ estimation increased with distance. For example, considering distances ranging from 100 to 125 m, from 160 to 225 m, and from 290 to 440 m the standard deviation for channel A was 1.1, 1.33, and 1.9, respectively. Applying the same ranges for channel B, which had the largest standard deviations overall, resulted in standard deviations 1.1, 2.3, and 4.0, respectively. The trend was the same even though only single angle ranges are considered.

The standard deviation of $A$ estimated from fitting *PL* to sound pressure-level measurements, shown in Fig. 4 was found to be 1 or below 1 dB for all tracks.

In the source-level estimations presented in this report, assuming a sensitivity uncertainty of 0.7 dB and an estimated $PL = (15.5 \pm 1)\log_{10}(R)$ for the 100 m tracks (Fig. 4), the total uncertainty adds up to 3 dB.

To study the repeatability of source-level estimates, four runs of Eelex 8000 at 20 kn speed at 100 m CPA were used. The average standard deviation of the 1/3 octave band (base 2) source-level estimation was 1 dB. Comparing the 100 m CPA track source-level estimation with the 300 m CPA track, which was repeated twice, yielded a standard deviation of 0.4 dB.

## Measurement Guideline for Recreational Boats

The experiences and results from the two measurement campaigns conducted here, combined with the Bureau Veritas grade B1 guideline (Bureau Veritas 2018), were used to develop a practical measurement guideline for the estimation of the source levels from recreational boats in shallow waters.

The scope of this guideline is to assess the underwater sound pressure levels normalized at a distance of 1 m from a recreational boat. The measured quantity is the sound pressure level radiated by the recreational boat considered as a monopole source, measured at a certain position in the water. The sound pressure level was normalized to the level at 1 m from the source, using the measured distance from the hydrophone position. The resulting quantity was expressed in terms of the sound pressure spectral density level (in dB re 1 $\mu Pa^2m^2/Hz$).

The following section describes in detail the general recommendations for the test site, the measurement and post-processing procedure, and how to present the results.

By following this guideline, the estimation of a recreational boat's source level can be used for comparison with scientific published studies, environmental impact studies, and mitigation measure calculations and as input to source models.

## Setup and Procedures

### Test Site and Measurement Conditions

The measurement area shall have a low noise level, such that the majority of boat runs have sound levels at least 10 dB above the background level. Note: It is recommended that the area should be at least 3 km away from commercial vessels and other boats. Wave height should be as low as possible, preferable $<0.5$ m, as it affects both the boat's behavior and the background noise levels. Avoid areas with strong currents, which may affect the recording and the position of the hydrophone in the water. Do not perform the measurement in rain as it increases the ambient noise level.

The area should have a size to allow the boat to run in a straight heading at the target speed for at least 500 m.

The seabed should be as smooth and homogeneous as possible to minimize the influence of varying propagation loss.

The water depth should be at least 20 meters. The actual water depth should be measured in the area and especially along the test track and at the hydrophone position.

The sound speed profiles shall be measured before and after the test runs.

The result of the first sound speed profile shall be taken into consideration regarding where in the water column the hydrophone should be placed to have the most predicable propagation loss. Note: The second measurement is used to detect changes in the sound speed profile during the course of the measurement and is used to estimate measurement uncertainties.

The background noise shall be recorded at least 30 min before and after the measurement and 2 min before each run.

The signal stability shall be checked every 15 min in order to ensure the reliability of the measurement.

### Instrumentation

At least one hydrophone shall be used.

The hydrophone should have a known response in the frequency range of 20 Hz–50 kHz.

The hydrophone should be omnidirectional, i.e., have a directivity of <2 dB.

The hydrophone should be calibrated (uncertainty ±2 dB) as well as the entire system (hydrophone, cable, and data collection system) prior to the measurement.

The system should record with at least 50 kHz sampling frequency and have a dynamic range of at least 80 dB.

## Deployment

The hydrophone shall be placed at least 1 m from the seabed and in the lower half of the water column in order to avoid disturbances associated with the sea surface. Note: If the sound speed profile suggests that the sound energy is significantly directed to another depth layer, the hydrophone may be placed accordingly. If not, the hydrophone should be placed below the midst of the water column (e.g., at a depth of 15–29 m if it is 30 m deep at the site).

The hydrophone shall be disconnected from wave motions. The hydrophone can be anchored either on the seabed or suspended from the surface. If the hydrophone is close to the surface, the measurement has a higher risk of being disturbed by wave motion and rig noise.

There should be no air-filled buoy or similar air-filled cavity such as an autonomous logger unit, within 3 m of the hydrophone, as this may interfere with recording.

If the hydrophone is mounted on a rope between the bottom weight and the buoy, it shall be kept vertical in the water and thus not tilted due to currents or waves. Note: If the line is assumed vertical but is not, the hydrophone is not where it is expected to be, which means that distance estimates and depth values are incorrect.

Data recording shall be synchronized with a GPS clock prior to measurements. Note: The data recording can be done either via a cable to land or to a boat or in an autonomous unit in the water.

The position of the surface buoys and the hydrophone positions shall be measured with a GPS receiver.

The error margin of the hydrophone positions should be <5 m.

If a boat is used as measurement platform, it should be anchored at least 100 m from the hydrophone to minimize wave-induced noise when they hit the boat hull.

## Test Track

The start, closest point of approach (CPA) and end point of the course should be marked with surface buoys for easier navigation.

Each run should be at least 500 m long.

Two separate tracks should be employed. The primary tracks CPA should be 100–200 m distant from the deployed hydrophones position.

The CPA of the second track should be 1.5–2.5 times the distance, compared to the primary track. If only one track is used, the measurement uncertainty will increase due to lack of PL estimation verification.

The primary tracks CPA should be 100–200 m away from the deployed hydrophone's position.

### Test Procedure

If a run is disturbed by a boat nearby, the run shall be repeated.

A GPS receiver shall be positioned at the stern of the boat, set to record the position every second to get an accurate recording to the boat's position and speed during the runs.

The boat should have a straight course and even speed/rpm throughout the run.

The designated speed should have been reached before entering the track.

The course shall be repeated at least two times. Note: It is recommended to avoid driving so that the boat hits any wind-driven waves or from the boat's own wake.

The measurement shall be repeated for at least two different speeds: 5 kn and a second speed. Note: Preferable, these speeds should be one without cavitation and one with cavitation. The 5 kn is a common speed into harbor and in sensitive areas. The second speed should be chosen based on a typical speed the boat is designed for. Boats that are driven in a non-optimal way can be very noisy, which results in an uneven comparison if the non-optimal source level is compared to other boats at optimal speeds.

In some areas, other speed limits can occur, and these speeds are worth including as well.

Before testing, engine, propeller type, number of blades and location in the boat, draught, boat size and type should be noted in the protocol.

During the measurement, the speed, power, engine rpm, and run number shall be noted in the protocol.

### Post-Processing

As a first step, GPS tracks are extracted and combined with acoustic data.

The run shall be segmented into 19 segments, centered on a given set of angles between the boat and the hydrophone system. Note: The set of angles is exemplified in Fig. 2 and defined as $\pm 45^\circ$ to $\pm 135^\circ$ in $5^\circ$ increments.

In order for the segments to contain a certain amount of data, the segments should have a length of 50 m.

### Data Segments

For all 19 segments, a PSD shall be calculated using the Welch method, with 1 s time segments and a 50% overlap, yielding a PSD with a bandwidth of 1 Hz.

To calculate the spectrum with 1/3 octave band resolution, the *mean narrow band value* in each band is used.

The calculated spectrum, whether it is narrow band or 1/3 octave band, shall be compared to a corresponding background spectrum:

(a) If the signal-to-background level is above 6 dB, the data point shall be used directly without any modifications.

(b) For a signal-to-background level of 3–6 dB, the background shall be subtracted from the signal.
(c) If the signal-to-background level is less than 3 dB, this data point shall be removed from further analysis.

The propagation loss shall be corrected for in each of the 19 time segments, by taking into account the distance from the hydrophones to the center of each time segment.

The estimation of $A$ should be done using the following order:

1. PL measurement, based on separate calibrated source or boat runs
2. PL modeling
3. Based on previous knowledge of PL in the area
4. Using $\mathrm{PL} = 17 \cdot \log_{10}(\mathrm{R})$.

After the propagation loss correction, all data time segments shall be averaged in the linear domain to create a single spectrum for the run. Thus, the sound pressure spectral density level measured by hydrophone $h$ is

$$L_h = 10 \cdot log_{10} \frac{\sum_t 10^{L_t/10}}{n_t},$$

where $L_t$ and $n_t$ are the sound pressure spectral density level of time segment $t$ and the number of time segments, respectively.

When multiple hydrophone channels are used, their spectra of each run shall be averaged in the linear domain. The measured sound pressure spectral density level of the run is

$$L_r = 10 \cdot log_{10} \frac{\sum_t 10^{L_h/10}}{n_h},$$

where $n_h$ is the number of used hydrophones.

When multiple runs have been conducted with equivalent running conditions, the spectra of the runs shall be averaged in the linear domain. Portside and starboard side passages are then averaged in a similar manner to create a single spectrum for the specific running condition. Therefore, the boat spectrum is

$$L_b = 10 \cdot log_{10} \frac{\sum_t 10^{L_r/10}}{n_r},$$

where $n_r$ is the number of runs.

## Presentation of Results

The protocol shall contain one page identifying the boat to be measured; the location, time, and date of the measurements; and the scientific leader, whom is responsible for the implementation of these guidelines.

The second page shall clearly state the boat characteristics, measurement-specific data, the propagation loss estimation model used, and the sea state. Note: The boat characteristics include engine type, fuel type, propulsion type (e.g., propeller type), and design speed (if known). The measurement data form include the measured boat speeds in knots and the engine rpm for these speeds, the date from the GPS, and the GPS time as well as the recording time.

The measured sound pressure spectrum levels should be presented in 1 Hz spectrum and a 1/3 octave band spectrum, for each running speeds.

The main tones of the narrow band spectrum should be noted in a table and identified.

**Abstract**

Underwater noise was measured at 25 German offshore wind farms (OWFs) under standardized conditions. The measurements included different turbine types up to 8 megawatt rated power and different foundation types. Water depths ranged from 18 m to 40 m. The two main measurement positions were 100 m from a pre-selected offshore wind turbine (OWT) and in the center of the OWF. Underwater sound was recorded for up to 6 weeks to cover different wind and turbine conditions. The aim was to identify the most relevant influencing parameters of noise radiated by operating OWTs.

The cross-project analysis, based on broadband levels as well as third octave spectra and data, was divided into three wind classes that covered the range from OWT idleness to rated power. Noise from OWTs with gear boxes was slightly higher compared to those with direct drives. No significant differences were found for different foundation types. A trend analysis shows that an increase of radiated noise with increasing turbine size (characterized by its rated power) statistically does not exist. Noise from wind farm-associated vessel traffic was estimated for an exemplary OWF with 87 turbines and was found to be approx. 11 dB lower than the noise radiated by the OWTs.

## Introduction

The number of offshore wind turbines (OWTs) has strongly increased over the last decade and will increase worldwide significantly over the next decade due to the expansion of renewable energy. Meanwhile, the effect of OWT construction noise (impact pile driving) on marine mammals is well reputed; see, for example, Dähne et al. (2017) and Lucke et al. (2009). The ecological impact of underwater noise from operating OWTs and associated vessel traffic, however, is not yet fully investigated. Several studies indicate that the noise origin are mechanical oscillations of components like the gear box or the generator, which propagate through the foundation structure into the water, and this noise input can dominate the ambient noise measured in the vicinity (Betke et al. 2005; Madsen et al. 2006, Norro and Degraer 2016; Yang et al. 2018). Based on the few available underwater noise studies for operational OWT, Tougaard et al. (2020) and Stöber and Thomsen (2021) tried to extend the current knowledge in order to be able to model future soundscapes. Tougaard et al. (2020) used a general linear model, whereas Stöber and Thomsen (2021) used linear regressions to assess correlations between sound pressure level, measurement distance, turbine size, and wind speed. Both studies used data from smaller and older OWTs, which were gathered in various distances to the turbine and at different wind speeds. Driven by the demand for renewable energy, turbine size has increased significantly over the last 15 years. Upcoming projects will have turbine sizes above 10 megawatt (MW) nominal power. Furthermore, new turbine installation includes direct-driven (gearless) generators. In the North and Baltic Sea, monopile turbines, up to 10 meter (m) diameter, were installed in the latest OWF projects. Therefore, it is uncertain whether the noise from smaller and older OWTs can be extrapolated to the newest generation of OWTs.

In Germany, part of the approval process includes underwater noise measurements prior to construction (background or ambient noise) and during operation, according to a standard procedure developed by the Federal Maritime and Hydrographic Agency (Müller and Zerbs 2011). Currently, about 30 OWFs are in operation, and operational noise measurements were performed in a standardized manner on 25 of them. Post-processed data were uploaded in the MarinEARS database of BSH.

Technical properties of the measured OWTs are diverging: beside different brands with possible subtle design differences, they are erected on different foundation types like monopiles or jacket constructions (Fig. 1), and they have either gear boxes or gearless drives; see Table 1. Although the database of 25 measured OWTs is not extensive, differences in sound radiation that are caused by different turbine parameters should appear in the measurement results. The turbine size has also increased significantly over the years; recent plannings state power ratings of up to 15 MW.

OWTs from 3 to 8 MW are analyzed; hence, some evidence is expected whether larger turbines radiate more noise than smaller ones.

From earlier investigations (Betke 2014; Tougaard et al. 2020), it is known that OWT operational noise occurs mainly at frequencies below 1 kHz, or even below 100, and the acoustical energy is concentrated in a few narrow spectral lines. The strongest of these tones have typically rms levels of 120 dB re 1 µPa at 100 m distance. Mostly, these narrowband sounds recorded underwater are caused by the

tooth mesh frequencies of the gear box and by periodically alternating forces in the generator. In areas with high shipping density (e.g., along main shipping lanes, like most parts of the German Bight of the North and Baltic Sea), operational OWT noise does occur much above the ambient noise level. One important question is if the noise caused by operating OWTs is the only possible impact or if the vessel traffic related to the operation of an OWF will also have an influence on the overall level within as well as in the vicinity of an OWF? Therefore, in some of the German OWF projects measured in 2019 till 2021, the vessel noise caused by the operating OWFs was partly determined, and the underwater noise was also investigated.

## Methods

All operational noise measurements per OWF were conducted within the first years of their operation (new OWTs). The measurements were conducted in the period from 2013 to 2021. The water depth at the measurement locations varied from 18 m to 40 m. The typical setup used throughout the measurements is shown in Fig. 2. The hydrophone was decoupled from the marker buoys; its height above the sea floor was approximately 2 m. The complete setup was designed to minimize self-noise. The devices stayed at their position for 4 to 6 weeks. In general, there were four positions per OWF: (i) 100 m from a pre-selected OWT, preferably one that was located at a corner of the OWF, (ii) in the OWF center, and (iii) 1 km and (iv) 5 km outside the

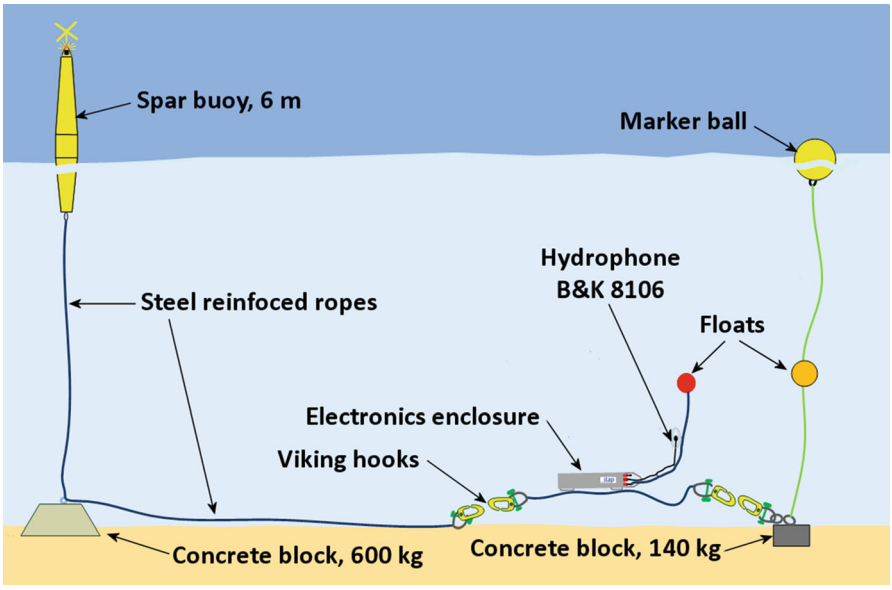

**Fig. 2** Measurement setup with mooring details for operational noise measurements within German OWFs

**Table 2** Definition of wind classes

| Wind class | Wind speed at hub height | Turbine state |
|---|---|---|
| Low | <3.5 m/s | Off or very low power |
| Medium | 7.5–11 m/s | 30–75% rated power |
| High | >11 m/s | >75% rated power |

OWF boundary. For the current evaluation, only the 100 m position was selected, since they promised the highest signal-to-noise ratios between operational noise of the OWTs and the ambient noise.

Sound was recorded intermittently for 10 min every 2 h in an uncompressed data format (wave, 24-bit; $f_s$ 44.1 kHz) due to the fact that the weather conditions, mostly wind and therefore the power generation of OWTs, will mostly change on larger time scales. This scheme proved to provide enough data for the later analysis for different wind conditions. Before deployment and after recovery of the instruments, hydrophones were calibrated with a Brüel and Kjær 4229 calibrator. The actual sound pressure within the calibrator cavity was monitored with a GRAS 46AG condenser microphone; the value went into the calibration. This calibration process is in accordance with ISO 17025 (2022) and given best practice (HELCOM 2021).

The raw data (uncompressed wav files) were evaluated with a validated software package developed at itap (IONIS). In a first step, the equivalent continuous sound pressure level ($L_{eq}$; this quantity equals the rms level) in accordance with the German measurement guideline (Müller and Zerbs 2011) was determined in intervals of 5 s. Based on the 5 s values, the $L_{eq}$ and the exceedance levels $L_{05}$, $L_{50}$ (median), and $L_{90}$ were calculated for both broadband and third octave bands according to the German measurement guideline (Müller and Zerbs 2011). In some cases, and in order to identify tonal noise components radiated by the OWTs, narrowband spectra with 1 or 2 Hz resolution were computed as well. The results were then arranged by three wind classes "low," "medium," and "high"; see Table 2. The wind farm operating companies supplied power and wind versus time data for the relevant OWTs in 10 min steps (mean values). The values in Table 1 were derived from a number of such datasets. The German measurement guideline (Müller and Zerbs 2011) requires at least 3 h of usable sound data per wind class. Despite the intermittent recordings, this was significantly exceeded in all measurements (raw data per wind class ranged from 8 h to more than 50 h).

## Measurement Results

A typical narrowband spectrum of a 6 MW OWT is shown in Fig. 3. The peak at 73 Hz also determines the overall or boradband sound presure (SPL). The spectrum has 1 Hz resolution and 5 minutes averaging time. Most OWTs had only a single prominent spectral peak; there were all found in the frequency range 50 to 200 Hz; however with differing amplitudes.

Figure 4 displays the broadband sound pressure levels of all measured OWTs build-up on different foundation types for the wind class "low" (OWTs off) and

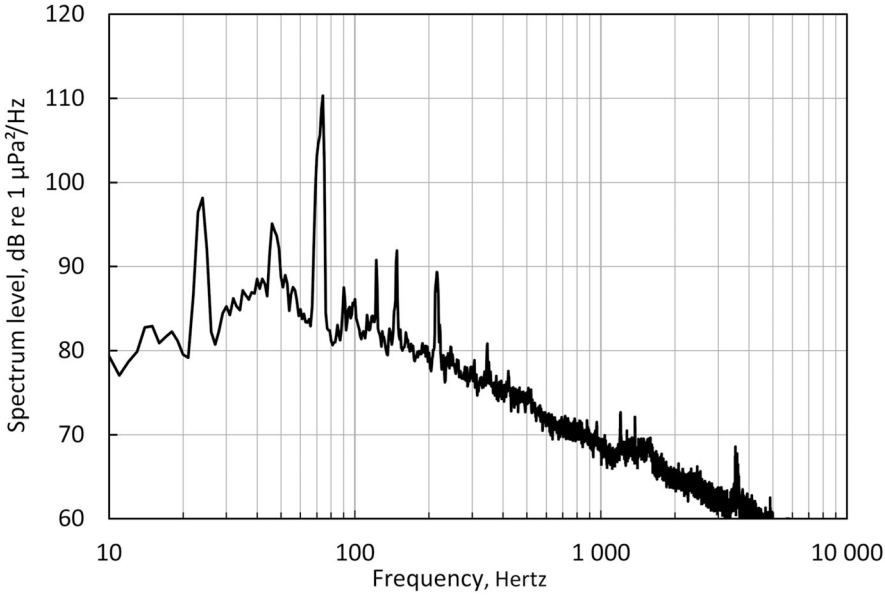

**Fig. 3** Typical narrowband spectrum of the operational noise of a 6 MW measured in a distance of 100 m for the wind condition high (full power)

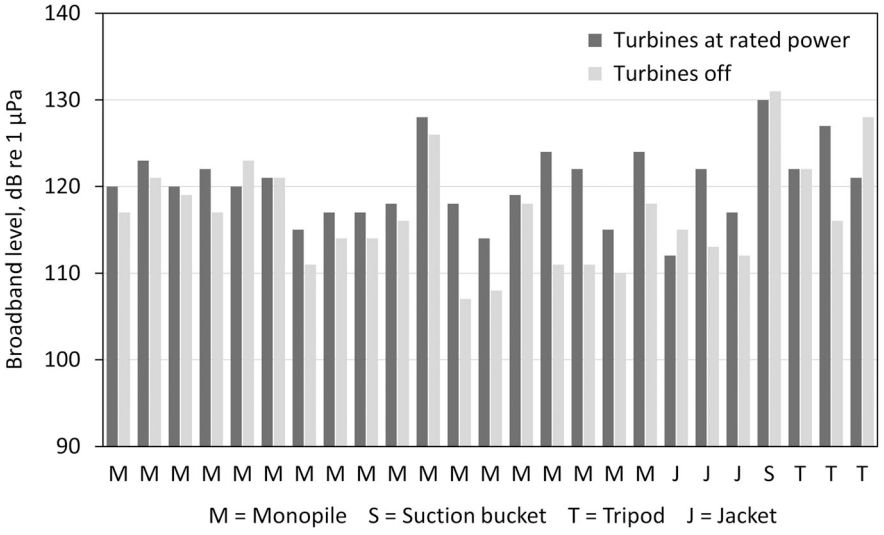

**Fig. 4** Broadband sound pressure levels measured in 100 m distance to the offshore turbines at maximum power and wind class high for different foundation types

"high" (OWTs >75% rated power). In this figure and the following ones, the $L_{50}$ (median value) is shown, which was computed from the whole observation period of 4 to 6 weeks per wind class based on 5-s $L_{eq}$ values. Eighteen of the 25 foundations

were monopiles; the remaining were four-legged jackets and other foundation types. It can be seen that in 22 out of 25 measurements, the sound pressure levels at 100 m distance to the foundation are, as expected, higher in wind class "high" compared to "low" except for the suction bucket, one monopile, and one tripod foundation. The increase between OWTs off ("low") and at rated power ("high") seems to be also depending on the ambient noise. In the case of high ambient noise levels in the vicinity of the OWT, the increase of the broadband level of operating OWTs is limited. Apparently, there is no systematic-level difference between wind classes "low" and "high" for the two foundation groups monopiles and non-monopiles; the actual levels are given in Table 3. Additionally, the differences between wind classes "low" and "high" might be influenced by other parameters like OWT type or gear-/gearless-driven OWTs.

Figure 5 compares broadband averaged sound pressure levels ($L_{50}$) of OWTs with gear box to gearless or direct-driven ones with capacities between 2 and 8 MW. Again, no obvious difference was detected, but Table 3 suggests that gearless OWTs might

**Table 3** Average (median) sound pressure levels measured in 100 m distance from different OWT types operating under full power (ranged between 2 and 8 MW) for the two different foundation types, monopiles and non-monopiles (based on Fig. 4), and separated into with and without gear box (based on Fig. 5)

| Parameter | Average broadband SPL from Fig. 4 and Fig. 5, dB re 1 µPa |
|---|---|
| Monopile foundations | 121.5 |
| Other foundations | 122.0 |
| Drive with gear box | 122.3 |
| Gearless (direct) drive | 120.0 |

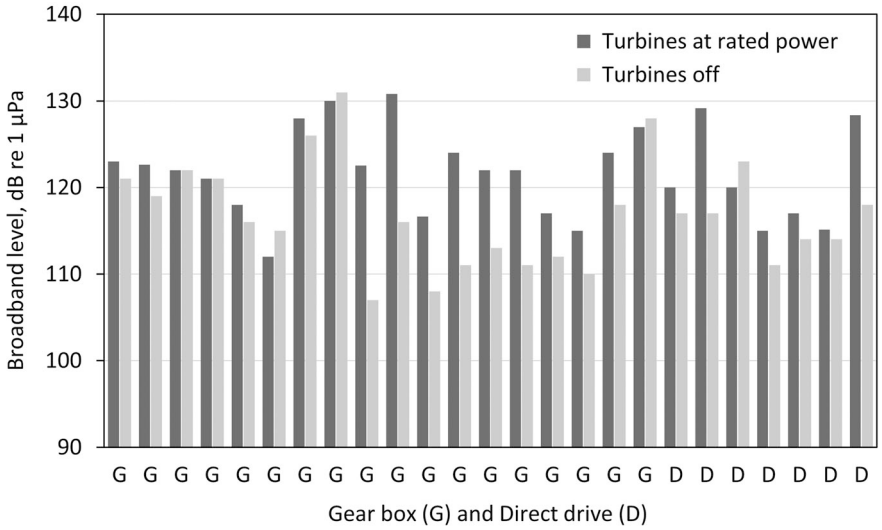

**Fig. 5** Broadband sound pressure levels for turbines with maximum power (ranged between 2 and 8 MW) with gear box and with direct drive measured in 100 m distance

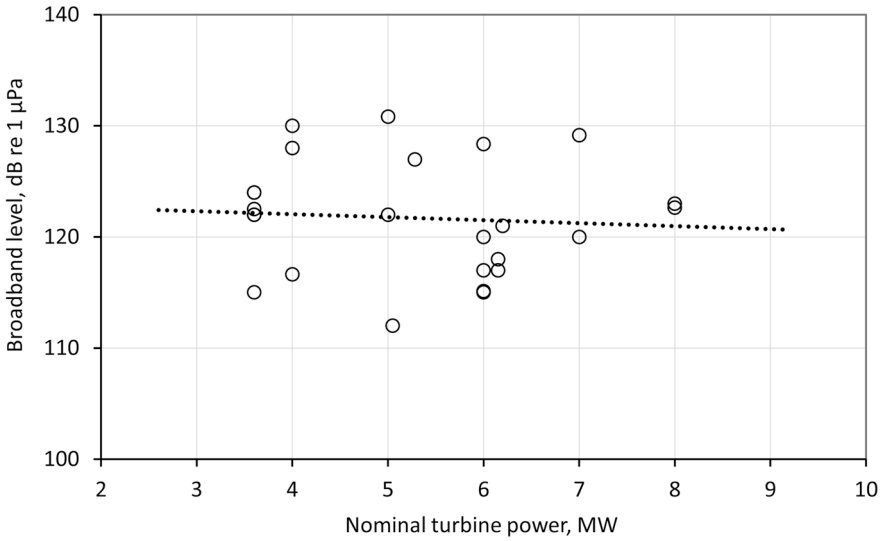

**Fig. 6** Broadband sound pressure level (SPL) measured in 100 m distance versus rated turbine power. The dotted line is a linear regression fit with $L = -0.27\ P + 123$ dB, where P is the rated power and L is the broadband SPL

have 2 dB lower levels in average in the vicinity of the foundation. However, this difference should be treated with caution because of the small sample size, the various combinations of foundation designs and OWT types, as well as the differences in ambient noise levels. Averaged sound pressure levels did not increase with turbine size or turbine power, respectively. In fact, a small negative linear correlation between turbine power and measured sound pressure levels was determined (Fig. 6). With increasing OWT size or increasing power rating, the diameter of the monopile foundation increases significantly as well. Thus, the OWT size is not an independent parameter.

## Wind Farm-Related Shipping Noise

Based on the results in Figs. 4 and 5, the ambient noise levels in the vicinity of OWTs ranged between 107 and 131 dB in wind class low (OWTs off). The only reason for such a high difference in the measured ambient noise can be shipping noise or other anthropogenic sources, like noise from surrounding OWFs in operation. The operational noise measurements in Germany for OWFs grouped in a "cluster" were usually performed in parallel for all OWFs in the cluster. The idea behind this approach was to investigate if operational noise from surrounding OWFs will influence the ambient noise in one specific OWF. These combined measurements point out that in wind class "low," the OWTs are off in all OWFs of the cluster. Therefore, observed differences in ambient noise are probably caused by ship movements related to the OWF maintenance/operation or by public shipping outside the OWF.

A typical situation for an OWF far away from shore is that an offshore service vessel stays in the OWF for 2 to 4 weeks before it returns to the base port for bunkering or crew changes. Exceptions are OWFs which are close to the coast so that service teams can make a round trip within a working day during daylight. Typically, inside the OWF, the service vessel moves between OWTs from time to time to deboard the service teams. Occasionally, crew transfer vessels may be active in the area as well. However, most of the time, the service vessel will be in standby position within the OWF or in the surrounding.

Figure 7 depicts the AIS (automatic identification system; a system by which ships communicate their position and other voyage-related information) track of the offshore service vessel "Bibby WM Horizon" as an example over a period of 52 days in 2021 during the operational noise measurements. The vessel was active in the 2 interlinked OWFs "EnBW Hohe See" and "EnBW Albatros" with 87 turbines of the 7 MW class. During this time interval, the vessel left the area southward toward the coast for its base port only three times for several days (crew changes and bunkering). For about 70 h, the ship was driving inside the OWF with a speed >2 knots (kn); maximum speed inside the OWF was 10 kn. The AIS track points are spaced approx. 30 min; shorter intervals were not available from the Sat-AIS provider.

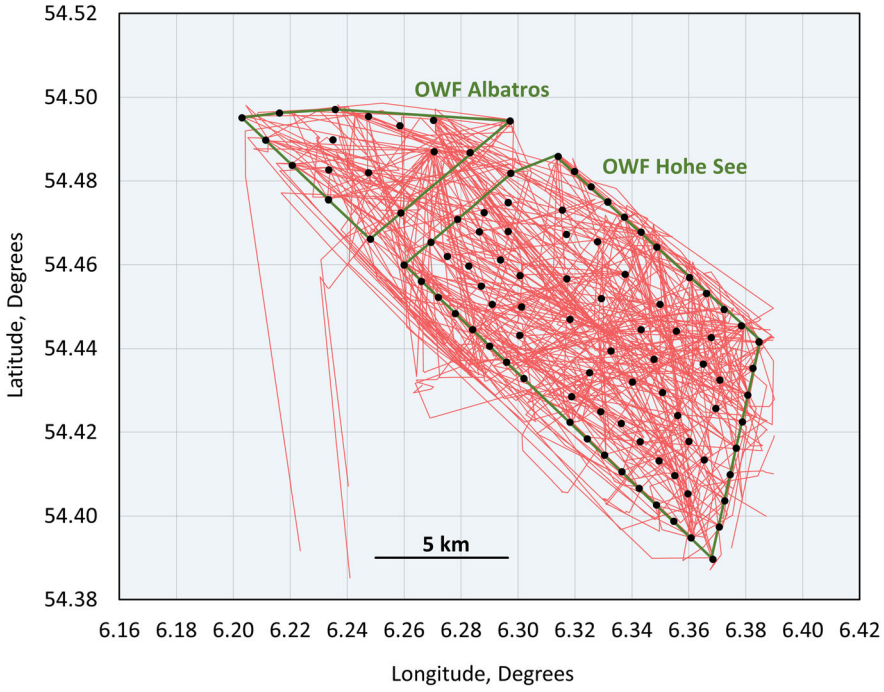

**Fig. 7** Movement of a typical offshore service vessel in and close to an OWF, recorded over a period of 52 days during operational noise measurements

**Table 4** Comparison of the sound energy produced by the OWF and a typical offshore service vessel during stay inside the OWF

| Sound source | Average sound power | | Sound energy emitted into the sea in 50 days | |
|---|---|---|---|---|
| 1 service vessel during transits in OWF (2 to 10 kn) | 0.8 W | 118.8 dB re 1 µW | 3.3 MJ | 125.1 dB re 1 J |
| 87 wind turbines | 10.9 W | 130.4 dB re 1 µW | 47.2 MJ | 136.7 dB re 1 J |

For an estimate of the overall sound energy emitted into the water by both sound sources, (i) OWTs and (ii) service vessel, several assumptions must be made to get a first approximation. First, the service vessel's source level is required. For this specific service vessel, no valid source-level measurement is available, but a similar vessel of this class from itap's measurement archives has a source level of L = 170 dB re 1 µPa @ 1 m. For the noise of a single OWT, a permanent value of L = 120 dB re 1 µPa @ 100 m, based on the measurements of this study, is assumed. Sound propagation was approximated with a 15 $\log_{10}$ (distance ratio) law over the first kilometers. The actual results are listed in Table 4.

With the above assumptions, the OWT cluster emits about 11.5 dB more sound energy within a given time interval than the service vessel in the OWF. The sound pressure level cannot be derived straight from this result since the SPL depends on the location and also on time, because the service vessel is moving. For a long average and at large distances from the OWF, the difference between sound levels caused by all OWTs and the service vessel is 11.5 dB. However, this is a theoretical value, since several kilometers outside the OWF, its noise emission is normally not measurable.

The 11.5 dB difference is mainly caused by the small operation time compared to that of the OWF, which is assumed operational 24 h/day. Additional noise sources like crew transfer vessels or the service vessels' dynamic positioning system might make this difference smaller.

## Discussion

In Holme et al. (2023), a subsample of the measurements of this study (only OWFs Gode Wind 01, Gode Wind 02, and Borkum Riffgrund 02) was used in distances between 63 m from pre-selected OWTs and 5.000 m from the OWF to investigate the influence of turbine size (6.3 and 8.5 MW), wind speed, and foundation types (only monopile and suction bucket) on operational noise. Holme et al. (2023) did not find a correlation between the measured broadband sound pressure level and turbine size or foundation type. They also found out that the noise from OWTs had no significant influence on the broadband ambient noise level at distances of 1 km and more from the OWF boundary. The ambient noise levels inside and outside the observed three OWFs varied without OWTs off (wind class "low") by up to 5 dB, which is a hint that the influence of vessel activities will significantly dominate the ambient noise inside but also outside the OWFs. In the case of operating OWTs in these OWFs, the overall broadband sound pressure level shows partly an increasing, decreasing, or constant

broadband level as function of distance. This finding is in accordance with the findings of this study that the ambient noise outside the OWFs mostly is dominated by other noise sources, most likely noise from OWT service vessels and from commercial ship traffic. For this study, time periods where vessels will be in the vicinity of the measurement positions (<1 km) were excluded to avoid any unwanted effect of crossing vessels. In the study of Holme et al. (2023), the same finding will be reported that nearby crossing vessel showed a fast increase of measured SPL and a fast decrease over several minutes, which is a strong hint that any vessel activity in the vicinity of any OWTs masks or exceeds significantly the overall broadband level generated by an operating OWTs for the short period of crossing nearby.

The measurements indicate that the overall noise emitted into the sea by an OWF (noise from the OWTs plus noise from service vessels) is dominated by OWTs and not by the vessels, since the period of vessel activities within OWFs is limited. Furthermore, based on the rare transits between OWF and base port, the noise from service vessels outside OWFs is limited, and an intermixture with other vessel noise is given. However, the impact of underwater noise from OWFs will also depend on the ambient noise, which is mostly dominated by public shipping noise, especially close to shipping lanes with high vessel traffic.

This study, as well as others (Holme et al. 2023), shows that the most relevant influencing parameters of operating OWTs are currently not identified or well understood.

Within this study, only OWTs during the first years of operation were monitored, but based on experiences from onshore wind farms, a change in the radiated noise from wind turbines running over a long period cannot be excluded. This suggests that modelling the soundscapes of future OWF scenarios might not be possible by interpolating existing measurements from smaller OWT size. In Holme et al. (2023), it was demonstrated that the modelling based on interpolations by Tougaard et al. (2020) will overestimate the noise from OWFs, like Gode Wind 01, Gode Wind 02, and Borkum Riffgrund 01, by up to 8 dB. However, to get statistically valid soundscapes for continuous noise in the water, the often dominating factor shipping noise must be taken into account.

**Acknowledgments** This work was funded by the Federal Maritime and Hydrographic Agency (BSH) and the Federal Ministry of Transport and Digital Infrastructure (BMVI). Special thanks go to our colleague Tobias Müller and itap's seafarers as well as to all involved OWF operating companies for the good support.

**Abstract**

Construction of offshore wind turbines, via impact pile driving, generates and radiates intense acoustic and sediment borne energy through the water column and ocean bottom. The acoustic waves generated by impact pile driving include interface (Scholte) and shear waves in the ocean bottom in addition to compressional waves in the water column and sediments. The particle motion component of acoustic energy is particularly important to fishes and invertebrates. Scholte waves contribute significantly to the particle motion generated in the seabed and have maximum amplitude at the seafloor. Scholte wave contribution to the measured data is identified using Random Decrement technique in this study. Data measured during the construction of the Coastal Virginia Offshore Wind (CVOW) project are analyzed. The CVOW project involved the construction of two 6- megawatt wind turbines located 43 km east of Virginia Beach, Virginia. The turbines were pinned to the seabed using mono piles of diameter 7.8 m. A suite of particle motion sensors, including Ocean Bottom Recorders (OBX),

was deployed to monitor the acoustic pressure and particle velocity on the seabed during December 2021 to January 2022. To examine the potential effects of sound on fishes and invertebrates, the behavioral thresholds and behavioral audiograms of some of these animals to the particle motion component of sound were compared to the measured data. These measurements were part of the Bureau of Ocean Energy Management (BOEM) sponsored Real-time Opportunity for Development Environmental Observations (RODEO) Program [Work supported by Bureau of Ocean Energy Management (BOEM)].

## Introduction

The quest for renewable sources of energy has led to the increase in the development of offshore wind farms over the last decade. Most of the current offshore wind farm developments are in shallow waters (less than approximately 30–50 m) and the preferred method of construction in shallow waters is either using a single cylindrical tower (monopile) or jacket type of structure. Installation of either of these wind turbine substructures requires driving piles into the seabed. Pile driving generates acoustic and seismic waves in the air, water column, and the seabed. Generation of Mach waves during impact hammer pile driving and its propagation characteristics has been well studied and described in Reinhall and Dahl (2011), Potty et al. (2011), Kim et al. (2022), Miller et al. (2016), Wilkes and Gavrilov (2017), and Amaral et al. (2020a). The acoustic energy radiated from the pile directly and reflected from the boundaries of the waveguide contributes significantly to the sound received at any distance from the pile in the water column. The contribution of sound produced during any construction of offshore wind farms can change the underwater soundscape and alter the habitats of marine mammals, fishes, and invertebrates by potentially masking communications or causing mortality, permanent threshold shift (PTS), temporary threshold shift (TTS), or behavioral disturbances for species that rely on sound for mating, navigating, and foraging (Amaral et al. 2020b).

In addition to the sound pressure generated in the water, compressional, shear, and interface waves are generated in the seabed that propagate outward from the pile in all directions (Amaral et al. 2020b). Compressional waves (P-waves) are the fastest traveling waves in the seafloor and are characterized by particle motion that is parallel to the direction of wave propagation, whereas shear waves (S-waves), which are slower than P-waves, have particle motion that is perpendicular to the direction of the propagating wave (Amaral et al. 2020b). Interface waves travel along the water-sediment interface at a speed about 90% of the shear waves with maximum particle motion amplitude at the interface (Kolsky 1963). Interface waves along the water-sea bottom boundary are called Scholte waves. The particle motion amplitude

of Scholte waves will have maximum amplitude at the interface and will decay exponentially away from the interface both in the water column and seafloor. Hence the effect of these types of waves will be felt only within one or two wavelengths from the seafloor. The low-frequency and slow-moving Scholte waves propagate over long distances and can generate large-amplitude oscillations along the water-sediment boundary. These Scholte waves have the potential to affect marine life that are sensitive to this type of disturbance living close to or within the seafloor sediment (Popper and Hawkins 2018).

Research interest in understanding the role of sound in the functioning of aquatic ecosystems, and the ways in which sound affects animal behavior and physiology, has gained increased attention in the recent past. While aquatic mammals use acoustic pressure, many fishes and invertebrates detect and use the acoustic particle motion (Nedelec et al. 2016). Since many aquatic animals sense particle motion, this component of the sound field should be taken into account while assessing the impact of the acoustic field on the environment. Measurements and model predictions of particle motion are few compared to acoustic pressure data, and experimental data on the response of fishes and invertebrates to particle motion are also scarce.

Many invertebrates appear to respond to vibrations (Roberts and Elliot 2017); for example, the bivalve *Scrobicularia plana* (peppery furrow shell) is sensitive to vibration and may therefore react to the foot-fall of its predator *Haematopus ostralegus* (oystercatcher). The anemone *Anthopleura elegantissima* (aggregating anemone) and the sea urchin *Strongylocentrotus purpuratus* (purple sea urchin) can detect vibrations within the frequency range of waves on the shore. Within the seabed, there is evidence to suggest that *Rimicaris exoculate* (deep sea shrimp) detect falling prey using vibration, and flatfish such as *Pleuronectes platessa* (European plaice) and *Solea* spp. may use vibrations to sense predators (Roberts and Elliot 2017). Roberts et al. (2016) conducted a study aimed to determine to what extent the common marine intertidal hermit crab, *Pagurus bernhardus* L. (Family Paguridae) is sensitive to substrate-borne vibration, and to fully define the sensitivity range and behavioral responses in relation to levels produced by anthropogenic activities. They presented results of this study along with published values of behavioral thresholds to vibration (both in water and substrate-borne) for crustaceans for comparison (Roberts et al. 2016).

Acoustic pressure and particle motion measurements were made during the construction phase of the Coastal Virginia Offshore Wind (CVOW) project. The CVOW project, which consists of two 6- megawatt wind turbines, is located 43 km east of Virginia Beach, Virginia. These measurements were made using Ocean Bottom Recorders (OBX) along with many other sensor systems. Four OBXs were deployed as a linear array, and data from one of the OBX are analyzed in the present study. Panel c in Fig. 1 shows the picture of an OBX and the axes definitions. The particle velocities are measured along these axes (x, y, and z directions), and acoustic pressure is measured on a hydrophone co-located with the directional sensors. The OBX sampled the data at 2 kHz during the CVOW deployment. In addition to the acoustic/seismic measurements, the OBX package also has a heading sensor which

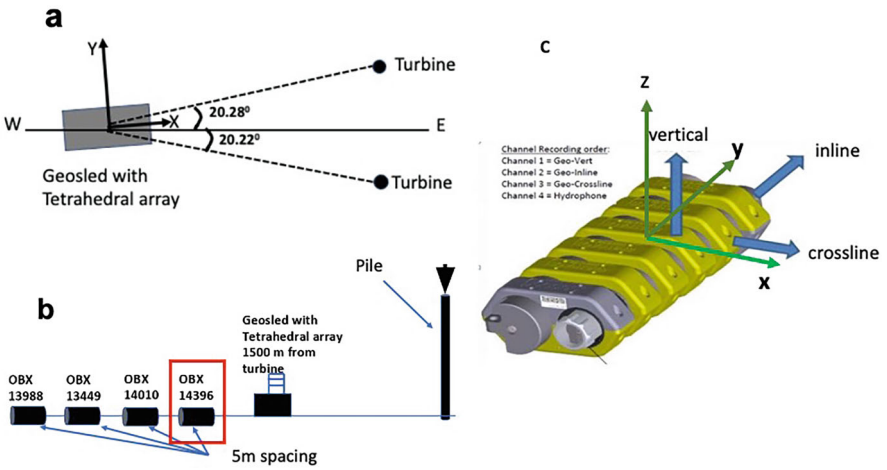

**Fig. 1** (**a**) Position of the OBXs in relation to the two CVOW turbines. The dashed line indicates the propagation path from the turbine to the OBX. (**b**) Geometry of the four OBXs which were attached to a sled. The sled was located at 1500 m from the pile driving locations. The spacing of the OBXs was 5 m. (**c**) Picture of an Ocean Bottom Recorder (OBX) with the axis definitions. Particle velocities are measured along the x, y, and z directions

measures the heading information that is used to properly orient the OBX, in the horizontal plane, in order to calculate the direction of arrival of acoustic signals. The CVOW turbines were installed on monopile type substructure (7.8 m diameter) with piles driven by impact hammer strikes. Locations of the OBX sensor packages in relation to the two turbines are shown in Fig. 1 (panels a and b). No bubble curtains were used during the construction of the north turbine whereas noise mitigation measures (bubble curtain) were used during construction of the south turbine. Based on the triangulated positions of the OBXs, the propagation of acoustic energy from the piles should arrive at 20° angle to the East (as shown in Fig. 1; panel a). The range from the pile to the OBX considered in this study is approximately 1500 m. This range was the closest distance from the turbine where deployments were permitted based on safety considerations.

Figure 2 (left panel) shows particle velocity measured on the first OBX sensor in the array (OBX 14396, highlighted by the red box in Fig. 1; panel b) during pile installation. Data shown in Fig. 2 correspond to the north turbine in which no sound reduction methods (i.e., no bubble curtain) were used during pile driving operations. Figure 2 shows approximately 1 minute of data during which approximately 50 hammer strikes were recorded. Each impulse in the figure correspond to one hammer strike. Upper panel on the left in Fig. 2 shows the vertical component of the particle velocity (in mm/s) whereas the lower panel shows the radial component (along the propagation path in the horizontal plane).

The radial component of velocity is obtained by projecting the X and Y components of the particle velocity components along the propagation path from the turbine to the OBX (shown in Fig. 1; panel a). The radial velocity is approximately

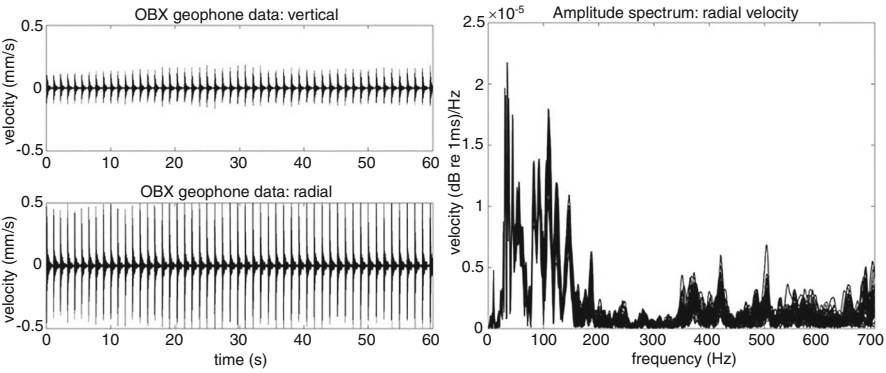

**Fig. 2** Particle velocity measured on the OBX sensor (left panel). Upper panel on the left shows the vertical component of the particle velocity (in mm/s) whereas the lower panel shows the radial component (along the propagation path in the horizontal plane). Right panel shows the amplitude spectrum of the radial velocity component

five times larger than the vertical velocity. Since the OBX is deployed on the seabed, it will measure shear and interface waves in addition to the compressional waves. This makes the OBX data complicated and identification of the contribution of the different wave types will be helpful in interpreting the data. The interface waves will have the maximum amplitude at the seabed; its amplitude decays exponentially away from the interface and cylindrically in range. The right panel in Fig. 2 shows the amplitude spectrum of the radial component of velocity from all 50 events shown on the left, showing the energy distribution as a function of frequency. The frequency content in the different events appears to be very similar showing very little spread in the spectral amplitudes especially at low frequencies. These low frequencies (below 200 Hz) seem to dominate the spectrum.

A technique known as Random Decrement (RayDec) approach is used to identify the Scholte wave arrivals in the data (radial and vertical components shown in Fig. 2). The RayDec approach provides the frequency band in which the Scholte wave arrivals dominate and the direction of arrival (DOA) of these arrivals. The RayDec algorithm calculates the frequencies and DOA of Scholte wave arrivals by searching the data (the vertical and horizontal components of velocity) at various times and frequencies and identifying the 90° phase shift between them (vertical and horizontal components) which is a characteristic feature of the Scholte wave particle motion (Hobiger et al. 2009; Potty et al. 2022).

Figure 3 shows the time-frequency distribution of acoustic energy (top left panel) calculated using wavelet-based analysis and the direction of arrival of Scholte waves (top right panel) calculated using the RayDec algorithm. The portion of the time series (six seconds long with five hammer strikes) which was used to create the time-frequency representations of acoustic energy and azimuth is also shown in bottom right. The time series analyzed corresponds to data from the north turbine (without bubble curtain). Azimuth estimates with a confidence level of 60% and above are only shown in the top right panel. Scholte wave arrivals can be seen in the frequency

band from 30 Hz to 90 Hz. Most of the arrivals, in the band 30 Hz to 70 Hz (indicated by blue color), appear to come at an angle of 20° north of the east-west direction. Arrivals can also be seen at 20 Hz and above 70 Hz which appears to come from different angles. This could indicate a different source (low-frequency micro-seismic energy) or coming through different interfaces/paths. There is also a 10 Hz and 60 Hz spectral component (left panel) which is present throughout and possibly not related to the hammer impact events.

The particle velocity and acceleration amplitudes at the measurement location, 1500 m from the turbines, are significant and have the potential to impact the behavior of fishes and invertebrates. The particle acceleration levels can be compared to the behavioral thresholds to assess the potential for impacts as shown in Table 1. The values shown are acceleration levels in dB re 1 μm/s$^2$ at four different

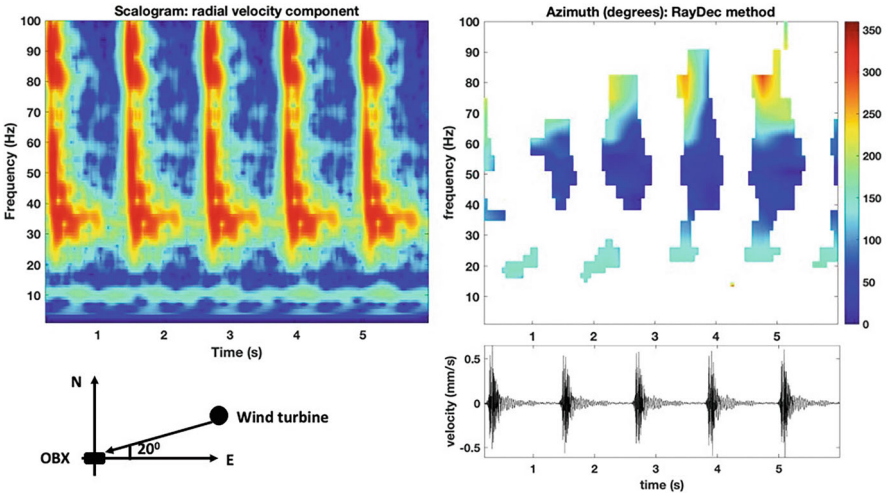

**Fig. 3** Time-frequency distribution of acoustic energy (top left panel) and direction of arrival of Scholte waves (top right) of the section of data (bottom right) analyzed. The propagation path from the north turbine to the OBX is indicated in the bottom left panel

**Table 1** Behavioral audiogram thresholds for fishes and behavioral response thresholds for a crustacean to vibration. Values taken from the literature and compared to CVOW data (Popper et al. 2014; Roberts et al. 2016). Bold numbers indicate threshold values lower than the CVOW levels. The values shown are acceleration levels in dB re 1 μm/s$^2$ at four different frequencies

| | 30 Hz | 35 Hz | 45 Hz | 83 Hz |
|---|---|---|---|---|
| Atlantic salmon | **41.33** | **41.1** | **40.7** | **38.5** |

| Atlantic cod | **31.33** | **28** | – | – |
| Plaice | **28.87** | **27.44** | **25.42** | **22.97** |
| Atlantic sand fiddler | **70.1** | **72.04** | 75.56 | 81.93 |
| *CVOW data* | *71.5* | *73.7* | *73.7* | *76.8* |

frequencies in the band where the acoustic energy is maximum (as shown in Fig. 3). The behavioral audiograms of four fishes (Atlantic salmon, dab, Atlantic dod and plaice) are taken from Popper et al. (2014), whereas the behavioral response threshold values for *Uca pugilator* (Atlantic sand fiddler) is calculated based on values from Roberts et al. (2016). Last row in Table 1 shows the acceleration level measured from the CVOW data as shown in Fig. 2. The threshold values are highlighted in bold numbers if they are lower than the measurement at different frequencies. The measured data are higher than the audiogram threshold values for all of the fishes considered. It indicates they can hear the sound, but whether that will lead to any behavioral changes in fishes is impossible to conclude without behavioral threshold values. The measured levels are slightly higher at two frequencies in the case of *Uca pugilator* (Atlantic sand fiddler) behavioral response threshold.

It should be noted that the results shown in Figs. 2 and 3 and Table 1 correspond to data from the north turbine which did not have a bubble curtain. The bubble curtain did reduce the acoustic energy produced by hammer impacts at the south turbine (with bubble curtain) measured on the OBXs. Figure 4 shows the comparison of the spectra of the data measured on OBX (indicated on Fig. 1 with a red box). As can be seen from Fig. 4, the received particle velocity (both vertical and radial components) levels drops by approximately 10 dB, for frequencies higher than 300 Hz, when bubble curtains were employed. At low frequencies (frequencies less than 300 Hz) the bubble curtain performs not as effectively as at higher frequencies. This frequency dependent performance of the bubble curtain is being investigated in detail currently by analyzing data from other receivers and through modelling.

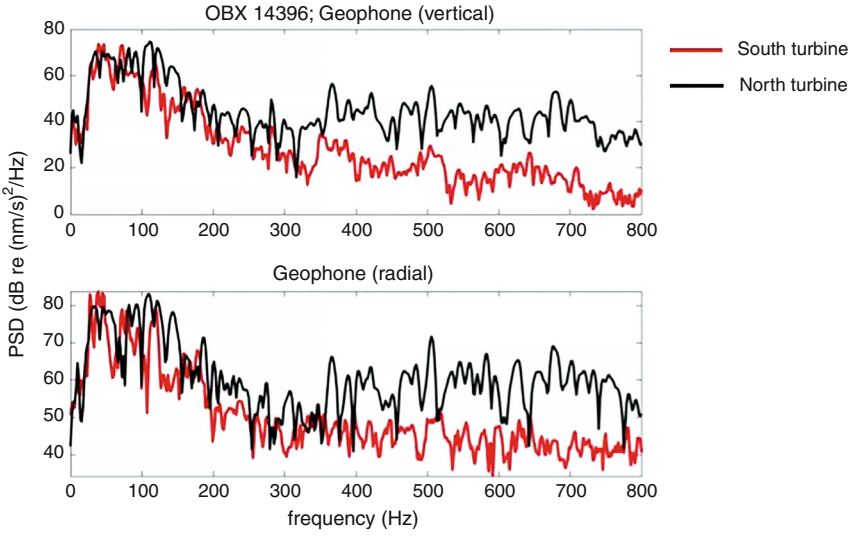

**Fig. 4** Power spectrum of OBX geophone data from the north turbine (black) and south turbine (red). The pile driving for the north turbine was done without bubble curtains whereas the south turbine employed bubble curtain

## Conclusions

The contribution of Scholte waves to the particle motion measured on the seabed at a range of 1500 m from impact pile driving operations was assessed in this study. The frequencies and direction of arrival of Scholte waves were identified using RayDec technique. The acceleration levels measured were also compared to behavioral audiograms and thresholds of some fishes and a crustacean. Preliminary comparisons indicate that the fishes and crustaceans considered in this study could hear or be behaviorally impacted by the pile driving operations at 1500 m.

**Acknowledgments** Study concept, oversight, and funding for the experiment were provided by the U.S. Department of the Interior, Bureau of Ocean Energy Management (BOEM), Environmental Studies Program, Washington, DC under Contract Number M15PC00002, Task Order M16PD00025. The OBX system was acquired under a DURIP grant. Collaborators in this project include Anwar Khan and Kristen Ampela (HDR, Inc.), Arthur Newhall (WHOI), and Tim Mason (Subacoustech., UK).

**Abstract**

This chapter examines underwater noise measurements recorded within and outside operating offshore wind farms consisting of 6.3 MW and 8.3 MW turbines, respectively. Each wind farm had multiple hydrophones recording simultaneously with the nearest being located 70–100 m from a turbine, while the furthest was positioned 5 km outside the wind farm. Data were collected over 5 weeks to facilitate a statistical examination of how the magnitude of underwater noise changes with turbine activity (power production data) and natural fluctuations (e.g., tides and wind).

The results imply that there is no significant relation between the broadband underwater noise levels and turbine activity for any of the examined wind farms in the monitored distances (up to 70 m). Influence from natural fluctuations was on the other hand evident from the measured noise levels. Moreover, a comparison between recorded noise levels and simulated noise levels from an

already-established empirical model shows that the model's extrapolated noise levels greatly exceed that of the recordings. This suggests that there are challenges associated with extrapolating aggregated results from smaller turbines to the realm of new, larger turbines. Thus, a new approach or more data are required to predict underwater noise from future operational wind turbines.

## Introduction

Earlier studies have been able to trace the vibro-mechanical oscillations from operating offshore wind turbines to changes in the ambient underwater noise levels (Betke et al. 2005; Madsen et al. 2006; Norro and Degraer 2016; Yang et al. 2018). The vibrations are excited by mechanical components such as rotating blades and the turbine's operating gear box which causes vibrations to propagate down through the turbine tower and subsequently manifest as underwater noise radiating away from the foundation. However, while it is evident that turbine activity previously has been detectable in the recorded underwater noise levels, there remains an indefinite understanding of how the underwater noise level will scale with increasingly larger turbines and offshore footprint. For instance, the number of offshore wind turbines will over the coming decades increase exponentially due to an increasing demand of renewable energy resources (COM 2020, 741). Such expansion will cause the spatial coverage of turbines in the ocean to increase accordingly.

Tougaard et al. (2020) and Stöber and Thomsen (2021) set out to address this by aggregating primarily third party's underwater noise measurements with the purpose of establishing an empirical formula that could predict noise levels for larger turbines. Tougaard et al. (2020) used a general linear model to assess the correlations between sound pressure level and measurement distance, turbine size, and wind speed. Stöber and Thomsen (2021) used linear regression to assess the correlation where the distance dependency was removed by assuming that their data sources were subject to same transmission loss of 15 $\log_{10}(r)$ where r is the radial distance from the source. Both studies relied on aggregated data from primarily smaller turbines (0.45–6.15 MW) collected under different environmental conditions and distances to the turbines. Such methodologies are challenged by the difficulty in (1) disentangling the contribution from correlating variables (e.g., wind speed and power production) and (2) estimating the accurate sound source levels as the transmission loss varies across sites.

The motivation of this chapter is to get a better understanding of how underwater noise relates to turbine activity in the vicinity of an operating wind farm. This study has recorded the underwater noise levels in and around ~250, ~330, and ~450 MW offshore wind farms consisting of 6.3 or 8.3 MW turbines, respectively (see Table 1).

**Table 1** Wind farm information

| Wind farm | Nominal power | Wind farm size | Turbine type | Rotor diameter | Foundation type |
|---|---|---|---|---|---|
| Gode Wind 1 | 6.3 MW | ~330 MW | SGRE 6.3–154 (direct-drive) | 154 m | Monopile |
| Gode Wind 2 | 6.3 MW | ~250 MW | SGRE 6.3–154 (direct-drive) | 154 m | Monopile |
| Borkum Riffgrund 2 | 8.3 MW | ~450 MW | V164–8.3 (planetary gear) | 164 m | Monopile and suction-bucket jackets |

The relation between underwater noise and turbine activity is then examined by analyzing the co-variability of underwater noise, wind speed, and power production for multiple turbines sampled in different distances to the source. Data were collected over 5 weeks to facilitate a detailed statistical examination of how the magnitude of underwater noise changes with turbine activity (power production) and natural fluctuations (mainly tides and wind).

## Measurement Campaigns

Noise levels were recorded from three offshore wind farms in the Summer of 2020 (Gode Wind 1 and 2) and Spring/Summer of 2021 (Borkum Riffgrund 2) for five continuous weeks. The Gode Wind turbines have power production capacities of 6.3 MW, while the Borkum Riffgrund 2 turbines have a capacity of 8.3 MW. Each wind farm had four to five hydrophones recording simultaneously with the nearest being located 70–100 m from a turbine, while the furthest was positioned 5 km outside the wind farm. The 5-km position is used as a reference of the ambient noise signal when analyzing the impact from turbine activity on changes in underwater noise levels. The assumption is that there is no influence of turbine noise at 5 km due to the geometrical propagation loss having diminished the signal. All sites have similar water depth of approx. 30 m.

## Hydrophone Setup

Two types of hydrophones were deployed: (1) a completely continuous recording device and (2) a hydrophone that recorded for 10 min every 2 h (see Table 2). The reason for utilizing two different types of hydrophones is that these measurement campaigns were part of the underwater noise measurement requirement for offshore wind farm commissions stated in the German StUK4 (BSH 2013). Thus, in addition to the BSH-requested hydrophones, four additional continuously recording high-resolution hydrophones were deployed to record the underwater noise levels. These devices were positioned as close as safely possible to the pre-selected turbines per wind farm to ensure one could record the actual turbine signal. Furthermore, the

All other positions are monopile foundations

measurement position close to the turbines were selected in such a way that any disturbing background noise from vessel lanes, other turbines in the vicinity, etc. were minimized.

Each hydrophone had a fixed position at 1.5 m above seabed throughout the campaign and followed the measurement protocols outlined in ISO 18406:2017 and BSH (2011). All hydrophones were calibrated by itap GmbH using a pressure chamber process.

The Gode Wind MP5a data were excluded from the analysis as the data were found to be compromised. This was determined by the deployment of two hydrophones close to each other (MP5 in this case).

## Data Pre-processing

Figures 1 and 2 show that the recorded broadband SPLs oscillate steadily with time (10 min averages of 5 sec SPL measurements). The variation is ranging from 115 to 130 dB, and this steady oscillation is therefore a dominant feature in the noise recordings. The periodicity is first examined through power spectral analysis of the calibrated noise recordings (5 s averages) as seen in Fig. 3. From this, it is evident that all four positions are influenced by the semi-diurnal tidal modes $M_2$, $S_2$, and $N_2$ (~2 cycles/day), while three of the measurement positions are further dominated by the $M_4$ shallow water overtide of the principal lunar (~3.85 cycles/day) (Bartels 1967). The MP7a (GOW02) data don't have the $M_4$ mode even though its water depth of ~33 m is like that of MP5a (GOW01) with ~32 m. This difference might be

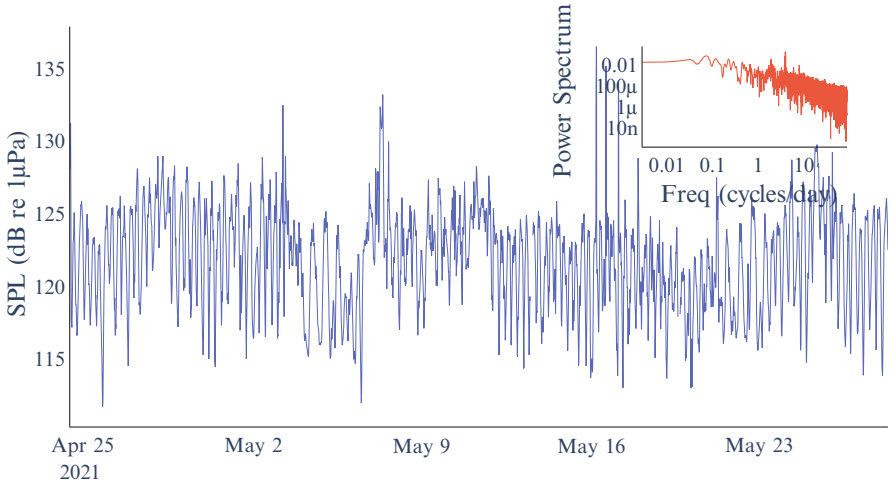

**Fig. 1** Time series of 10-min averaged broadband SPL (BKR02, MP4b, 63 m from a WTG). Top right subplot shows the corresponding power spectral density

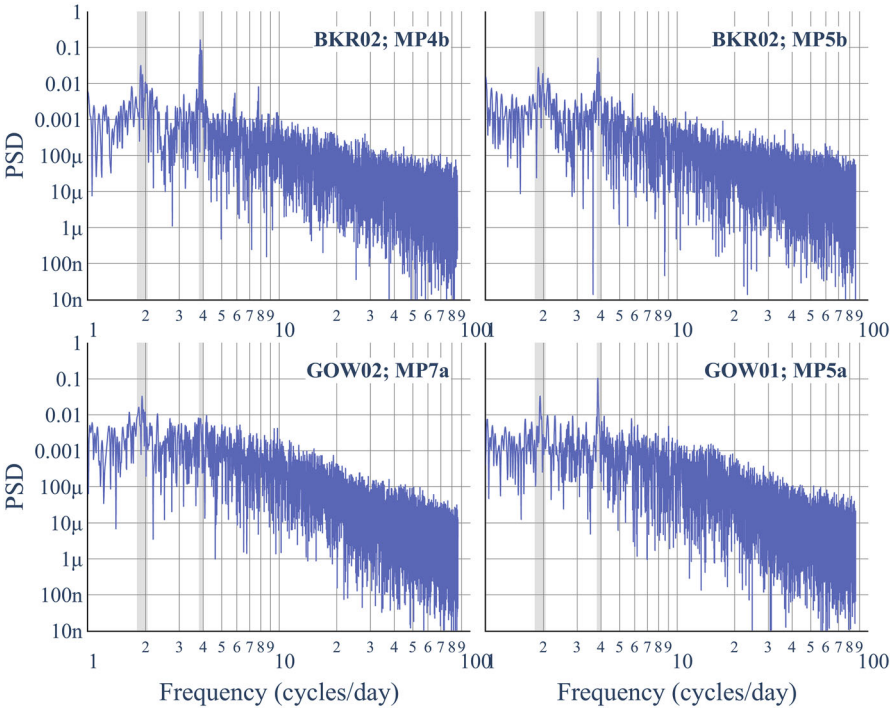

**Fig. 2** Power spectral densities (PSD) of broadband SPL computed through Lomb-Scargle Periodograms. The gray bars denote different observed tidal oscillations (e.g., M2 and M4)

a consequence of some site-specific attribute as the MP7a position is located ~12 km northeast of MP5a.

The power spectral analysis indicates that the changes in SPL predominantly are attributed to tidal variations. Thus, daily averaged SPLs are calculated to remove any bias from the subsequent analyses with wind and power production data. As SPL is a logarithmic metric, the daily averages are calculated through logarithmic means. This is done by (1) taking the anti-log of the SPL series, (2) calculating the mean, and (3) re-applying the decadic logarithmic factor again.

Additionally, in the subsequent analysis, a 30-min moving median filter is applied to the data to remove any noise impacts caused by nearby passing vessels. This is applied prior to calculating the daily averages. The data shows that service vessels visiting the turbines occasionally caused elevated noise when passing the deployed hydrophones. This was visible in the raw broadband SPL data as a sudden and short-duration noise increase of 5–10 dB SPL. Such a change cannot result from turbine-induced noise as it was observed during low winds and since it was characterized by a sudden increase and decrease in noise. Moreover, it takes ~10 min for the turbine to either steadily ramp up or down from full capacity. The sudden noise increase could therefore not be a turbine signal.

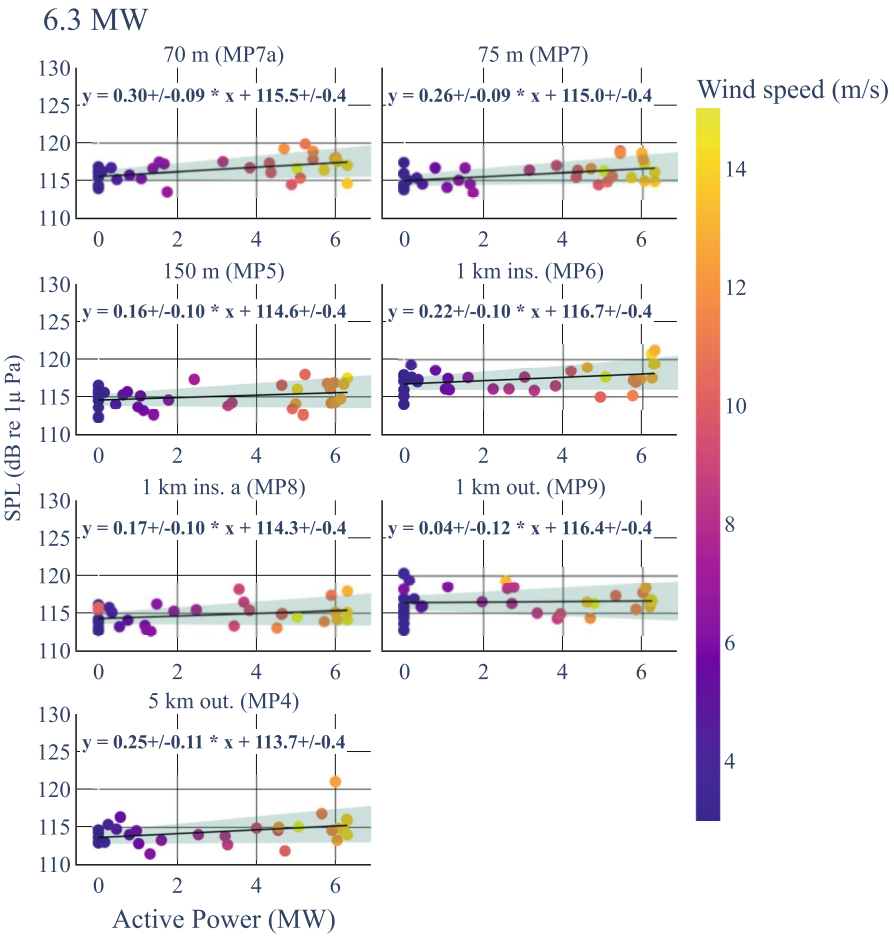

**Fig. 3** GOW01 and GOW02: Daily averaged SPL with respect to power production at the nearest turbine and wind speed (color). Regression coefficients denote the best estimate ± the corresponding standard deviation. Shaded area is 95% confidence intervals based on a two-sided Student *t*-test. Turbines are off at 0 MW, and there is no significant difference in slopes across measurement positions

## Underwater Noise Versus Turbine Activity

The relation between underwater noise and turbine activity is examined by using power production data as a proxy of turbine activity. This metric is directly proportional to the blades' revolution per minute (RPM) and therefore an indicator of the vibrational motion and general activity within the nacelle. In the analysis, 10-min time series of mean active power is converted to daily averages to facilitate a comparison with the daily averaged SPLs. For each hydrophone, the SPL data is

compared with the nearest turbine's power production data. This is because there can be minor differences in the power production data between turbines due to site-specific conditions (e.g., wakes), maintenance, or curtailment requirements. Besides the daily averaged power production data, the daily averaged wind speed measurements recorded at the nacelle are also utilized in the analysis (10 min means converted to daily averages). This level of detailed information enables an examination of how the underwater noise levels change with both turbine activity and naturally caused phenomena (e.g., wind variations).

Theoretically, there exists a log dependency between the displacement velocity (turbine activity) in the structure and underwater SPL. This can be concluded as there exists a log dependence between acoustic pressure in water and SPL. From assuming a linear mechanical system, the displacement velocity in the structure (vibrations) is directly proportional to the RPM (turbine activity). In water, the propagation is in the far field through plane waves where sound pressure is directly proportional to particle velocity. The law of continuity applies for the normal pressure and displacement as the boundary conditions at the pile-water interface. Thus, the particle velocity in water is directly proportional to the displacement velocity in the structure, which implies that the displacement velocity in the structure is directly proportional to acoustic pressure in water. As there is a log dependency between acoustic pressure and SPL, then there also exists a log dependency between the displacement velocity (turbine activity) in the structure and underwater SPL.

The relations between SPL, active power, and wind speed are first examined in Fig. 3 (6.3 MW) and Fig. 4 (8.3 MW). For all measurement positions, it is observed that there is no logarithmic relation between turbine activity and SPL which would be expected. For Gode Wind 1 and 2, some positions exhibit a minor linear SPL increase with power production and wind speed, whereas no relation is evident for Borkum Riffgrund 2. The relations and their significance are first quantified by estimating the linear least-square regression coefficients, their standard deviations, and the corresponding 95% confidence intervals (CI; estimated through a double-sided Student *t*-test).

By comparing the regression coefficients at different positions relative to the turbine and wind farm, it is evident that there is no significant difference in slope (dB/MW) with distance. This is further illustrated in Fig. 5 where the significance of difference in estimated slopes is tested using the 5-km control measurements. This comparison shows that the slopes are not statistically different. Thus, the minor change in elevated broadband SPL values for Gode Wind 1 and 2 must be a wind contribution rather than an influence from turbine activity as a similar relation exists at distances of 5 km away from the wind farm.

The dual influence from the co-varying turbine activity and wind speed on the underwater noise levels is a testimony to the challenges in disentangling the contribution of two statistically dependent variables. Such an effort is therefore only possible if one has multiple hydrophones recording simultaneously in different distances to the turbine.

For Borkum Riffgrund 2 (8.3 MW), there is no impact on daily averaged SPL from neither power production nor wind speed as shown in Fig. 4. This contrasts

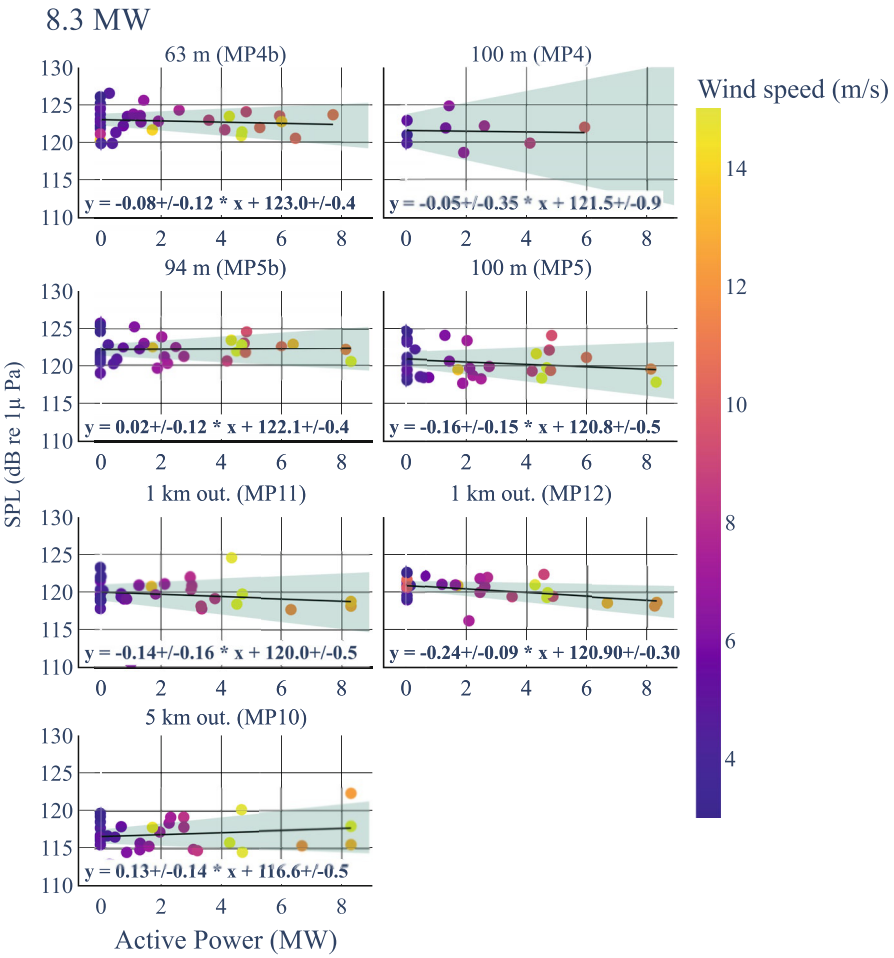

**Fig. 4** BKR02: Daily averaged SPL with respect to power production at the nearest turbine and wind speed (color). Regression coefficients denote the best estimate ± the corresponding standard deviation. Shaded area is 95% confidence intervals based on a two-sided Student *t*-test. Turbines are off at 0 MW, and there is no significant difference in slopes across measurement positions

with the smaller 6.3 MW turbines at Gode Wind where a minor wind dependence might exist (slope is significantly different from 0). The Borkum data were sampled in the Summer of 2021 which generally was a period characterized by low winds. This is also noticeable in the data as a slight non-uniform distribution of SPL data points for different MW. Regardless, it is observed that the variation in SPL during turbine standstill greatly exceeds any potential for turbine-inflicted SPL increases at its maximum power production capacity (8.3 MW). Thus, the great variation in SPL at turbine standstill must indicate that there is some other process that causes the signal to change in low wind conditions (either natural or anthropogenic). Other

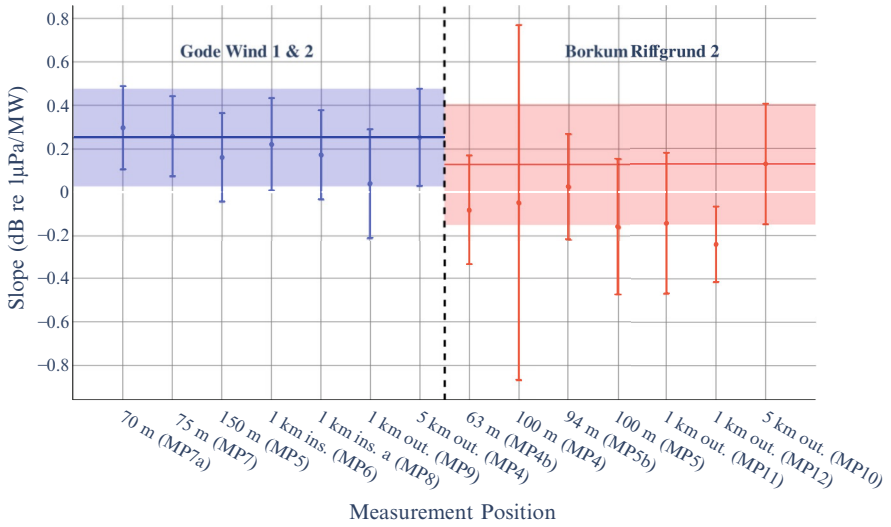

**Fig. 5** Slope (dB/MW) at different positions relative to the turbine and wind farm. Error bars are the 95% CI, while the horizontally oriented bars represent the reference measurements 5 km outside the wind farm with its 95% CI. Left part of the figure is Gode Wind 1 and 2, and the right part of the figure is for Borkum Riffgrund 2

anthropogenic sources could be vessel traffic not identified and removed in the pre-processing (either recreational or transportation), whereas natural influences could be changes in water currents and heavy precipitation which don't average out in daily means.

Moreover, when comparing the average broadband SPL across sites, the values are up to 5 dB greater at Borkum Riffgrund 2 than at Gode Wind despite no turbine-activity dependence. This indicates that there are general differences in ambient noise levels across sites. It can generally be noted that the ambient noise levels are higher across the German Bight than many previously monitored sites (e.g., those presented in Tougaard et al. (2020)). Thus, part of the missing relation between SPL and power production is likely a direct consequence of this area's high ambient noise levels. With that said, there are observed neither single nor cumulating effects from interfering wind turbines on the ambient noise levels.

Even though the analysis shows no link between turbine activity and SPL, it is still clear that the average noise levels throughout the measurement period are lower further away from the turbines. For instance, BKR02 MP9, MP10, and MP11 have lower noise levels than those inside the wind farm. The three measurement positions are located, respectively, 1 and 5 km east of the wind farm. Thus, the reduced noise levels might be a consequence of the hydrophones being located further away from the nearby vessel traffic route (German Bight, Western Approach).

Moreover, both monopile and suction-bucket jacket foundations are examined in the chapter. Most of the foundations are monopiles, but there are recordings for suction-bucket jackets at BKR02 MP4, MP4a. However, the results show that there

are no noticeable differences on the broadband SPL between the two foundation types. This is evident as there are no differences observed neither in the power spectral densities (Fig. 2) nor on the dependence from turbine activity (Fig. 4).

## Comparison Between Data and Model

This section compares the underwater noise measurements with the model predictions of Tougaard et al. (2020). Their model is currently the most comprehensive published study and therefore the best publicly available knowledge and starting point when wanting to predict the underwater noise from future operating wind farms. As noted by Tougaard et al. (2020), this empirical equation has not been tested against independent measurements to validate its predictive power (e.g., cross-validation tests). Thus, the motivation for this chapter is to test the model to benchmark its predictive capabilities as their model primarily was based on data from smaller turbines.

This study only uses Gode Wind in the comparison as the broadband SPL signal had a minor dependence on the wind speed (albeit no dependence on turbine activity). Borkum Riffgrund 2 is deemed unsuitable for this analysis as it is a pure ambient noise signal. The recorded noise levels can therefore not be a representative for an 8.3 MW turbine.

In the model, the Tougaard et al. (2020) equation is used:

$$\mathrm{SPL}_{\mathrm{predictor}} = 109\ \mathrm{dB} - 23.7 \cdot \log_{10}\frac{\mathrm{distance}}{100\ \mathrm{m}} + 18.5 \cdot \log_{10}\frac{\mathrm{wind\ speed}}{10\,\frac{\mathrm{m}}{\mathrm{s}}} + 13.6 \cdot \log_{10}\frac{\mathrm{WTG\ size}}{1\ \mathrm{MW}} \quad (1)$$

For this case, the maximum scenario is analyzed where wind speed is set to 13 m/s, produced power set to 6.3 MW, and the distance as a variable parameter respective to the source. Firstly, all turbines within Gode Wind 1 and 2 (~580 MW) are positioned on a uniform grid based on their coordinates. Secondly, the noise contribution from all 97 sources is calculated based on Eq. 1 for each grid cell. Here the different sources are added together as:

$$\mathrm{SPL}_{\mathrm{sum}} = 10 \cdot \log_{10} \sum_{i}^{N} 10^{\frac{\mathrm{SPL}_{\mathrm{predictor_i}}}{10}} \quad (2)$$

The model prediction is plotted in Fig. 6, and the comparison with the corresponding noise recordings is presented in Table 3. For the measured SPL, only the noise data for the same wind speeds and active powers are used to ensure compatibility with the model estimates. For this, the linear regression coefficients presented in Fig. 3 are used as a representative of the SPL distribution (data-based SPL).

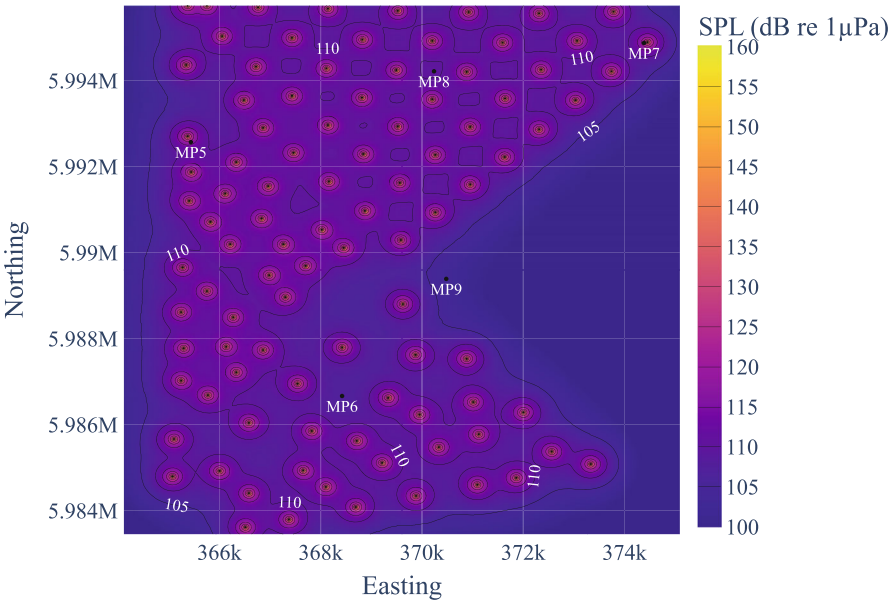

**Fig. 6** Modeled SPL for a ~580 MW OWF based on Tougaard et al. (2020) (assuming 6.3 MW turbines and wind speed of 13 m/s). The *x*-*y* axis contains Easting and Northing values (*m*) with respect to origin

**Table 3** Comparison between model-based and data-based estimates (mean ± 1 standard deviation)

| | Distance | Model-based SPL | Data-based SPL | Model overestimation |
|---|---|---|---|---|
| MP7a | 70 m | 125.4 dB | 117.3 ± 0.9 dB | ~8 dB |
| MP7 | 75 m | 124.7 dB | 116.5 ± 0.9 dB | ~8 dB |
| MP5 | 150 m | 117.9 dB | 115.6 ± 1.0 dB | ~2 dB |

The data-based estimates are calculated from the linear regression coefficients between power and SPL. Only the nearest positions are presented as the model estimates decreases with distance

From Table 3 it is evident that the Tougaard et al. (2020) model overestimates the noise by ~8 dB at the nearest positions of ~70 m. The data-based and model-based results converge as the distance from the turbines increases. This is a result of the model yielding decreasing noise levels with distance due to its transmission loss, whereas the data-based estimates almost remain constant within the recorded distances. Hence, no comparisons were made with the recordings further away as there was no turbine effect on the broadband SPL.

These results can therefore provide a contribution to benchmarking of underwater noise predictions for future studies to avoid under- or overestimations of noise levels. While the results don't show what SPL to expect from these turbine types and sizes, they do provide an upper limit to what the noise levels can be in a certain distance.

## Conclusion

This chapter found no changes to the ambient broadband SPL from neither 6.3 nor 8.3 MW operating wind turbines. While this partly was attributed to the high ambient noise levels of the German Bight, it remained evident that natural effects (e.g., wind speed and tidal changes) were the dominating forces behind changes to the ambient noise levels. Nearby crossing vessels caused short-term elevated noise levels, which were filtered out in the analysis. Furthermore, the results showed that the recorded noise levels were up to 8 dB lower in distances up to ~70 m to the turbines than those predicted through the Tougaard et al. (2020) model. This suggests that there are challenges associated with extrapolating aggregated results from smaller turbines to the realm of new, larger, and technologically different turbines. Such findings have implications to efforts set to predict the noise impact of future offshore wind farms, as broadband SPL does not scale with increasingly larger turbines.

**Acknowledgments** The authors would like to extend their special thanks to the German Bundesamt für Seeschifffahrt und Hydrographie (BSH) for making this study possible.

**Abstract**

The Vancouver-Fraser Port Authority-led Enhanced Cetacean Habitat and Observation (ECHO) Program has managed underwater listening stations (ULSs) on the approach to the Port of Vancouver since 2015, measuring the sound levels generated by thousands of vessels. Since 2017, these systems have measured at or above a 128 kHz sampling rate.

Anomalously high sound levels were observed in 212 of the measured ships signatures at frequencies typically associated with navigational, fisheries, and scientific sonars. Sixty-one of these detections were found to originate from a novel continuous sound source in the 20–30 kHz frequency range. During a separate underwater noise monitoring program, a similar high-frequency continuous sound source was identified proximate to a berthed vessel. The vessel engineer identified it as an ultrasonic antifouling system. The sounds from these systems are detectable at 4–6 km from the vessels in deep water.

The measurements indicate that echolocation by lower-frequency delphinids, such as killer whales, may be completely masked when a ship is 3 km away and that porpoises flee from the source at distances of 1.5 km. In shallow waters, a porpoise 70 m from the source is predicted to experience temporary threshold shift (TTS) after 1–2 s, and permanent threshold shift (PTS) after 200 s. It is recommended that use of these systems be restricted or prohibited when there is a possibility of exposing marine mammals to potentially harmful sound levels.

## Introduction

It is well known that the underwater radiated noise (URN) from ocean-going vessels is highly variable and depends on factors such as vessel length, type, and speed as well as draft, trim, age, and propulsion system (Wales and Heitmeyer 2002; Simard et al. 2016). Long-term measurements of opportunity are an important means of characterizing the variability of vessel URN. With that in mind, the Vancouver-Fraser Port Authority (VFPA) worked with Ocean Networks Canada (ONC) and JASCO Applied Sciences to use the East Node of the VENUS underwater observatory in the Strait of Georgia as platform for an underwater listening station (ULS). The initiative was part of VFPA's Enhancing Cetacean Habitat and Observation (ECHO) Program. Ships entering or leaving the port were encouraged to participate in the study by traveling past the ULS (Fig. 1). Their automatic identification system (AIS) messages triggered an automated analysis of the vessel's URN. The Strait of Georgia ULS program operated from September 2015 to April 2018 and yielded a total of 7693 vessel URN measurements.

Based on the success of the Strait of Georgia ULS, Transport Canada commissioned JASCO to establish a ULS at Boundary Pass, which is directly on the traffic route in and out of Vancouver (Fig. 1). From August 2018 to May 2020, autonomous acoustic recorders were employed until the cabled ULS hardware was installed at Saturna Island. As an example of the value of large data sets of vessel sound levels, analysis of the combined data from measurements in Strait of Georgia and Boundary Pass and measurements made by the Joint Monitoring Programme for Ambient

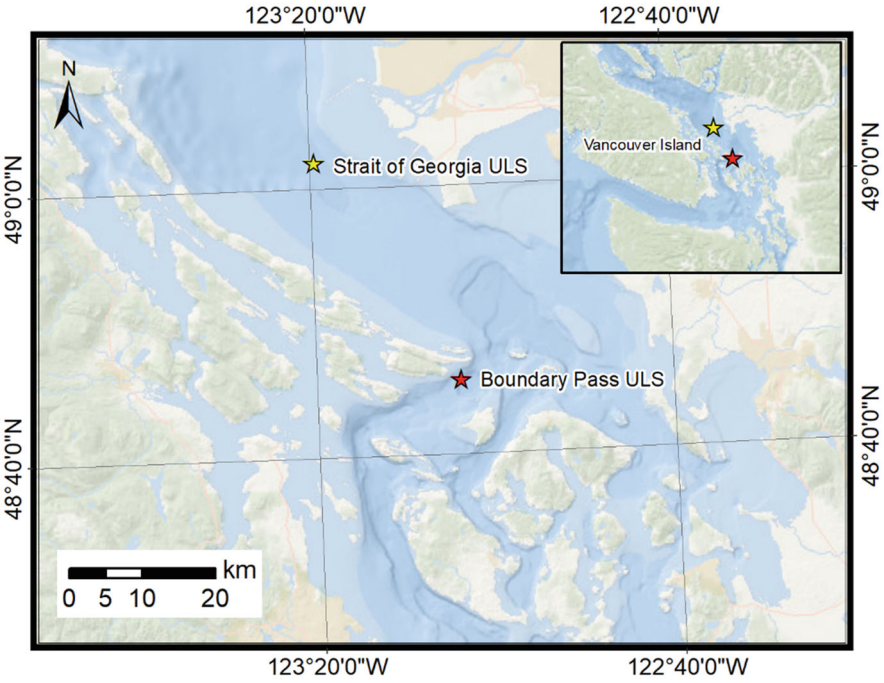

**Fig. 1** Location of the measurement zone for the Strait of Georgia and Boundary Pass Underwater Listening Stations (ULSs)

Noise North Sea (JOMOPANS) resulted in a robust new model for vessel source levels that depends on length, speed, and vessel class (MacGillivray and de Jong 2021). The new model stipulates that the vessel spectra have a 6 dB standard deviation due to the variability in vessel URNs that were measured. The availability of the Boundary Pass ULS has facilitated other URN research, such as evaluating the effects of slowing down vessels (JASCO Applied Sciences and SMRU Consulting 2020), developing methods for estimating the density of marine mammals (Urazghildiiev et al. 2020), and measuring changes in vessel source levels after refitting their propulsion systems.

The sampling rate during the Strait of Georgia Program and early phases of the Boundary Pass project was 128 kHz so that frequencies up to 64 kHz are available for analysis in the data (the Boundary Pass sample rate was increased to 512 kHz when the ULS was deployed in 2020). Active acoustic sources (sonars) such as navigational, fisheries, and scientific echosounders emit sound below 64 kHz and thus should be present in the data if they were in use. An exploratory analysis of the data sets was performed to evaluate the prevalence of sonars in the Strait of Georgia and Boundary Pass data available up to November 2019. Of 15,983 vessel measurements recorded by that time, sonars were detected in 212 measurements. Of those, 110 were single-frequency navigational echosounders and 41 were multifrequency

sonars (likely fisheries and scientific echosounders). The remaining 61 detections were a novel continuous sound source in the 20–30 kHz frequency range. The source was emitted by 14 unique vessels in three vessel classes: 2 tugboats, 2 bulkers, and 10 passenger ships. The received sound levels reached a maximum twice during the passage of larger vessels, suggesting distribution along the vessel hull. The source was detectable at 4–6 km from the vessels, which suggests that the source did not have the downward beam pattern of a typical echosounder.

The ULS systems in fixed locations have proven to be extremely valuable for answering a multitude of research questions; however, in many cases, the measurements must be made at the locations of the sound sources. In 2019, SMRU Consulting conducted an underwater noise monitoring study for VFPA to measure the sounds levels proximate to berthed ships while they were on or off shore power. They also measured the sound in a confined area (Burrard Inlet) from the harbor operations including a Seabus and regular seaplane flights (Angadi et al. 2020). The same high-frequency continuous sound source centered at 23 kHz detected in the ULS data was also identified proximate to a berthed vessel when it was on shore power or its own power. The vessel engineer identified the sound source as an ultrasonic antifouling system. These relatively new devices place ultrasonic transducers along the hull or in onboard water piping and storage equipment to deter biofouling and the transfer of invasive species. These systems are available for full-size commercial vessels and pleasure craft.

The ultrasonic antifouling systems consist of a controller and one or more transducers that are secured to the inside of a ship's hull plates or the outside of pipes and fittings that require protection against the growth of algae, macroalgae, and invertebrates such as barnacles. Accumulations of biofouling on a vessel hull require vessels to consume more fuel and emit more greenhouse gases to achieve the same speed through water. The intention of developing the ultrasonic cleaning systems was to reduce leachates from toxic paints that are an alternate method of reducing biofouling (Legg et al. 2015; Habibi et al. 2016). Developing commercial ultrasonic antifouling systems is the result of research into methods of controlling harmful cyanobacterial blooms (blue-green algae (BGA)). Lee et al. (2001) found that exposure of BGA to ultrasound for 1–5 min caused gas vacuoles inside the cells to collapse, leading to BGA settling to the bottom. This initial work also suggested that the ultrasound affected the ability of the cells to photosynthesize, a result that was subsequently validated (e.g., Zhang et al. 2006). Further work found that ultrasound also affected the ability of barnacles to settle on surfaces, likely by killing the cyprids as a result of cavitating their internal structures (Guo et al. 2011). The best results occurred using an ultrasound frequency of 23 kHz at a pressure of 20 kPa (200 dB re 1 $\mu Pa^2$). These systems have also been shown to cause avoidance in Cuvier's beaked whales (Trickey et al. 2022).

Promotional materials from manufacturers of commercial ultrasonic systems that are now available suggest that the transducers protect a radius of 6–10 m. Each transducer consumes approximately 20 W of electrical power, which, if the transducer were perfectly efficient, would result in an acoustic source level of approximately 187 dB re 1 $\mu Pa^2m^2$. The electrical-to-acoustic conversion efficiency of the

transducer, coupling to the vessel hull, hull material, and number of transducers along the hull all affect the sound levels coupled into the water. The systems are available for commercial-size vessels; however, the primary market for the systems appears to be pleasure craft and yachts.

No trade-off analysis of whether the impacts of sound from these systems may have a greater impact on the environment than the leachates has been performed. Legg et al. (2015) identified effects of noise as a possible environmental effect; however, no conclusions were drawn. The goal of this chapter is to present measurements of sound levels emitted from ultrasonic antifouling equipment that were measured in the real world that can serve as an input to an impact trade-off study. The measurements have been interpreted based on our current knowledge of the thresholds at which sound affects marine mammals. This chapter (1) describes how the measurements were made at the ULSs and Burrard Inlet; (2) describes the source and its radiated sound levels; and (3) provides estimates of the possible effects of these sources on marine mammals in terms of hearing threshold shifts and masking potential.

## Methods

### Measurements

The acoustic data analyzed in this study were collected by various equipment. From September 2015 to April 2018, the Strait of Georgia ULS data were collected by an AMAR G3 in streaming mode (JASCO Applied Sciences, Dartmouth, Canada), connected to M36-V35-100 hydrophones(−164 dBV/μPa nominal sensitivity level; GeoSpectrum Technologies Inc., Dartmouth, Canada). The system was calibrated before deployment with a G.R.A.S. 42 AA pistonphone calibrator (Holte, Demark). During its recording period, system sensitivity was checked daily using an icTalk source (OceanSonics, Truro, Canada). Data from December 2018 to October 2019 were collected using autonomous AMAR G4 recorders suspended above the seabed. These systems were also fit with GeoSpectrum M36-V35–100 hydrophones that were calibrated at deployment and retrieval using the G.R.A.S. 42 AA calibrators. All AMAR data were sampled at 128 kHz. The positions of the hydrophones were determined to within 1 m accuracy by surface localization of the acoustic releases on the moorings. The positions of the ships measured by the AMARs were determined using their AIS tracks. The Strait of Georgia ULS was at a 170 m water depth, and the AMARs at the Boundary Pass location were at 197 m water depth.

The Burrard Inlet data were collected with two Coastal Acoustic Buoys (SMRU Consulting, Friday Harbor, USA). These buoys had two Reson 4014 hydrophones (Teledyne Reson, Slangerup, Denmark), one at mid-water column (10 m) and one just above the seabed (20 m). The hydrophones were sampled at 250 kHz and were calibrated before deployment and after retrieval using a G.R.A.S. 42 AA calibrator. The first Coastal Acoustic Buoy was 73 m from the berthed vessel, and the second was 237 m from it.

## Data Analysis

### Measured Sound Levels

The basic analysis applied to all the data followed the Welch (1967) method: time series audio data were converted to power spectral densities using the Fast Fourier Transform (FFT) with a 50% overlap and a Hann window. A frequency-dependent calibration curve for the hydrophone and recorder was applied to the spectra. The spectra were then summed to generate decidecade sound pressure levels as needed for the analysis (Heaney et al. 2017).

### ULS Vessel URN

The ULS hydrophone data were processed using ShipSound (JASCO Applied Sciences, Victoria, BC) to obtain the URN measurements for each vessel passage. ShipSound tracks vessels broadcasting on AIS as they transit the 1 × 4 km measurement funnel at the measurement sites (Fig. 1). When the transits are complete, the URN measurements are automatically performed. To complete the measurement record, the AIS data are employed to compute the speed over ground of the vessel and identify other nearby vessels. Online web services are queried to obtain the wind and current speeds which are used to compute the speed through water of the vessel.

Source level (SL) was calculated by adding the propagation loss ($N_p$) to the received sound pressure level ($L_p$) at the hydrophones (Eq. 1).

$$L_{\text{URN}} = L_p + N_p \text{ dB} \tag{1}$$

At the ULS, where measurements are collected at distances less than 1 km, propagation loss at the 20–30 kHz operating frequency of the ultrasonic antifouling systems is well approximated by spherical spreading plus seawater absorption:

$$N_p = 20 \log_{10} r + \alpha r \text{ dB} \tag{2}$$

where $r$ is the slant range from the vessel to the hydrophone and $\alpha$ is the frequency dependent absorption of sound by seawater computed using the formula of Ainslie and McColm (1998).

To obtain the URN, analysis was performed for all measurements within a data window defined by a ±30° azimuth angle centered from the closest point of approach (CPA) to the hydrophone. For acoustic data within the measurement window, ShipSound analyzes acoustic data in decidecade frequency bands from 10 to 63,100 Hz. The data are processed using 1-s FFTs with 50% overlap and a power-normalized Hann window which generates the power spectral density (PSD) levels versus time. Since the AIS transmitter/receiver is not at the same location as the vessel's acoustic source, the cepstrogram methods described in Hannay et al. (2016) were employed to find the acoustic CPA. A human analyst then verified, and adjusted if necessary, the automated CPA time. The broadband and decidecade SL values were computed in decibels by taking the linear average of the SL from all 1-second sample locations within the ±30° data window. Background sound

pressure levels (NL) are computed by averaging measured sound levels in the 1-minute intervals just before and just after the vessel was within the measurement. If the difference between the measured SPL and NL was between 3 and 10 dB, the SPL was adjusted in accordance with the ISO 17208-1 standard. When the difference was less than 3 dB, data from those decidecade band levels were not included in the final source level results.

The acoustic CPA identified above was used by ShipSound to analyze the full ship signature, including the ultrasonic antifouling system. Since the ultrasonic antifouling sounds are distributed along the length of the vessel and the source levels computed here assumed a point-source configuration, they are only an approximation of the true source level. However, most results presented are based directly on the SPL data and do not rely on the source level estimates.

### Automated Identification of ULS Vessel Passages Containing Sonar

The ShipSound data were exported from the database to a CSV file with one row per vessel passage. The data were searched to find any passages where any of the decidecade band received levels in the sonar band (20 kHz and higher) were greater than 100 dB, and the level in any one of the bands was at least 3 dB greater than the level in the 10 kHz band. All passages satisfying the criteria were then manually reviewed, and all were found to contain sonar (Precision of 1.0). The recall of this method was not evaluated.

## Results

Figure 2 shows a 30-minute time series and spectrogram during the passage of a vessel with the ultrasonic antifouling system turned on. The AIS data indicated that the vessel was traveling at 14 knots. The primary frequency of the source at 23 kHz was visible about 6 km before CPA and 4 km after CPA, with the first harmonic at 46 kHz also visible near the CPA time. Figure 3 is a 1-second zoom in on the data near CPA, which shows that there is no distinctive structure to the sound; aural listening to the data confirms that it is a slightly raspy tone (when slowed down by a factor of 10 to be audible). The spectrograms of Coastal Acoustic Buoy data from Burrard Inlet shown in Fig. 4 are from the same date, likely the same vessel shown in Figs. 2 and 3. These data were sampled at 250 kHz, and four harmonics are clearly visible. The received SPL from the ultrasonic antifouling system at the Coastal Acoustic Buoy was 156 dB re 1 $\mu Pa^2 \pm 2$ dB throughout the 4-hour measurement. Figure 5 shows the source levels measured for all 61 of the detections of the ultrasonic source.

## Comparison of Sound Levels to Effects Thresholds

To examine the possibility of marine mammals experiencing hearing threshold shifts or disturbance from the passage of an ultrasonic antifouling system, the hearing

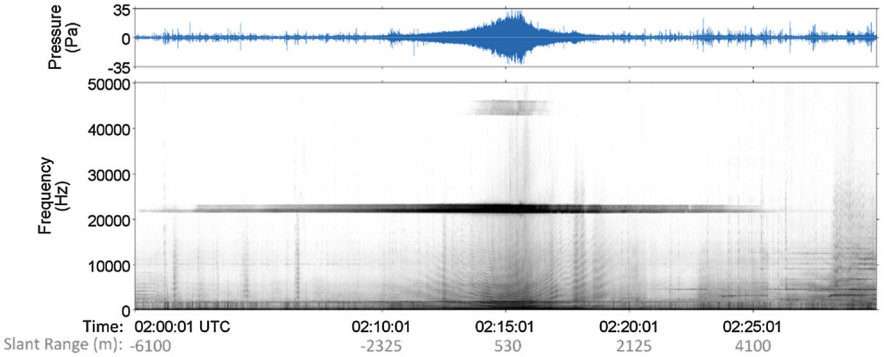

**Fig. 2** Thirty-minute time-series and spectrogram during the passage of a vessel with the ultrasonic system active at the Boundary Pass recorder at a speed of 14 knots at a minimum radial distance of 331 m. The system was detectable for 25 min, 15 min before the vessel closest point of approach (CPA) and 10 min after (4–6 km). These data were high-pass filtered at 100 Hz to remove noise from the time series and enhance the presentation of the vessel passage. Fast-Fourier transform (FFT) duration: 0.25 s, advance 0.125 s, Hann window. The vessel was at a slant range of 331 m at CPA

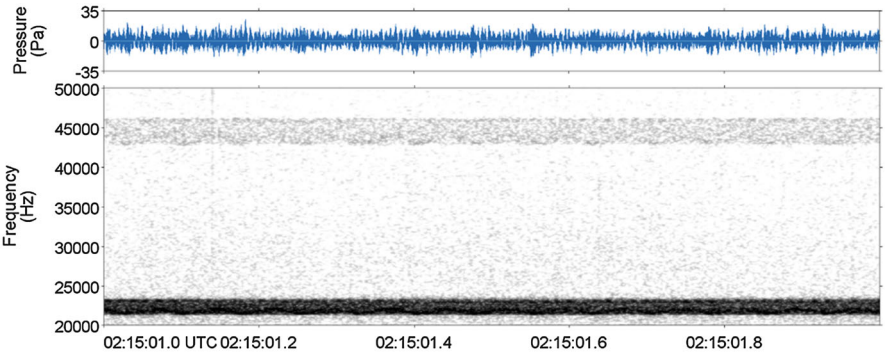

**Fig. 3** One second of data near the closes point of approach (CPA) shown in Fig. 2. Fast-Fourier transform (FFT) duration: 0.01 s, advance 0.001 s, Hann window

weighted SPL and sound exposure levels are shown in Fig. 6 for the same vessel when it passed within 114 m horizontal distance of the ULS (227 m slant range, this passage occurred on a different day than the data in Fig. 2). If we assume a stationary marine mammal, none of the marine mammal groups would have experienced temporary or permanent threshold shift at the location of the ULS sensors (see Southall et al. 2019 for tables of the SEL where temporary or permanent threshold shift begin to occur). It has been shown recently that harbor porpoises have a fleeing reaction when auditory frequency weighted sound pressure levels are 103 dB re 1 μPa$^2$ or higher (DEA 2022). From the current measurements at the ULS, porpoises will flee from vessels with this source at distance less than or equal to 1500 m.

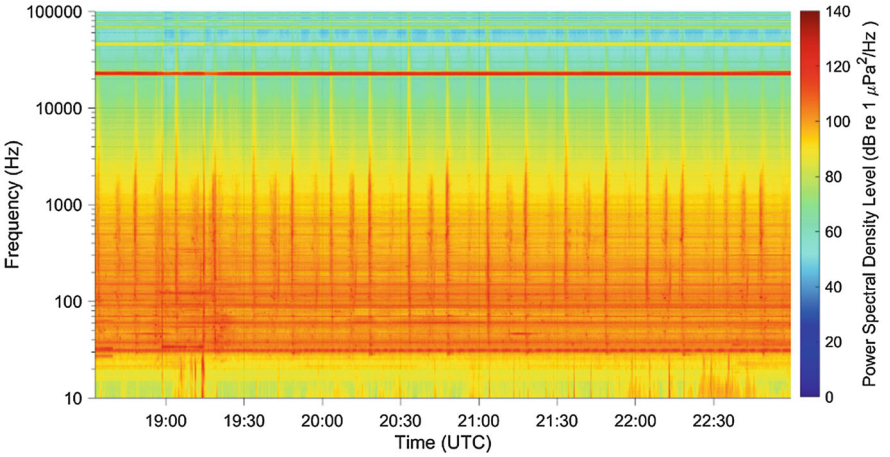

**Fig. 4** Spectrogram from the Coastal Acoustic Buoy measurements at Burrard Inlet measured 73 m from the same vessel as in Figs. 2 and 3. The increases power spectral density levels above 100 Hz occurring approximately every 15 min are from the departure or arrival of Seabuses that passed within 150 m of the buoy

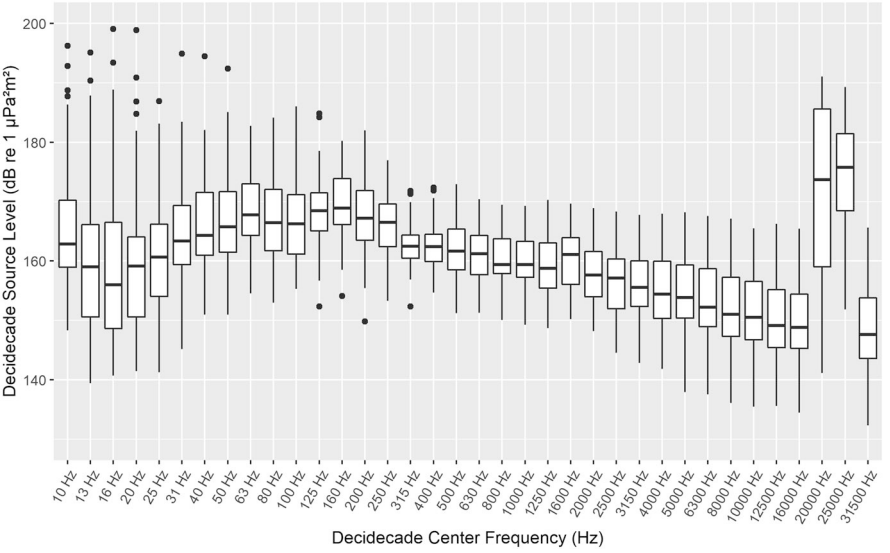

**Fig. 5** Box-and-whisker plot of source levels by decidecade band of the vessels with the ultrasonic antifouling system from all 61 measurements from the ULS systems (September 2015 to October 2019). For each decidecade, the dark horizontal lines are the median values; the top and bottom of the boxes shown the interquartile range; the lines shown the values above and below the quartiles, with dots to indicate outliers. The ultrasonic antifouling systems are in the 20 and 25 kHz decidecade bands

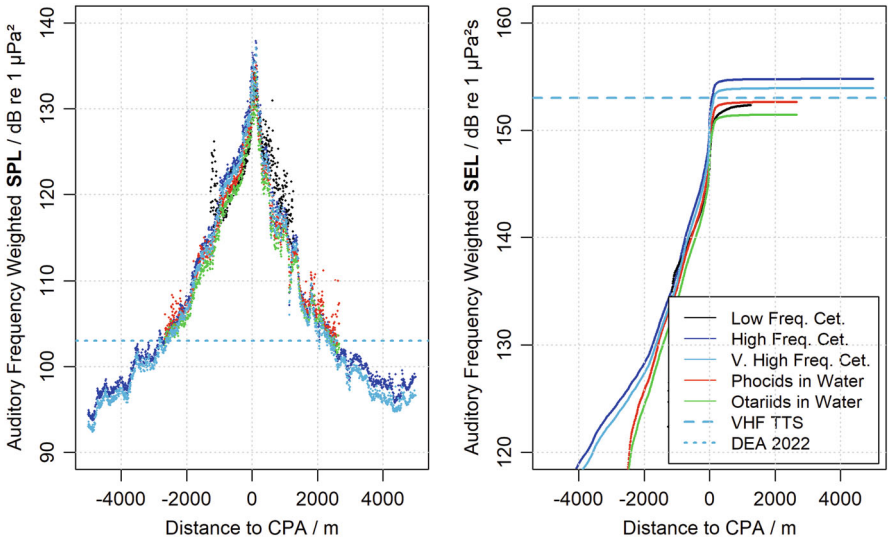

**Fig. 6** Sound levels measured during the passage of the same vessel as the previous figures at a radial closest point of approach (CPA) distance of 114 m. The slant distance between the hydrophone and vessel at CPA was 227 m. (Left) Auditory frequency weighted sound pressure levels (SPL) and (right) cumulative auditory frequency weighted sound exposure levels (SEL). The auditory frequency weightings are defined in Southall et al. (2019); the acronyms are: *LF* Low-Frequency cetaceans (baleen whales), *HF* High-Frequency cetaceans (most dolphins), *VHF* Very High-Frequency cetaceans (porpoises), *PW* Phocid seals in Water, and *OW* Otariid seals in Water

A more general estimate of effects may be found by using the source levels shown in Fig. 5 to simulate the passage of a vessel at different closest point of approach distances and at different speeds (assuming the ultrasonic source level is not correlated with vessel speed). The results shown in Fig. 7 show that at slower speeds there is a greater accumulation of SEL and that the TTS threshold is exceeded at longer distances, up to 450 m for a vessel at 4 m/s, but only 225 m at 10 m/s. The distance to the behavioral disturbance threshold is ~3 km. Note that this analysis assumes the ultrasonic source is a point source since the spatial distribution of sensors along the hull is uncertain. While this is undoubtedly a conservative assumption, the TTS estimates beyond ~100 m range are nonetheless expected to be reasonable given that the results are consistent with the actual measurements shown in Fig. 6.

Due to the measurement occurring in deep water (197 m), the received levels at the ULS were substantially lower than those measured at Burrard Inlet in 20 m water depth. The levels measured in shallow water were ~156 dB re 1 µPa$^2$ (see Fig. 8). The measurements indicate that very high-frequency cetaceans (porpoise) could experience temporary threshold shifts 73 m from the berthed vessel in 1–2 s and permanent hearing threshold shifts in ~200 s. High-frequency cetaceans, such as Southern Resident killer whales, would experience TTS in ~100 s and PTS in 10,000 s (approximately 3 h).

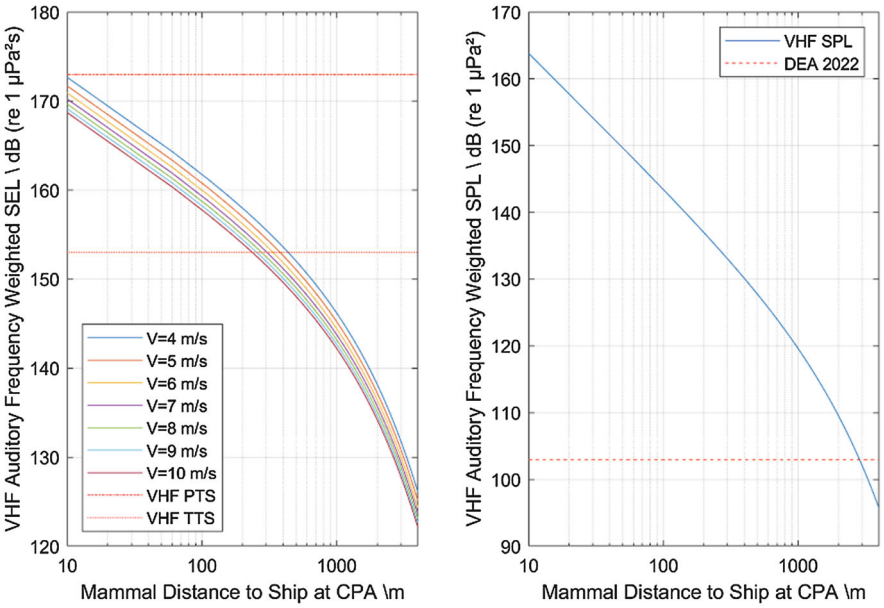

**Fig. 7** Estimates of the (left) very high-frequency (VHF) auditory frequency weighted SEL and (right) SPL using the mean source level from Fig. 5 (182.9 dB re 1 µPa$^2$ in the 20 kHz decidecade band and 180.4 9 dB re 1 µPa$^2$ in the 20 kHz decidecade band, respectively). There is greater accumulation of sound at slower vessels speeds than at higher ones. The Southall et al. (2019) thresholds for PTS and TTS from nonimpulsive sound sources are shown on the left, and the DEA (2022) behavioral disturbance threshold of 103 dB re 1 µPa$^2$ is included on the right

## Masking Effects

It is also possible to estimate auditory masking from the source using the concept of available echolocation range (AER). AER is similar to the concept of listening range reduction (LRR) (Pine et al. 2020), except that the reference value is inverted such that 100% AER means the full listening range is available, which is equivalent to an LRR of 0%. AER is a measure of the percent of the distance from a mammal that is obscured by a sound source compared to what they would normally be able to hear. AER is defined in Eq. 3, where $NL_2$ is the SPL when the masking noise present, MR allows for $NL_2$ to be reduced by a masking release factor, $NL_1$ is the SPL without the masking present, and $N$ is the geometric spreading coefficient of acoustic propagation in the environment.

$$\mathrm{AER} = 100\% \times \left(10^{2\frac{\mathrm{NL}_2 - \mathrm{MR} - \mathrm{NL}_1}{N\ \mathrm{dB}}}\right) \tag{3}$$

The factor of 2 is required since the bidirectional available echolocation range was computed.

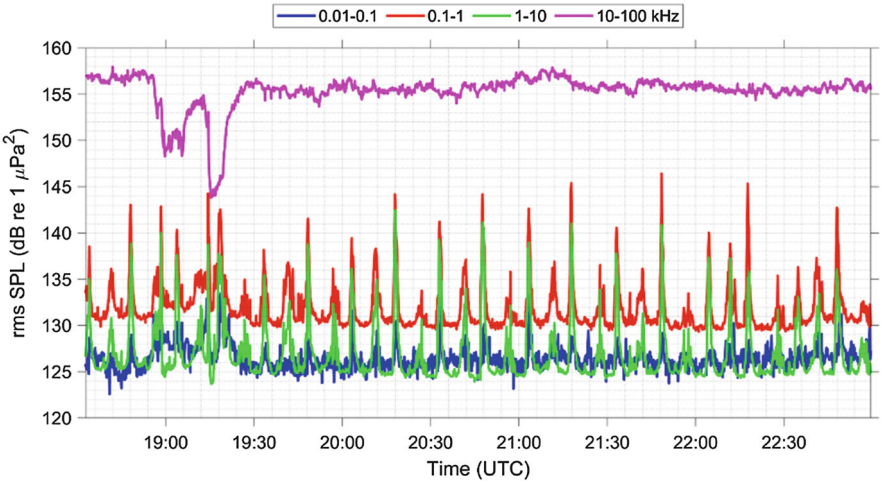

**Fig. 8** Band sound pressure levels (SPL) measured by the Coastal Acoustic Buoy at Burrard Inlet measured 73 m from the same vessel as in Figs. 2, 3, and 4. The reduction in SPL around 19:00 UTC is believed to have been caused by shadowing from passing vessels and/or maintenance activities. The increases in SPL occurring approximately every 15 min are from the departure or arrival of Seabuses that passed within 150 m of the buoy

The masking was analyzed for each decidecade band assuming that this is approximately equivalent to the critical bandwidth of mammalian hearing. The reference noise level, $NL_1$, is taken to be the tenth percentile of the sound pressure level in each decidecade band over a long period (days to months) that includes the period when the masking noise occurred. In cases where $NL_1$ is below the hearing threshold of an animal, the value is replaced by the hearing threshold. The value of $N$ should be representative of the geometric spreading losses in the environment at the frequencies of interest. A value of 20 was employed here. *MR* values of 0 and 10 dB were employed to represent the spatial release from masking that odontocetes can obtain through their directional hearing (Erbe et al. 2016). The value of 0 dB represents zero masking relief if the animal is echolocating toward the source, and 10 dB represents a general case when echolocating away from the source at 20 kHz (Erbe et al. 2016; Accomando et al. 2020).

For high-frequency mammals, such as the SRKW found on the approach to the Port of Vancouver, the peak frequencies of the ultrasonic antifouling source overlap with the peak frequencies of the SRKW echolocation clicks. Figure 7 shows the available listening range for high-frequency cetaceans for the vessel passage shown in Fig. 2. Without spatial release from masking, the AER is near zero when the source is within 4–5 km of the animal. When the animal is able to employ spatial release from masking, the available listening range is reduced to near 0 when the source is 2–3 km from the animal (Fig. 9).

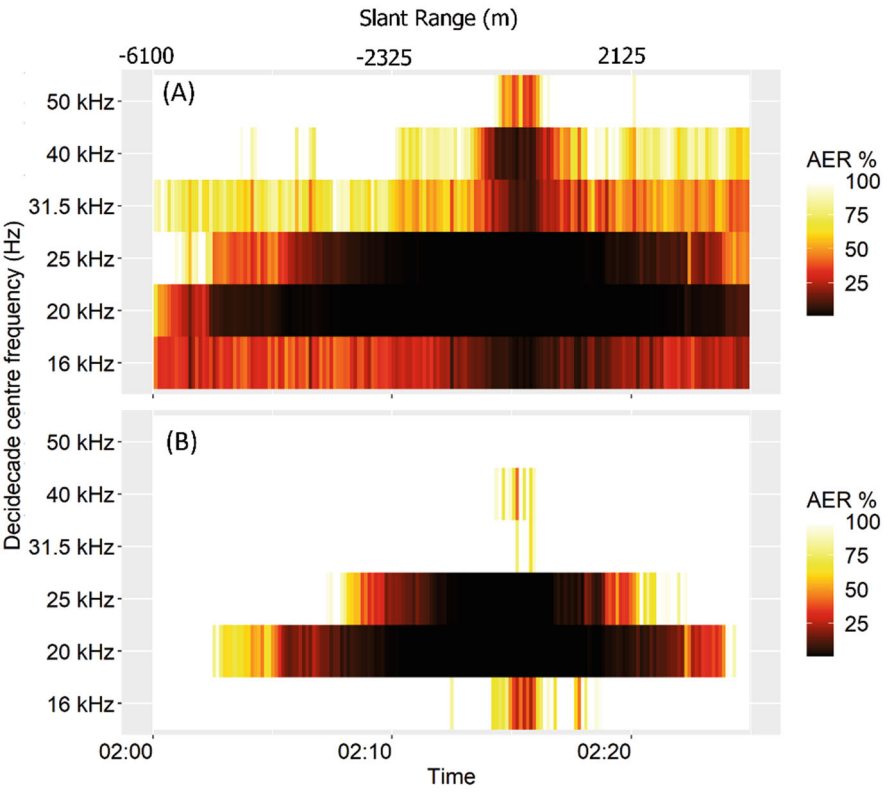

**Fig. 9** Available Echolocation Range (AER) assessment of the passage of the ultrasonic antifouling system for the decidecade bands of 16–50 kHz and the hearing sensitivity of high-frequency cetaceans. Here, a value of 100% is good and 0% indicates completely masked communications. (**a**) The case where an animal is echolocating toward the source, and (**b**) the case of 10 dB spatial release from masking

## Discussion

This chapter reports on two measurement programs that independently identified a novel ultrasonic source present in the areas around the Port of Vancouver. This source was identified as an ultrasonic antifouling system that prevents the build-up of algae, macroalgae, and sessile crustaceans on ships hulls, in pipes, in ballast tanks, etc. These systems work by killing the lower trophic level algae and crustaceans within a short distance (10 m) of the source (Lee et al. 2001; Zhang et al. 2006).

The source was detectable at distances of 4–6 km from the vessels. The analysis suggests that in deep water (200 m) the source will cause avoidance by very high-frequency mammals such as porpoises at a minimum distance of ~1.5 km, perhaps out to 3 km. These mammals could suffer hearing injury at very short distances in

deep water. Measurements were also made in shallow water (20 m) that trapped the sound and minimized attenuation. In these conditions, the measurements suggest permanent hearing injury would occur for very high-frequency cetaceans in less than 2 min if they were closer than 70 m to the source. If the source were turned on while a porpoise was within 25 m of the source, the permanent threshold shift would be even more rapid.

The results shown here are for the systems measured near the Port of Vancouver. The makes, models, number of transducers and electrical drive levels of the systems are unknown. Most of the systems recorded had the same characteristics as were shown here; however, one of them had the frequency-hopping behavior that was also detected in Trickey et al. (2022) To fully understand the risks to marine life posed by the ultrasonic systems, a comprehensive study of the levels as function of the system types, vessel types, and system configurations is required.

The ultrasonic antifouling sources were introduced as a means of keeping vessel hulls clean and preventing the transfer of invasive species. Biofouling of ships hulls increases drag on the vessel and can lead to an increase in fuel consumption (and greenhouse gas production) of up to 55% (Munk et al. 2009; GloFouling Partnerships 2021). Biofouled vessels (and ballast water) are often responsible for transporting invasive species, which provides an additional strong incentive for reducing biofouling. An alternate means of minimizing biofouling is the use of specialized paints that contain copper and zinc or other biocides. The longest acting versions of these paints are self-polishing, which means the flow of water over the hull releases the active biocides for 4–5 years, making the immediate region around the ship's hull toxic to algae and larval crustaceans. The most toxic compounds, such as tributyltin were banned decades ago, which has reduced their accumulation in higher order marine life such as porpoises (Law et al. 2012). There are other coatings that can also be applied that reduce the ability of organisms to adhere to a ship's hull; however, they are significantly more expensive than the biocide paints and are not in wide use. Similarly, a maintenance routine of proactive hull cleaning can help reduce biofouling but at the cost in labour and idle vessel time to perform the cleaning (Swain et al. 2022). A trade-off analysis, bringing in experts from different disciplines, is likely needed to determine which set of impacts is most acceptable: higher costs, acoustic impacts, toxic chemical pollutants, or green-house gas emissions and invasive species.

Following the presentation of the ultrasonic hull cleaner's sound levels (this chapter) and effects on Cuvier's beaked whales (Trickey et al. 2022), many researchers approached the authors to state that they had also encountered this source. In one instance, a researcher reported that they were no longer able to conduct tests near their university because the harbor was so affected by the ultrasonic source. Many others reported that the sources were available for sale at numerous booths at small craft boat shows and vendors had no understanding of how the systems worked or their possible side effects on marine life that is not attempting to attach to a boat's hull. The authors also became aware that the International Maritime Organization may soon endorse ultrasonic hull cleaning as a preferred "green" technology.

It appears there will be a rapid increase in the use of ultrasonic hull cleaners before the scientific community fully understands the hull cleaner's effects on marine mammals. Given the capacity for the ultrasonic systems to impact marine mammals at long distances (kilometers), this suggests that these systems may have greater impacts on marine mammals than the antifouling paints. It is recommended that their use in areas with sensitive or endangered species of marine mammals be restricted. Further study of the risk to marine life as a function of ultrasonic system configurations will be needed to inform the discussions between system developers, users, and international regulators.

**Acknowledgments** The authors would like to thank Roberto Racca, Michael Ainslie, David Hannay, Max Schuster, Federica Pace, David Zeddies, and Thomas Buechler for productive discussions that highlighted additional considerations for understanding the possible ranges of exposures the ultrasonic systems present to marine life. We thank Transport Canada for funding the underwater listening stations on Canada's west coast allowing for collection and analysis of these important data. Thanks to Karen Scanlon for assistance with editing the chapter, and Josh Dolman for help with Fig. 1.

**Abstract**

Impact pile driving is a transient anthropogenic underwater sound source that can potentially affect marine life. Mathematical modelling tools are essential for predicting sound levels before installing new offshore wind farms. Different modelling approaches are required for modelling the sound generation in proximity to the pile, the mitigation of the noise with the use of air-bubble curtains, and the sound propagation at a larger distance. In addition, the interface and coupling between the different modelling approaches should be carefully considered without losing important details. In this work, a multi-model approach for estimating pile-driving sound in a realistic environment is described. The short-range predictions (up to 750 m) provide detailed spectral and temporal output in various metrics in the water (acoustic pressure, particle velocity) and the seabed (stress and displacement vectors). For the long-range predictions beyond 750 m, only the acoustic pressure metric is calculated, including the range-dependent

Sound modelling · Impact · Propagation · Pile driving · Noise mitigation

## Introduction

Anthropogenic offshore activities have raised serious concerns about their impact on marine life in different ways depending on the spatial, temporal, and spectral pattern of sound. One of the main impulsive underwater sound sources of concern is offshore pile driving due to the increasing numbers of offshore wind farms. Furthermore, in the next decade, it is expected that the number of offshore wind farms under construction will accelerate in European countries to provide alternative energy sources. To preserve the marine ecosystem and maintain sustainable development, many countries define noise thresholds at a specific distance in various metrics. Therefore, an environmental impact assessment that includes the prediction of noise levels is required prior to the construction of the installation of piles in most projects. Given the expected noise levels, appropriate noise mitigation systems (NMS), i.e., air-bubble curtains, hydro-sound dampers, or noise mitigation screens, are usually required to reduce the noise. To address this challenge, underwater sound modelling tools can assist in predicting potential sound sources and propagation characteristics.

There is no standard modelling approach for the pile-driving sound. Various computational methods (such as finite element, finite difference, semi-analytic and empirical models) have been used to predict the generated noise during pile driving and propagate the sound field to larger distances where the noise thresholds are defined (Tsouvalas 2020). These models should include the properties of the pile (i.e., length, thickness, hammer properties), the installation tool, and the site-specific environmental parameters (i.e., sediment type, sediment layers, water depth). Although finite element models can provide detailed results, they are computationally slow. In contrast, the fast empirical models are less detailed, especially when noise mitigation systems (NMS) are deployed. Air-bubble curtain systems have been widely used in many offshore projects to mitigate the impact pile-driving noise over the last decade. An accurate description of the acoustic characteristics of the air-water mixture is essential before modelling the noise mitigation mechanism in such cases.

In our work, a computationally efficient and validated pile-driving model is used to predict the generation and propagation of the sound field associated with impact piling at large (from the pile) distances, overcoming the limitations of earlier models (Tsouvalas 2020). In addition, the same model can be easily modified for various system configurations to investigate the water- and soil-borne noise transmission paths in a detailed and systematic way (Peng et al. 2021a, b). Furthermore, the sound

source modelling tool can be combined with different sound propagation modelling approaches to include long-range propagation effects such as the variable bathymetry (Sertlek et al. 2019). The source and propagation modelling approaches are described in the following sections.

## Sound Source Modelling in Impact Pile Driving

During pile driving, the sound propagates through the pile, water, and sediment layers after the source excitation by a hammer and interacts among these different domains (Tsouvalas 2020). In addition, low-frequency sound propagation in shallow waters can propagate long distances in vertical and horizontal directions. Therefore, the modelling approaches should consider the detailed composition of the sediment to capture the sound waves propagating through the multiple sediment layers. To achieve this aim, different modelling approaches have been used to model pile-driving sound such as:

- Finite element models (Reinhall and Dahl 2011; Zampolli et al. 2013)
- Finite difference schemes (MacGillivray 2013, 2015)
- Boundary element methods (Masoumi et al. 2007, 2009; Masoumi and Degrande 2008)
- Semi-analytical solutions by several authors (Tsouvalas and Metrikine 2014; Hall 2013, 2014, 2015; Deng et al. 2016a, b)
- Simplified formulas as damped cylindrical spreading (Duncan and Parsons 2011; Ainslie et al. 2014; Lippert et al. 2018a, b)

Some of these modelling approaches are compared during the COMPILE I Workshop (Lippert et al. 2016) to indicate their differences. In addition to the differences in the modelling of the sound generation, the assumptions related to the sediment play an essential role in the accuracy of model predictions. Some models describe the sediment as an equivalent fluid layer (Dahl and Reinhall 2011; Zampolli et al. 2013). Considering the elastic (Buckingham 2000) or poroelastic (Biot 1956a, b) properties of sediment could improve model accuracy (Tsouvalas 2020).

In this chapter, a semi-analytical solution that could provide a faster solution than the finite element method is used (Tsouvalas et al. 2015). This model assumes cylindrical symmetry for the pile and the surrounding environment. The pile is described as a cylindrical shell in an inviscid compressible fluid medium and horizontally stratified acousto-elastic half-space. The pile properties such as the pile length (L), radius (R), thickness (t), Poisson's ratio (v), and density of the shell ($\rho$) are used as the model inputs. A time-dependent force function is applied to the pile head in the air. The mathematical background is based on the normal modes and branch line integrations for an axisymmetric ring source. The set of equations are implemented in the software package, SILENCE, providing various model options and outputs depending on the requirements of the specific problems. The near-source module calculates the wave field in the close to the monopile by

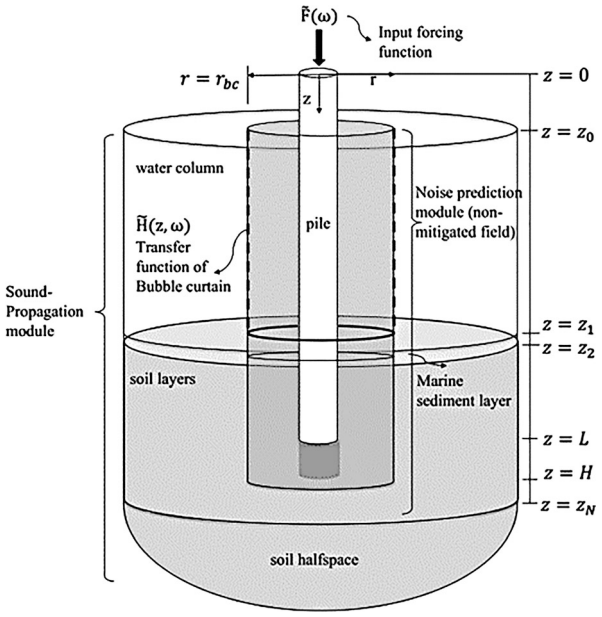

**Fig. 1** The geometry of pile driving sound source model (SILENCE). F(t) is the time-dependent force function due to impact or vibratory hammer. F(w) is the Fourier transform of F(t) (This figure adapted from Peng et al. (2021a))

considering the interactions between the pile, fluid, and soil. Once the wave field at the close range ($r \leq r_0$) is calculated, the far-field module is used to propagate this field to the large distances ($r > r_0$). Since the detailed mathematical description of this model is given by Peng et al. (2021b), it is omitted for the sake of simplicity in this chapter. A basic version of pile-driving sound modelling software (SILENCE) is freely available on the TU Delft Webpage (http://ua.citg.tudelft.nl/) for research and educational purposes (Fig. 1).

In Fig. 2, the amplitude of the particle velocity in the water and sediment layers are shown for a pile with a diameter of 7 m and a length of 78 m (Tsouvalas 2020). Scholte waves propagating along the fluid-solid interface could be noticed in this figure. The vibratory piling can also be modelled with a similar modelling approach based on a vibratory hammer force function. However, since the acoustic energy enters the water column from all vertical angles due to the different temporal structure of the excitation, the coherent Mach cones would not be clearly visible for the vibratory piling.

The calculated sound field close to the pile is propagated over long radial distances with the far-from-source module based on the integral boundary equations considering the reciprocity theorem. The detailed derivation of the far-from-source module is described by Peng et al. (2021b). This model can provide detailed outputs including sound pressure, sound velocity, displacement, and stress in the sediment layers. The modelling of the particle motion in the water and top sediment layer is critical to assess the impact of the pile-driving sounds on fish, which are sensitive to both the pressure and particle motion.

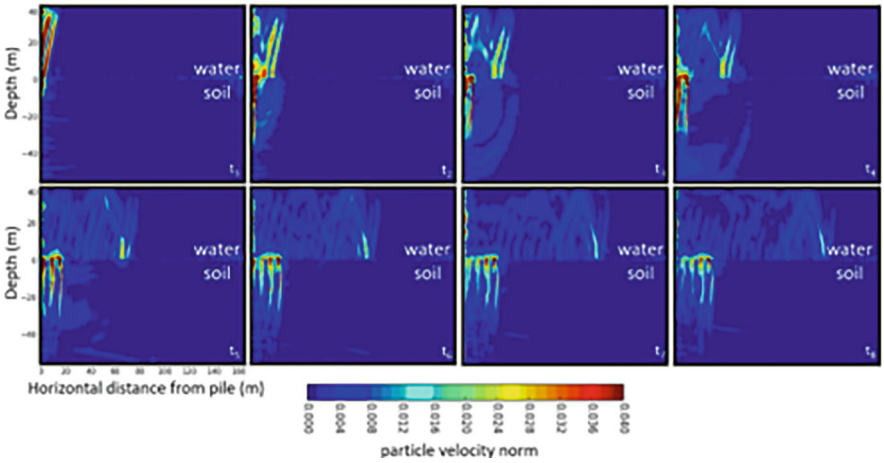

**Fig. 2** The amplitude of the particle velocity after the hammer impact (6 s to 120 s). (This figure is adapted from Tsouvalas (2020))

Once the generated noise during pile driving is modelled, the performance of the noise mitigation systems could be simulated to discover their optimum configuration. Describing the acoustic properties of an air-bubble curtain with effective parameters such as effective wavenumber or sound speed simplifies the problem (Bohne et al. 2019). In our approach, the effective wavenumber formula of Commander and Prosperetti (1989) is applied based on the parameters of the air-bubble curtain (Bohne et al 2020) to estimate the variation of effective local wavenumbers over the entire water depth and frequency band. The bimodal bubble size distribution is introduced by Lethr et al. (2002) with observations of small and large bubbles (Bohne 2020; Milgram 1983). An example of effective sound speed profile evaluation with depth is shown in Fig. 3 for 125 Hz. It can be noticed that the sound speed in the air-bubble curtain is lower than the sound speed in the water. As a result of this difference, a large impedance mismatch at the water and air-bubble interface causes the reflection of the sound wave field back to the source and attenuation as they propagate through the bubble curtain. These transmission coefficients between water and bubble interfaces are calculated and coupled to the free-field noise prediction model through a boundary integral method. The water column and air-bubble curtain are divided into multiple regions along the depth coordinates. At each vertical domain, a one-dimensional problem is considered with an input incident wave and properties of the layers to determine transmission coefficients for depth direction. Once the solution is obtained for the depth-dependent fluid dynamic properties, the local effective wavenumber and the transmission coefficients of the air-bubble curtain are determined. The obtained results with the hydrodynamic model are processed, including the propagation modelling through air-bubble curtains, and the result is translated to the relevant acoustic metrics.

The modelling framework of the noise mitigation with air-bubble curtains should consider a detailed configuration of the mitigation system including the pneumatic

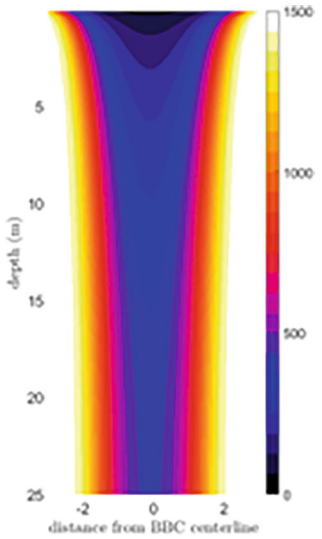

**Fig. 3** The effective sound speed. This result is calculated at 125 Hz for a water depth of 25 m

model for the simulation of the air circulation and transport from the air-supplied vessel to the hose on the seabed. A hydrodynamic model calculates the effective wavenumbers and sound speed through depth and range in the air-bubble curtain. Next, the output of the hydrodynamic model is used to calculate the depth- and frequency-dependent transmission coefficients of the air-bubble curtain. Finally, the mitigated sound levels are calculated as a combination of individual simulation steps and propagated to larger distances by an acoustic modelling approach. More detailed description of the sound mitigation model is given by Peng et al. (2023).

As a summary, the mathematical models require inputs for the pile parameters, environment, and air-bubble curtain configuration. The pile parameters include the length, diameter, thickness, penetration depth, density, Young's modulus, Poisson's ratio, and damping of the pile. The big bubble curtain (BBC) parameters include the distance from the pile, nozzle diameter, nozzle spacing, and airflow rate through the nozzle. The BBC parameters should be calculated by the pneumatic and hydrodynamic models with the feed pressure, hose length and diameter, nozzle diameter, and spacing.

## Sound Propagation in Range-Dependent Media

Long-range sound propagation requires the detailed modelling of the sediment properties, variations in bathymetry, and sound speed. Various modelling approaches (i.e., normal mode method, parabolic equation, ray tracing, energy flux) could be preferred depending on the environmental conditions and frequency range. Sound propagation modelling is usually required in shallow waters for impact pile driving.

Many EU countries (such as the Netherlands and Germany) define the noise criteria at 750 m (Heinis 2015; Heinis et al. 2019a, b; BSH 2011; 2013). Therefore, many modelling approaches ignore the range-dependent properties of waveguides due to the minor environmental changes up to 750 m. Instead, these models focus on the detailed modelling of elastic seabed properties that improve the accuracy of model predictions for pile driving due to the strong interactions between the water and sediment layer, especially at low frequencies. However, when sound propagation modelling is required at long ranges beyond 750 m, omitting the bathymetry changes could result in incorrect results. In this chapter, different modelling strategies are used in order to benefit from the advantages of different models. Up to 750 m, the sound pressure and particle motion are calculated, including the detailed sediment properties based on the range-independent waveguide assumption. Modelling sound propagation, including the detailed elastic properties of sediments, makes it possible to capture the sound energy in the sediment layer, which can tunnel under the bubble curtains and leak back to the water layer. This effect is usually critical for ranges up to 200 m where bubble curtains are typically deployed. Beyond 750 m, a sound propagation model of lower fidelity is used. Different propagation models could be chosen based on environmental conditions and frequency ranges, as shown in Fig. 4.

The parabolic equation model can use a starter field from sound source modelling tools and propagate this to larger distances, including the range-dependent variation in the water depth. Similarly, normal mode models, such as KrakenC (Porter 1991), could be used, including the elastic properties of the sediments and adiabatic approximation for the range dependency. If the elastic properties and layered sediments are ignored at high frequencies, mode-flux theory based on adiabatic approximation is an option. The wavenumber integration method can provide accurate results when the range dependency is weak. Comparisons between different propagation methods are investigated by Sertlek et al. (2019). At the interface of two different models, various approximations could be used (Reinhall and Dahl 2011:

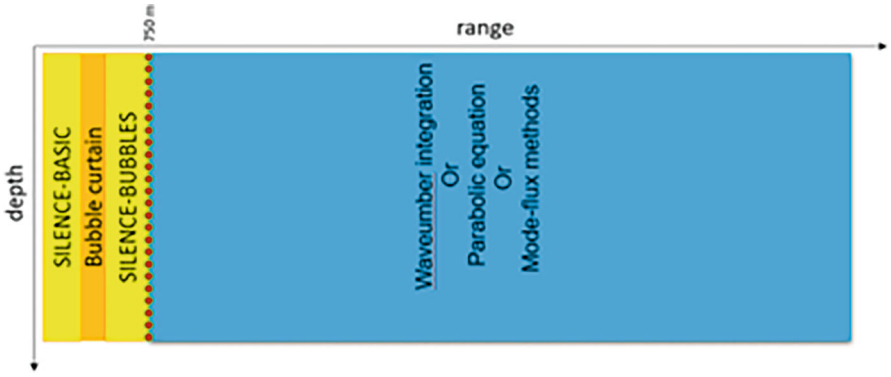

**Fig. 4** Multi-model approach for the simulation of pile-driving noise. The detailed source and propagation model close to the pile (up to 750 m) with the sound pressure, velocity, displacement, and stress outputs. Beyond 750 m, propagation models only with sound pressure outputs are used

TNO report). The mathematical descriptions of these potential approaches are beyond the scope of this chapter. Range-dependent propagation modelling can be used for creating sound maps to provide insight into the sound exposure level (SEL) during the off-shore wind farm constructions. Sound maps can be calculated based on a large number of radial slides between the source location and receiver point as shown in Fig. 5.

As could be noticed from the bathymetry slices, the range-dependent differences are usually minor at 750 m where the range-independent modelling approach is used.

Figure 6 shows a sound map created based on the described steps for a single impact piling strike at 125 Hz. First, the pressure field is modelled with SILENCE up to 750 m. An artificial scenario was created to test the proposed approach in the Baltic Sea. The offshore wind farm location is chosen based on the possible wind farm locations as shown in the EMODNET Human Activities data portal (www.emodnet-humanactivities.eu). The pile parameters are also chosen based on the realistic pile properties from Peng et al. (2021a). The length, diameter, and wall thickness of the pile are chosen as 76.9 m, 8 m, and 90 mm, respectively. The water depth at the piling location is 39.9 m. The maximum blow energy is 1750 kJ. The pressure field at 750 m is calculated for multiple receiver depth locations with 0.1 m resolution. Beyond 750 m, assuming a vertical line source, the sound propagation is calculated using the normal mode method with adiabatic approximation. The sound pressure is averaged over the depth.

Sound mapping helps to predict the maximum impact distances based on the impact thresholds of the different marine animals (Southall et al. 2019). Furthermore, the sound maps could be weighted based on the marine animals' hearing sensitivities and swimming depths over a large frequency band to provide input for the biologists.

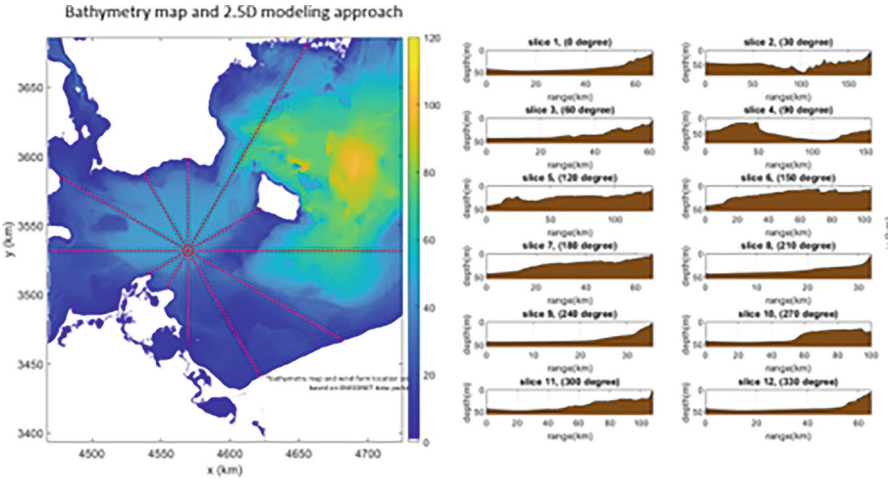

**Fig. 5** The radial slicing of bathymetry as input of sound mapping (on the left panel). Selected water depth profiles from the same area (on the right panel)

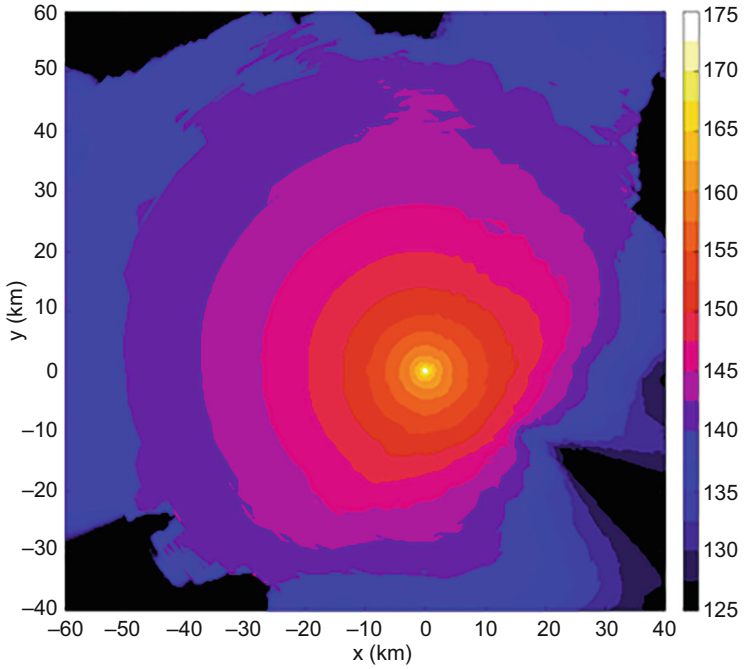

**Fig. 6** Sound mapping based on the multi-model approach for the simulation pile-driving noise. The sound pressure is averaged over the depth. SEL is calculated for a single strike at 125 Hz

## Conclusions

In this chapter, a framework for modelling underwater sound properties due to pile driving is described by considering the detailed environmental inputs, such as the elastic multilayered sediments and range-dependent water depth. As a general summary, the following procedure is followed to predict sound fields during offshore wind farm constructions:

- Modelling underwater sound during an impact pile driving with SILENCE
- Modelling the noise mitigation with a bubble curtain
- Modelling sound propagation up to 750 m with a high-fidelity sound propagation model considering elastic properties (including the particle motion and pressure)
- Modelling far-field propagation with a fast computational model beyond 750 m
- Sound mapping as combination modelling results for the individual radial slices

The proposed approach suggests using a set of various mathematical models at distances that can be accurately and practically implemented. The uncertainty in the environmental and pile parameters could be investigated individually for each region (source, near-field, and far-field). The pile-driving source model can generate outputs

for the sound pressure, velocity, stress, and displacement in the sediment layers. These outputs could be critical for assessing the impact of sound on the fish and invertebrates. Due to the limited availability of the required inputs for the sediment properties and computational expenses, the particle motion, stress, and displacement outputs are only calculated up to 750 m in this work. However, more detailed propagation modelling tools at long distances could be used in future works. Furthermore, the sound propagation modelling approach for the air-bubble curtain could be improved considering the detailed backscattering effects and continuity conditions for the acousto-elastic waveguides.

**Abstract**

The Soundscape Code was originally proposed in 2021 to rapidly assess and direct multidimensional comparisons of salient soundscape properties across time and space. The Soundscape Code metrics represent the amplitude, impulsiveness, uniformity, and periodicity properties of an acoustic environment. Here they were applied to recordings from four deep ocean environments along the US Outer Continental Shelf and the shallow water of the Great Barrier Reef. The assessment and comparison of soundscapes recorded in deep sea sand versus deep coral locations and deep versus shallow water coral sites showed the habitat soundscapes exhibited both similarities and unique acoustic properties which were metric dependent. This initial characterization will aid in directing further analyses and guide subsequent assessments to more comprehensively understand soundscape dynamics and the role the local soundscape plays in deep sea ecosystems and coral reef habitats.

## Introduction

The ocean soundscape is a term used to define and describe the acoustic properties of the marine environment at a specific place and time. The underwater soundscape was formally defined by IOS 18405 as the "characterization of ambient sound in terms of its spatial, temporal, frequency attributes, and the types of sources contributing to the sound field" (ISO 2017). Traditionally, variability in amplitude across time, space, and frequency has been the focus of soundscape studies captured by metrics of sound pressure level, power spectral density, sound exposure level, and source-amplitude-related parameters such as number of sources and source classification. Indices such as the Acoustic Complexity Index and Entropy Index have been applied to passive acoustic recordings as a proxy for biodiversity by relating measures of frequency and amplitude over specified time periods (Staaterman et al. 2014; Sueur et al. 2008). Here, consideration of properties that capture elements of a soundscape in addition to the more commonly used amplitude metrics in alignment with the Soundscape Code (SSC) established in Wilford et al. (2021) are advocated. Metrics that define properties of impulsiveness, uniformity, and periodicity were assessed for their ability to facilitate efficient, quantitative, and comprehensive soundscape comparisons across time and space.

Wilford et al. (2021) examined passive acoustic recordings from seven different ocean environments representing global sound sources indicative of natural (biologic and nonbiologic) and anthropogenic activity in the development of the proposed SSC. The best measures were determined to be root-mean-squared sound pressure level (SPL) and peak sound pressure level (PK) for amplitude, kurtosis for impulsiveness, an autocorrelation-based metric for periodicity, and the Dissimilarity Index (Sueur et al. 2008) for uniformity. In this study, the SSC structure was applied to passive acoustic recordings from four locations along the Atlantic US Outer Continental Shelf (OCS) (two sandy bottom locations and two cold water coral locations) and one shallow, warm water coral habitat of the Great Barrier Reef. Ecosystem health and function is linked to local soundscape characteristics in shallow water coral reef habitats (Lamont et al. 2022; McWilliam et al. 2017), but at present it is not known whether this relationship extends to deep water coral reef habitats. The goal was to assess the performance of the SSC in identifying similar and contrasting soundscape characteristics associated with deep sea sandy bottom habitats, deep sea cold water coral reefs, and a warm water coral reef.

## Methods

Five long-term data sets were analyzed using the metrics of the SSC to establish baseline soundscape information, and compare the soundscapes of deep-sea coral and noncoral environments with the soundscape of a shallow coral environment. Recordings were made at four deep-sea sites along the OCS region off the southeastern United States consisting of deep-sea coral (Savannah Deep, SAV; Richardson Hills, RH) and noncoral, sandy bottom (Wilmington, WIL; Blake Escarpment, BLE)

habitats. Recordings from a shallow (6–18 m) coral reef environment part of the Great Barrier Reef (GBR) were examined in contrast to the deepwater sites of the OCS (Fig. 1). The OCS recordings at SAV, WIL, and BLE were made in 2018 as part of the Atlantic Deepwater Ecosystem Observatory Network (ADEON – https://adeon.unh.edu/). The ADEON recordings were made with AMAR G3 recorders (JASCO Applied Sciences, Dartmouth, NS, Canada) sampled at 375 kHz on a 1/20 min duty cycle. The RH recordings were made as part of the DEEP SEARCH program (https://ecogig.org/deepsearch). The DEEP SEARCH recordings were made in 2019 with an icListen Smart Hydrophone (Ocean Sonics, Truro Heights, NS, Canada) sampled at 128 kHz on a 1/30 min duty cycle. Data from the Great Barrier Reef site were recorded in 2013 on an AMAR G3 recorder at a 64 kHz sampling rate with a 13/14 min duty cycle. Recordings from the OCS sites were appropriately downsampled to an upper 32 kHz usuable frequency, so be consistent

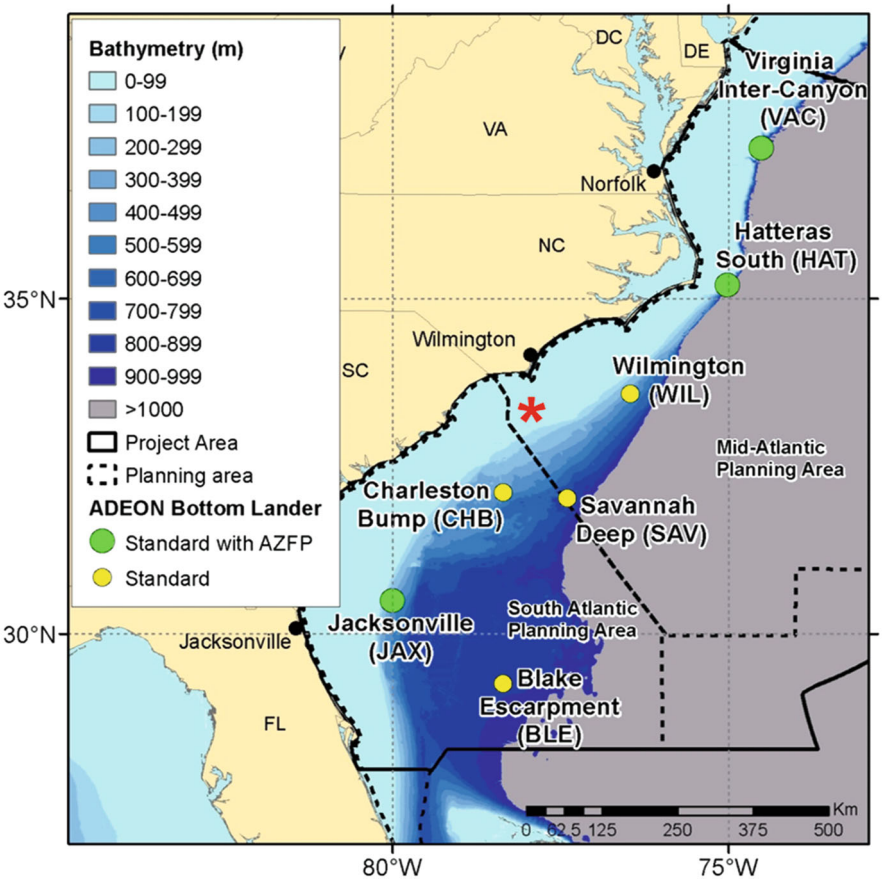

**Fig. 1** Recorder locations and bathymetry for the OCS sites: Wilmington (WIL), Savannah Deep (SAV), Blake Escarpment (BLE), and Richardson Hills (red *)

for comparison with the 32 kHz usable frequency maximum of the GBR recordings. All acoustic data were calibrated using hydrophone sensitivities and identical methodologies so that accurate and meaningful comparisons could be made. A mid-April to mid-May time period was analyzed at the five sites. This analysis period was chosen so that all recordings were related to a similar time period, as recordings from RH and GBR data were the limiting recordings with only April/May data available. Consistency across seasons among the OCS sites was an important factor in the most accurate comparisons. Recognizing the GBR site is in the southern hemisphere and off season compared to the northern hemisphere locations, its proximity to the equator negates the strong influence of seasons observed at the OCS sites which allows for meaningful comparisons given the limiting factor of data availability.

A SSC matrix was computed from the acoustic time series at each of the five sites in four frequency bands: Broadband (BB) (10 Hz- >10 kHz), Low (10–100 Hz), Mid (100 Hz – 1000 Hz), High (1000 Hz – 10 kHz), and Ultra-High (Ult-High) (>10 kHz). The metrics were calculated according to Wilford et al. (2021) for each frequency band. Frequency bands were isolated with Finite Impulse Response (FIR) filters implemented in MATLAB (Mathworks Inc., Natick, MA). The SSCs compare the average level and overall variability of each metric by reporting the median and size of the central 95th percentage (C95) of 1 min metric time series. A color-coding scheme within the SSC matrix reflects the range of metric medians and C95 values across all sites. The overall project range for each metric category was divided into quartiles, and each cell of the Soundscape Code table was colored based on quartile (Q1 blue, Q2 green, Q3 yellow, and Q4 red).

Connections between SSC metric groupings and habitat location/type were explored using k-means clustering computed in JMP Pro™ 14.0.0 (JMP Statistical Discovery LLC, Cary, NC). The number of clusters (k) constraining the analysis relates to the number of sites. For clustering with all the sites, four to six clusters were analyzed, which corresponds to cluster sizes one cluster more ($k = 6$) and one cluster less ($k = 4$) than the five total sites ($k = 5$).

## Results

The SSC output (Fig. 2) provides a high-level, overall comparison of the soundscapes from the five locations. The SSC output provides a large amount of detailed information that can be harvested for detailed comparisons between locations and metrics. Here only a high-level summary of results is captured for comparisons across locations and habitat types (sandy vs live hard-bottom reefs, shallow vs deep reefs).

GBR SPL amplitude medians dominated in the BB, Mid, High, and UH band with PK dominating in all frequency bands. Accompanying the highest median levels at GBR were the lowest variability C95 metrics compared to OCS sites, which report considerable variability in all bands. BLE and WIL had the highest SPL median levels in the Low band. RH had the most variable amplitude metrics.

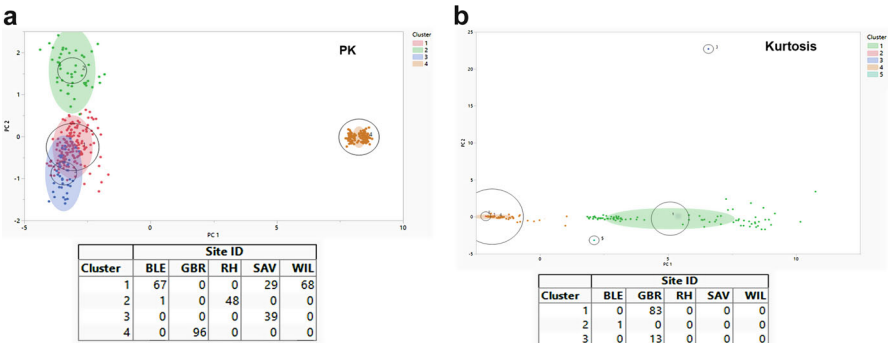

**Fig. 2** Soundscape Code output for the five sites analyzed. The two rows for amplitude reflect the SPL (upper amplitude row) and PK (lower amplitude row) metrics. The ranges reported in the lower right panel indicate the range of SSC medians and C95s across all sites. The total range of the SSC medians and C95s was divided into quartiles, and the cell colors correspond to which quartile the value falls into from low to high: blue, green, yellow, and red

GBR was the most impulsive site in both median and variability parameters. The primary driver for this was related to the presence of snapping shrimp signals visible in the spectrograms. The OCS site impulsiveness (kurtosis) was assessed on the C95 variability as opposed to median levels, as all median kurtosis levels were in the lowest quartile. Among the deep-water OCS sites, RH kurtosis values were the most variable across frequency bands which suggests this site is the most impulsive OCS soundscape. BLE and WIL kurtosis parameters suggest that the soundscapes at these sites contain salient impulsive signals in the Ult-High and Mid frequency bands, respectively. Snapping shrimp signals were not visible in the OCS spectrograms.

GBR reported higher D-index uniformity medians in frequencies above 100 Hz compared to the OCS sites. GBR D-index variability was extremely small compared to OCS sites. For the most part, OCS sites appear acoustically dynamic especially in the Low band. BLE differs in this assessment with the lowest uniformity medians across all frequencies.

While the periodicity medians were all zero, periodic signals appear well represented in all sites, represented by increased variability in isolated frequency bands. WIL and RH were most influenced by periodic signals in the Low frequency band. All sites except SAV showed high levels of periodic variability in the higher frequency bands. The high frequency periodicity was likely related to echolocation signals visible in the spectrograms.

Clustering of SSC metrics revealed trends similar to those observed in the SSC matrix (Figs. 2 and 3). In all SSC metric clusterings, except for periodicity, GBR was clearly separated and identified as different from the OSC sites (Figs. 3 and 4). For some metrics, such as PK, the OCS sites showed distinct clusters for the cold water coral reefs at RH and SAV (Fig. 3). Both the deep water coral sites of RH and SAV clustered without any contributions from the sandy bottom sites of BLE and WIL. The sandy bottom SSC metric clusters from BLE and WIL did have significant overlap with the deep cold water coral reef at SAV, but no overlap with the cold water reef at RH. Clustering for amplitude metric SPL and uniformity metric D-Index (not shown) had similar clustering results with GBR clustering very separately from the

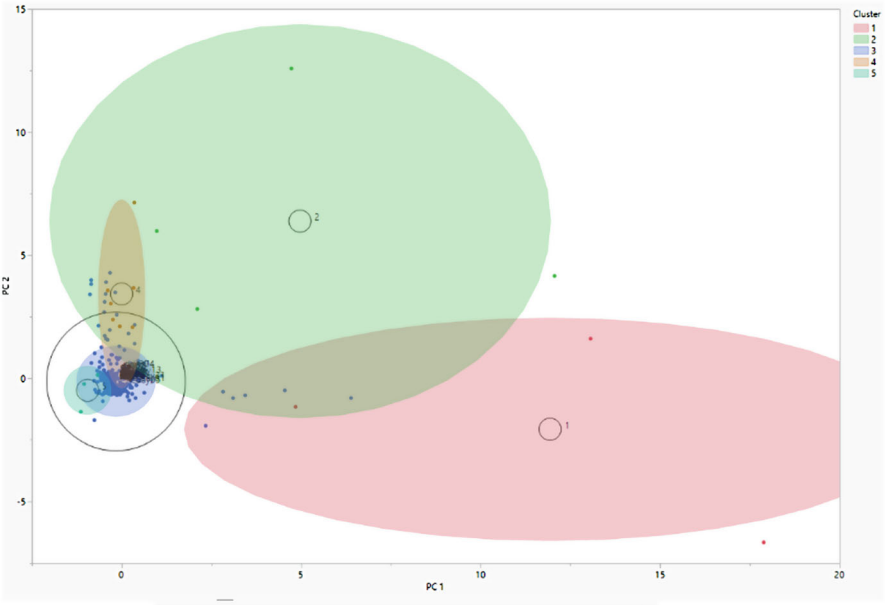
**Fig. 3** Example cluster analyses for (**a**) PK and (**b**) kurtosis impulsiveness measures of the SSC 1-min values over the duration of the month time period. Shaded regions indicate where 50% of the observations in the cluster fall. Shading is the 50% portion of all points within a specific cluster, whereas the color of shading and points denotes cluster number

OCS sites, and the cold water coral reef soundscapes at RH and SAV clustering separately from each other but with SAV significantly overlapping with the sandy habitats of BLE and WIL.



Examination of the clustering for the impulsiveness metric of kurtosis again showed GBR separated out with no overlap with the OCS site soundscapes. However, unlike PK, SPL, and D-Index where there was separation between the two cold water coral reef SSC metrics, there was no separation of any OCS sites by location or habitat (Fig. 3b Cluster 4).

The periodicity SSC metric clustering pattern was unique. GBR did not separate apart from the OCS sites (Fig. 4). Cluster analyses that constrained the number of clusters from 3 to 6 all resulted in a single cluster with contributions from all five soundscape locations. Clusters other than the main periodicity cluster contained only outliers which were defined as including less than seven total data points stemming from one or more locations.

## Conclusion

The application of the SSC proposed by Wilford et al. (2021) to soundscapes recorded in deep and shallow water locations offered the opportunity to determine if soundscape characteristics could be meaningfully compared across habitats with the potential to acoustically inform habitat type and function. The SSC output indicated that the shallow coral reef habitat was the loudest, most impulsive, and least variable (both in terms of metric variability and uniformity). The SSC output for GBR was visibility different in the SSC matrix color presentation and overall visual pattern, identifying it as dissimilar from the OCS locations.

Clustering analysis demonstrated the utility of the SSC metrics in grouping soundscapes with similar characteristics. The GBR soundscape separated from the

**Fig. 4** Periodicity measures of the SSC 1-min values over the duration of the month time period. Cluster 3 contains 331 values spread across all sites. The remaining clusters have seven or less outlier points each

OCS sites as distinctly dissimilar in terms of amplitude, impulsiveness, and uniformity, but not for periodicity indicating that the shallow GBR soundscape is likely reflecting an ecosystem that functions differently from the deep-water habitats of the OCS. Clustering of the SSC amplitude and uniformity metrics in the OCS sites further showed separation of the cold water reef habitats compared to the sandy bottom habitats, again suggesting that these two habitats support different ecosystem components and/or function.

As more is learned about how marine life sense and perceive sound, as well as understanding which signal/soundscape characteristics are biologically meaningful to marine life, soundscape characteristics other than traditional amplitude measurements will likely play a larger role. Measures of impulsiveness, uniformity, and periodicity capture different information in the temporal and spectral domains than amplitude. Here the exercise of applying the multidimensional SSC metrics to

different habitats demonstrates that soundscapes can be meaningfully categorized and differentiated on characteristics other than just amplitude, and that the consideration of acoustic metrics in addition to amplitude may noninvasively provide insight into ecosystem changes and function.

Carolina, USA. But the changing contributions of the various fishes to the soundscape that varies diurnally, seasonally, and over 20 years have not been characterized. Multiple passive acoustic recording systems have been used to make these recordings at a variety of locations. After calibrating these recording systems, an analysis of the soundscape was performed using power spectral band (PSB) sums, which sum the acoustic energy in frequency bands associated with known soniferous fish species. The analysis reveals some interesting patterns related to fish ecology: (1) sound production occurs after sunset with a nightly peak in sound pressure levels; (2) there is a seasonal increase in the power spectral band sums, correlated with increasing water temperatures; and (3) species in the Sciaenidae family have distinct periods of sonic activity. The temporal progression of these species in their spawning areas was plotted using PSB sums. Examples are presented of these soundscapes and descriptions of the changes observed in the soundscapes from samples taken over 20 years (1997–2018).

## Introduction

Various species of fish make sounds (individually and in choruses) while mating and during aggressive encounters (Mok and Gilmore 1983; Rountree et al. 2006). For more than 20 years, passive acoustic monitoring of the estuarine soundscapes has been used to understand the behavior and seasonal occurrence of fishes that produce sounds (Luczkovich et al. 1999, 2008; Sprague et al. 2000). Sounds that are recorded in estuaries in North Carolina are mainly due to fishes in the drum family (Sciaenidae). These fishes produce nocturnal choruses of varying intensity. The chorusing is associated with spawning activity (they are advertisement calls made by males). But the entirety of the data has not been examined for patterns indicating that the sound intensity measured in the same month or season varies across multiple years.

Therefore, it is the objective in this retrospective to investigate the following questions:

1. How does the chorusing vary geographically in the soundscape (using the focal year 1998)?
2. How does the chorusing change temporally within a year (using the focal year 2006)?
3. How does the chorusing change across years (focal years of 2006, 2017, and 2018)?

## Calibration of Hydrophones and Recording Systems

Three different recording systems were used, and each one is different in hydrophone sensitivity and recording system frequency response (Table 1). They spanned a range of purchase costs: $200 each ($370 corrected for inflation in 2023, using the tool at https://www.usinflationcalculator.com/) for the East Carolina University Sonobuoy with an analog cassette recorder, $5000 each for the Loggerhead LARS digital recorder (an equivalent model called Snap made by Loggerhead, Inc. costs $3995 in 2023), and $10,185 each (purchased in 2015, $ 11,300 in 2023) for the icListen smart digital hydrophone (Ocean Sonics, Inc.). A float collar, 50-m cable, battery pack, and Lucy instrument control software (V4) were also used with the icListen hydrophone, which raised the cost of the system to $22,308 in 2015 ($28,626 in 2023). A description of each system follows.

### ECU Sonobuoys

These sonobuoys were constructed at East Carolina University and consisted of a Gulton GLN-9190 hydrophone (−174 dB re 1 V/μPa sensitivity) connected to a Sony TCM 313 cassette recorder and a timing circuit (Luczkovich et al. 2008). The hydrophone output was recorded on a cassette audiotape (TDK D Type I normal-bias 90 min) for long-term storage and analysis. This recorder system was programmed to be powered on at intervals (30 min or 60 min) selected by the user. After powering up, the cassette recorder made ambient soundscape recordings that were 90 s duration, then shut off until the next power-on interval. A talking clock announced the local time at the start of each recording. Tape recordings with successive intervals lasted for 12–24 h, after which the sonobuoy was recovered and redeployed with new a tape.

### Loggerhead LARS

This recording system has an HTI 96-min hydrophone with a sensitivity of −164 dB re 1 V/μPa and a frequency range of 10 Hz−10 kHz. Digital recordings were made using a Dell Axim and the Loggerhead Pocket PC software application. The calibration procedures for the Dell Axim (LHCal.exe) were followed according to

**Table 1** The passive acoustic hydrophone recording systems and frequency responses of each system used

| Recording system | Hydrophone sensitivity | System frequency response |
|---|---|---|
| ECU Sonobuoy | −174 dB re 1 V/μPa | 30–2000 Hz |
| Loggerhead LARS | −164 dB re 1 V/μPa | 10 Hz–10 kHz |
| Ocean Sonics icListen HF | −171 dB re 1 V/μPa | 10 Hz–200 kHz |

the manufacturer using a signal generator as the input. The HTI 96-min hydrophone sensitivity specification was used (−164 dB re 1 V/μPa). A calibration adjustment was made (+175.5 dB was added to normalized LARS recordings to convert the file sample values to μPa for displays and analysis in Python).

## Ocean Sonics icListen HF

This is a "smart" hydrophone (Ocean Sonics model SB2-ETH) with digital recording and hydrophone combined in a single unit. Calibration was provided by the manufacturer (Calibration certificate C3154). This hydrophone has a sensitivity of −171 dB re 1 V/μPa and a system response frequency of 10 Hz–200 kHz. The float collar was used to suspend the icListen in the water column, which allowed the hydrophone to remain neutrally buoyant 1 m above the bottom. The float collar was attached to an anchored cage where the battery pack was cabled to the hydrophone.

## Calibrations of the Three Hydrophone Systems

Although the three recording systems each had calibrations based on hydrophone sensitivities, the same sounds were recorded with each to make sure they all produced the same levels in recordings. Reference tones and noise (200–10,000 Hz) were played back in a test pool and in the air, while recording the frequency response for each of the hydrophones. Sonobuoy recordings were compared with recordings made simultaneously using a reference hydrophone: Gunnar Rasmussen Hydrophone Model 10CS (−211.7 dB re 1 V/μPa sensitivity, frequency response 0.1–25,000 Hz). The reference hydrophone output voltage was simultaneously recorded to a digital recorder (SONY DAT tape or Zoom Recorder). Sine waves produced by a signal generator with input voltages measured on the oscilloscope were also recorded digitally. The amplitude of the reference hydrophone associated with the input voltages from the signal generator was also recorded for each sine wave test tone. The audiocassette tape in the sonobuoy and the reference hydrophone output were digitized on a Zoom F8 Recorder at 44.1 kHz with a +25 dB gain. The Gulton sonobuoy hydrophone was compared against the reference hydrophone using the known input voltages and digitized audio amplitudes as received at the two hydrophones to develop a calibration relationship. Digitized field tape recordings from the ECU Sonobuoys were recorded on the Zoom F8 multitrack recorder using the same settings.

An inter-hydrophone and recording system comparison test was conducted for the three systems used (ECU sonobuoy, LARS, and icListen) in a freshwater pool and in air to compare the sound pressure levels recorded and the frequency response of each passive acoustic recording system. Such inter-recorder calibration is essential to make comparisons of field recordings by each of the systems over time. To accomplish this inter-hydrophone calibration, comparisons were made of sound recordings from the three recording systems in the pool at distances of 11 m while playing a series of tones and white or pink noise signals through an underwater speaker (Clark Synthesis AQ-339) with a power amplifier (Pyle PMLRA200). For

air intercalibration measurements, an amplified JBL public address system (JBL model EON208P) was used to play the same sounds at a distance of 1 m from the three hydrophone and recording systems.

## Power Spectral Analysis

The procedure in this section was previously published (Luczkovich and Sprague 2022). Power spectral band sums (PSB sums) were computed for specific frequency bands associated with known fish sounds. Table 2 shows the frequency range associated with different fish species. These frequency bands were chosen as indicators of calls by the various species. The bands do not contain all frequencies in the calls. The PSB sum $S_{PSB}$ is the sum of all power spectrum components $P_n$ for frequencies in the band $f_{min} \leq f_n \leq f_{max}$

$$S_{PSB}(f_{min}, f_{max}) = \sum_{n_{min}}^{n_{max}} P_n \Delta f$$

where $n_{min}$ is the index of the smallest frequency component in the band, $n_{max}$ is the index of the largest frequency component in the band, and $\Delta f$ the frequency interval in the power spectrum.

The average PSB sum was computed for each band in Table 2 using 10 s of the recording. The PSB sums were plotted versus time to identify times in the recordings likely to contain fish sounds. One indication of fish activity is when the PSB sum for a frequency band increased with a different pattern than the other bands.

## Study Design

The 1998 ECU sonobuoy survey was used to develop maps of sounds heard at different locations using the Summed Nightly Drumming Index (SNDI), which was scored on 0 (no fish sounds) to 3 (loud chorusing) scale by a human listener for red drum *Sciaenops ocellatus*, spotted seatrout *Cynoscion nebulosus*, weakfish *C. regalis*,

**Table 2** The bands used in the power spectra analysis (power spectral band sums, with frequency max and min) and the fish species that are dominant within each frequency band. A similar table with different band numbers was previously published (Luczkovich and Sprague 2022). Atlantic croaker is assigned to Band IV in this table with a wider frequency range than what was used in the previous study

| Frequency band (Hz) | Common name, species (family) |
|---|---|
| Band I: 100–200 | Red drum, *Sciaenops ocellatus* (Sciaenidae) |
| Band II: 200–300 | Oyster toadfish, *Opsanus tau* (Batrachoididae) |
| Band III: 300–600 | Spotted seatrout, *Cynoscion nebulosus* (Sciaenidae)<br>Weakfish, *Cynoscion regalis* (Sciaenidae) |
| Band IV: 300–1000 | Atlantic croaker, *Micropogonias undulatus* (Sciaenidae) |
| Band V: 600–1500 | Silver perch, *Bairdiella chrysoura* (Sciaenidae) |
| Band VI: 1500–2000 | Striped cusk eel, *Ophidion marginatum* (Ophidiidae) |

and silver perch *Bairdiella chrysoura* (Luczkovich et al. 2008). These sonobuoys were deployed and recovered at random locations (located with GPS coordinates) chosen within two grids (Ocracoke Inlet and Bay River) every month from May through October 1998 (Fig. 1; see the detailed description of the sampling design in the original study Luczkovich et al. 2008). These geolocated passive acoustic recordings were used to produce spatial soundscape analysis via geostatistical kriging interpolation (ArcMap 10.6.1) of the nightly PSB sums for each of the power spectra bands associated with the fish species heard (Table 2) from the digitalized sonobuoy tapes.

The Bay River location was used thereafter for temporal comparisons with the LARS and icListen recording systems in focal years 2006 through 2018 (Fig. 2). Spotted seatrout and red drum are known to spawn in this Bay River grid location. Also, the Bay River grid location is affected by periodic hypoxic conditions and salinity variation, thus temporal changes in the soundscape were associated with these changing environmental conditions. Long-term continuous recordings were made at the Bay River grid fish and at known fish spawning hotspots (Fig. 2). The LARS recorders were used to record the soundscape from May through October 2006 (with a programmed recording duty cycle of 10 s recordings every 15 min). In addition, a water quality sonde (YSI model 6600) was deployed alongside the LARS to monitor temperature (Luczkovich et al. 2013a). The icListen recording system was deployed within the Bay River grid and at a nearby location from August through October in both 2017 and 2018. The icListen duty cycle was programmed to log 5-min recordings at 15 min intervals during this time.

## Spatial Variation in Soundscape

There are differences in the soundscape within the eastern (Ocracoke Inlet) and western (Bay River) sonobuoy grids, with red drum "knocking" sounds and spotted seatrout "grunting" sounds heard and scored using the SNDI index and then interpolated to create soundscape maps (Fig. 3 is the soundscape map for red drum; Fig. 4 is the soundscape map for spotted seatrout). Red drum were highly aggregated and localized in these two grids, occurring more often in deep water (>3 m), whereas spotted seatrout were widespread and occurred over much of the area of both grids; they were heard more often in shallow water (<3 m). The weakfish and silver perch were more dominant in the eastern grid (Ocracoke Inlet) in higher salinity waters (Fig. 5 is the map for weakfish, and Fig. 6 is the map for silver perch).

## Temporal Variation in Soundscape

### Diurnal Variation in the Soundscape

There was a regular nocturnal chorusing of fish on these passive acoustic recordings. Fish made sounds before sunset but PSD band sums peaked after sunset. As an illustrative example, a typical Sciaenidae fish chorus can be observed on 18 Aug

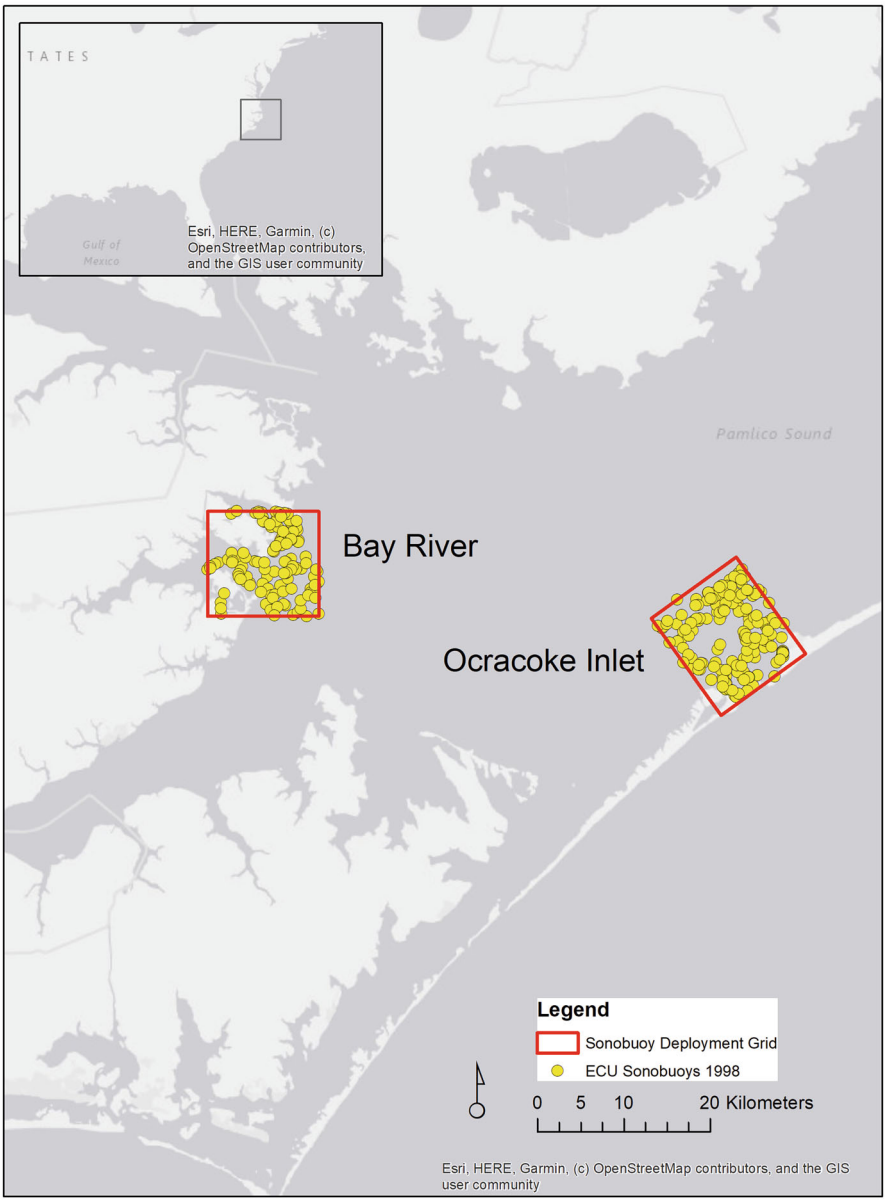

**Fig. 1** Overview map of the Bay River and Ocracoke Inlet study sites in Pamlico Sound North Carolina, USA. ECU Sonobuoys were deployed (yellow circles) May–Oct 1998. Also placed in the Bay River: the LARS recording system was deployed in May–Oct 2006; the icListen hydrophone recording systems was deployed in Aug–Oct 2017 and 2018 (Base map reprinted with permission from Esri, Inc.)

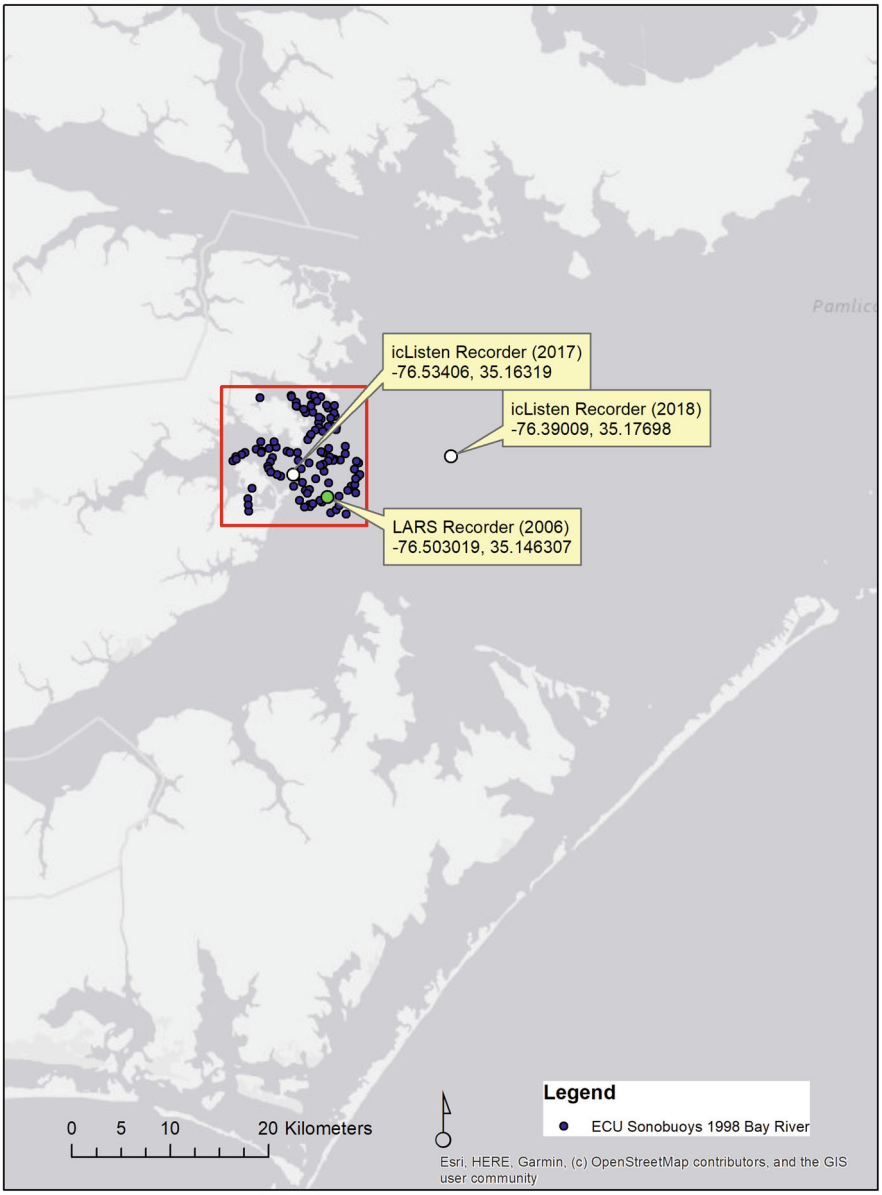

**Fig. 2** Overview map of the Bay River study sites in Pamlico Sound North Carolina, USA. ECU Sonobuoys were deployed at the points indicated during May–Oct 1998. The LARS recording system was deployed in May–Oct 2006 at the position indicated. The icListen hydrophone recording systems was deployed at two locations indicated during Aug–Oct 2017 and again in 2018 (Base map reprinted with permission from Esri, Inc.)

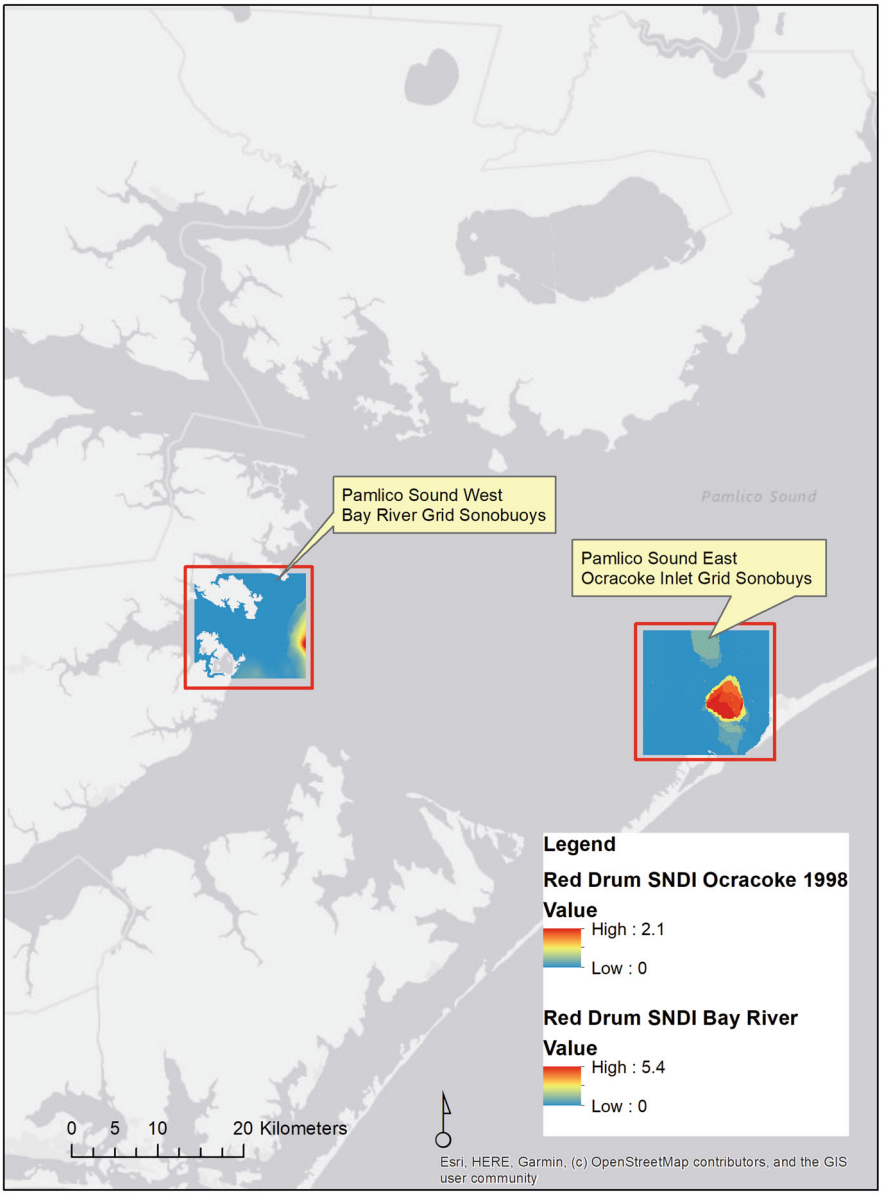

**Fig. 3** The soundscape map for red drum *Sciaenops ocellatus* based on kriging interpolation of Summed Nightly Drumming Index SNDI values from sonobuoy recordings made in 1998 at Bay River and Ocracoke Inlet grids in Pamlico Sound, North Carolina, USA (Base map reprinted with permission from Esri, Inc.)

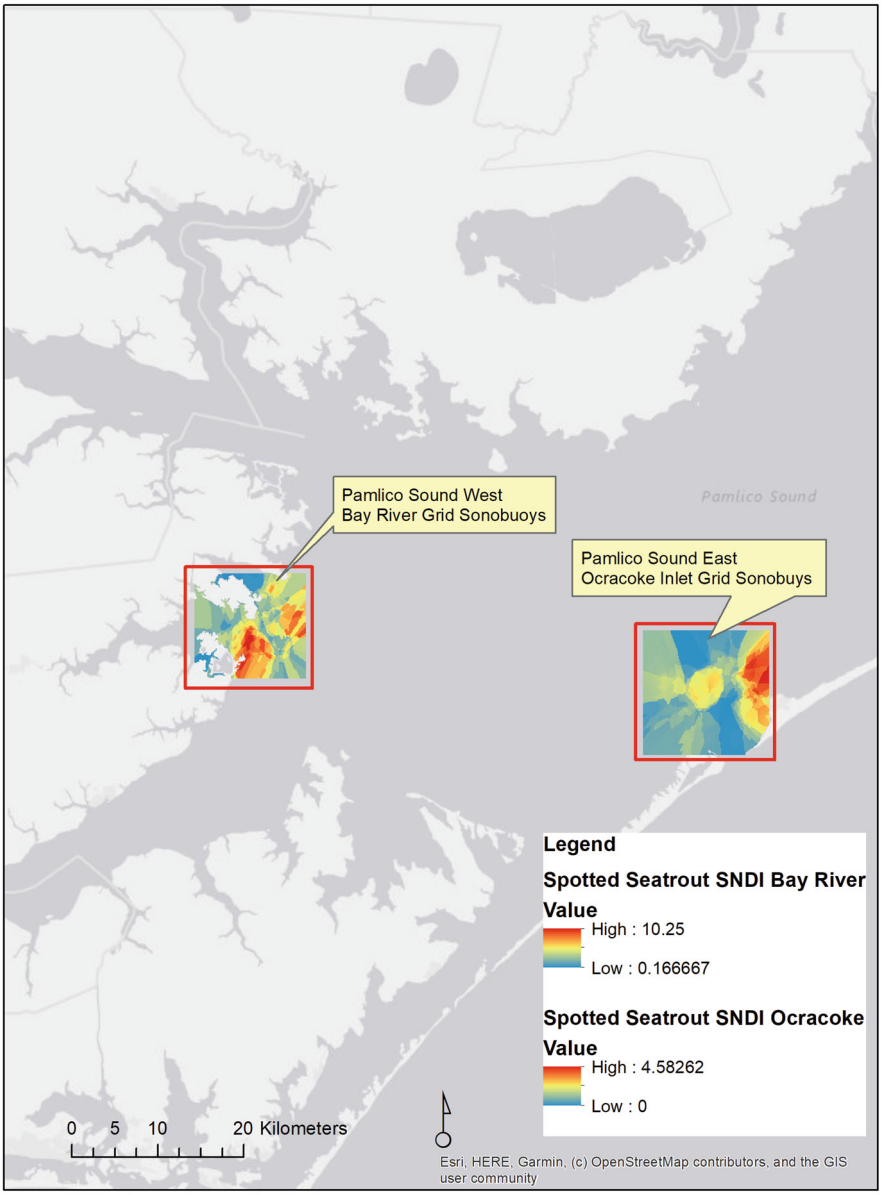

**Fig. 4** The soundscape map for spotted seatrout *Cynoscion nebulosus* based on kriging interpolation of Summed Nightly Drumming Index SNDI values from sonobuoy recordings made in 1998 at Bay River and Ocracoke Inlet grids in Pamlico Sound, North Carolina, USA (Base map reprinted with permission from Esri, Inc.)

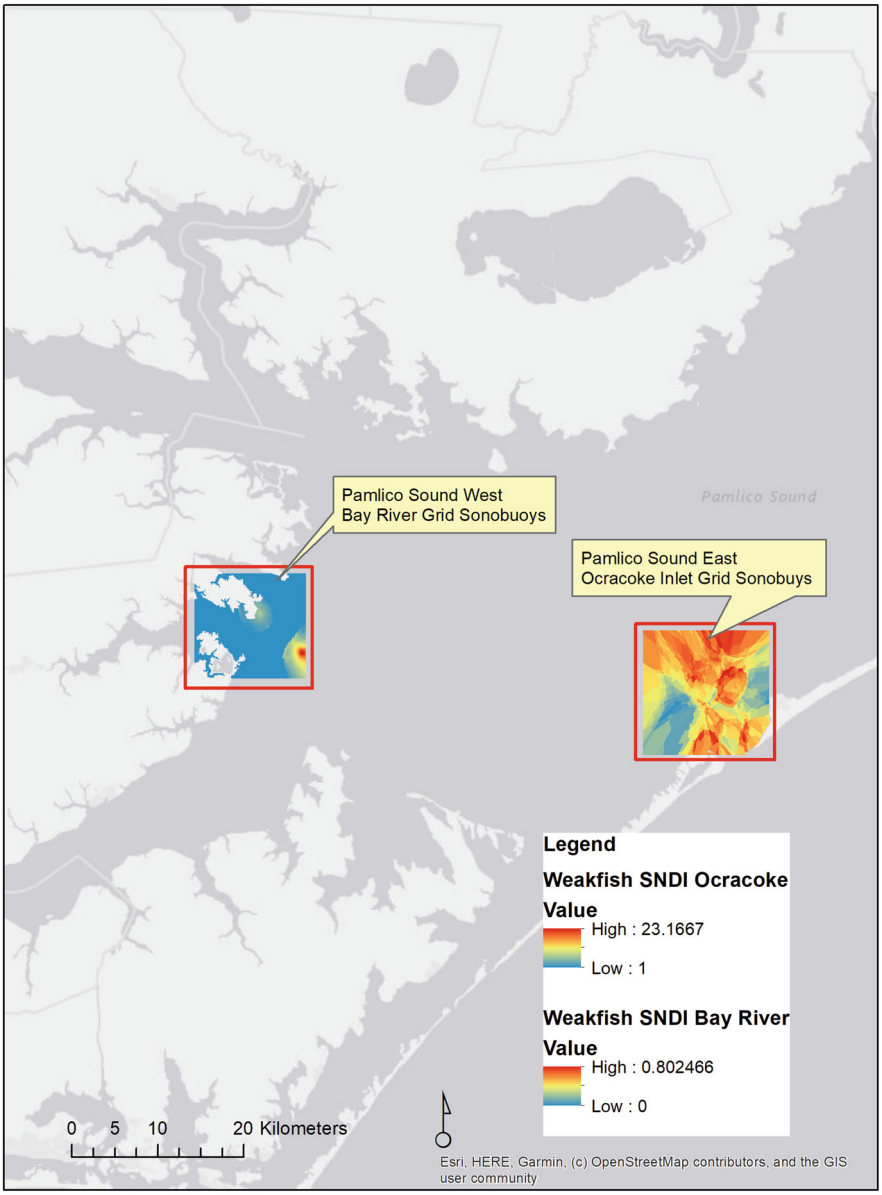

**Fig. 5** The soundscape map for weakfish *Cynoscion regalis* based on kriging interpolation of Summed Nightly Drumming Index SNDI values from sonobuoy recordings made in 1998 at Bay River and Ocracoke Inlet grids in Pamlico Sound, North Carolina, USA (Base map reprinted with permission from Esri, Inc.)

2018 in the Bay River grid area (Fig. 7). The PSB sums (Fig. 7a) indicated that the primary contributors early after sunset were red drum and spotted seatrout (Band I 100–200 Hz and Band III 300–600 Hz show peaks on 18 Aug 2018 at approximately 21:00 local time UTC −5 h; the calls of these species were confirmed by listening to

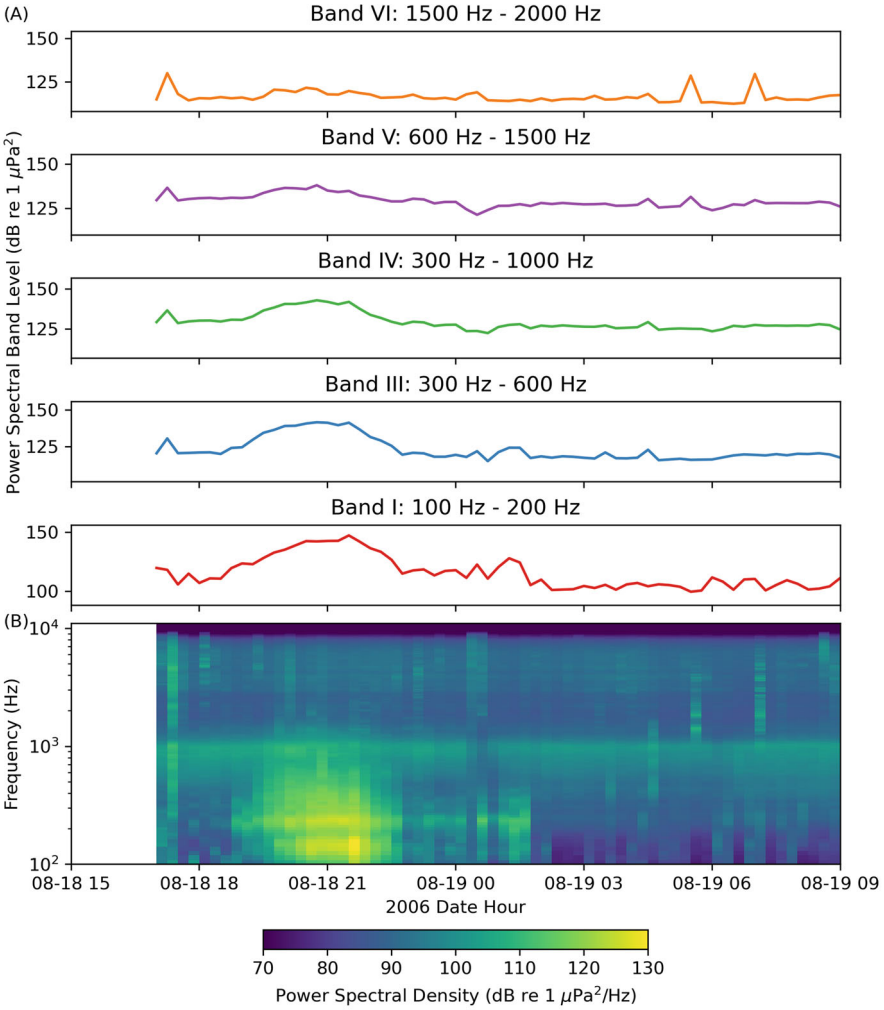

**Fig. 7** The nocturnal choruses of fish the Bay River grid on 18 Aug 2006 1700 through 9 Aug 2006 0900 (local time UTC −5. (**a**) The power spectral band sums (dB re 1 μPa$^2$/Hz) for the frequency bands indicated and associated with fish species are given in Table 2. (**b**) The composite spectrogram of recordings made that night using the LARS recorder system

these recordings). This mixed species sciaenid chorus ended by midnight on 18 Aug (0000 local time UTC −5 h, Fig. 7b). Later in this same set of recordings on 19 Aug between 0400 and 0600 local times (UTC −5 h), a rise was detected in Band VI associated with striped cusk eels *Ophidion marginatum* (Fig. 7a). These are higher frequency (1.5–2.0 kHz) "chattering" calls (Fig. 7b). These sciaenid choruses and individual striped cusk eel chatter sounds became less dominant by daybreak (after 0600 local time) and remained low during each diurnal period, increasing again at sunset the next night. This pattern repeated every night throughout the summer.

## Seasonal Variation in the Soundscape

The soundscape was recorded at a single location (Fig. 2, Latitude 35.146307N and Longitude 76.503019W) in the Bay River grid 2006 from 30 April through 04 October using the LARS passive acoustic recording system. In this long sequence of recordings, using a 10-s recording period with a duty cycle repeating at 600 s intervals (every 10 min), taken over 157 days or more than 5 months, the changing phenology of the soundscape was visualized in a composite spectrogram. The seasonal change in the soundscape reflected different species participating in the chorusing, changing environmental conditions that affected the calling behavior, including warming and cooling water temperatures, lengthening and shortening photoperiods, salinity fluctuations, hypoxic events, multiple species of Sciaenidae (silver perch, weakfish, spotted seatrout, Atlantic croaker *Micropogonias undulatus*, and red drum), Batrachoididae (oyster toadfish *Opsanus tau*), and striped cusk eels performing their nightly choruses with quiet daytime periods intervening were recorded. These increases and decreases in sound amplitude in each of the frequency bands associated with these different fish species (Table 2) are visible as nightly pulsing variations in the PSB sums plots (Fig. 8a 30 April–7 Jun; Fig. 9a 30 June–15 Aug; Fig. 10a, 20 Aug–25 Sep; Fig. 11a, 03 Oct–10 Oct; and Fig. 12a, 28 Sep–04 Nov). Each night, as the fish in the area reached a crescendo of calling activity in a chorus, the PSD sum increased, and in the daytime, as the fish chorusing activity ceased, the PSB sums fell back to a baseline. This pattern was repeated each night for the entire summer, but the choruses' dominant frequency shifted upwards as the environment changed. The water became warmer in May and June, rising from 13 °C on 3 May to 23 °C by 30 May on the water quality sonde deployed along with the LARS (Luczkovich et al. 2013b). As water temperature warmed, the dominant frequency of the fish choruses increased (Fig. 8b) from <200 Hz to 200–250 Hz by 30 May. Water temperatures stabilized in the summer months of July and August (26–28 °C), leading to a regular pattern of seatrout grunting choruses (Fig. 9), and then fell back to lower frequencies in the cooler water in Sep and Oct (Fig. 10, Fig. 11). In Fig. 8b, a frequency band around 200 Hz (Band I, 100–200 Hz) can be observed increasing in frequency each day through the month of May; this activity persisted during the daytime. This frequency band increase was due to an increase in oyster toadfish *Opsanus tau* calling (human listeners could discern individual toadfish calling during daytime on these recordings) and was associated with the warming of the water temperature at the site. Silver perch (PSB Band V

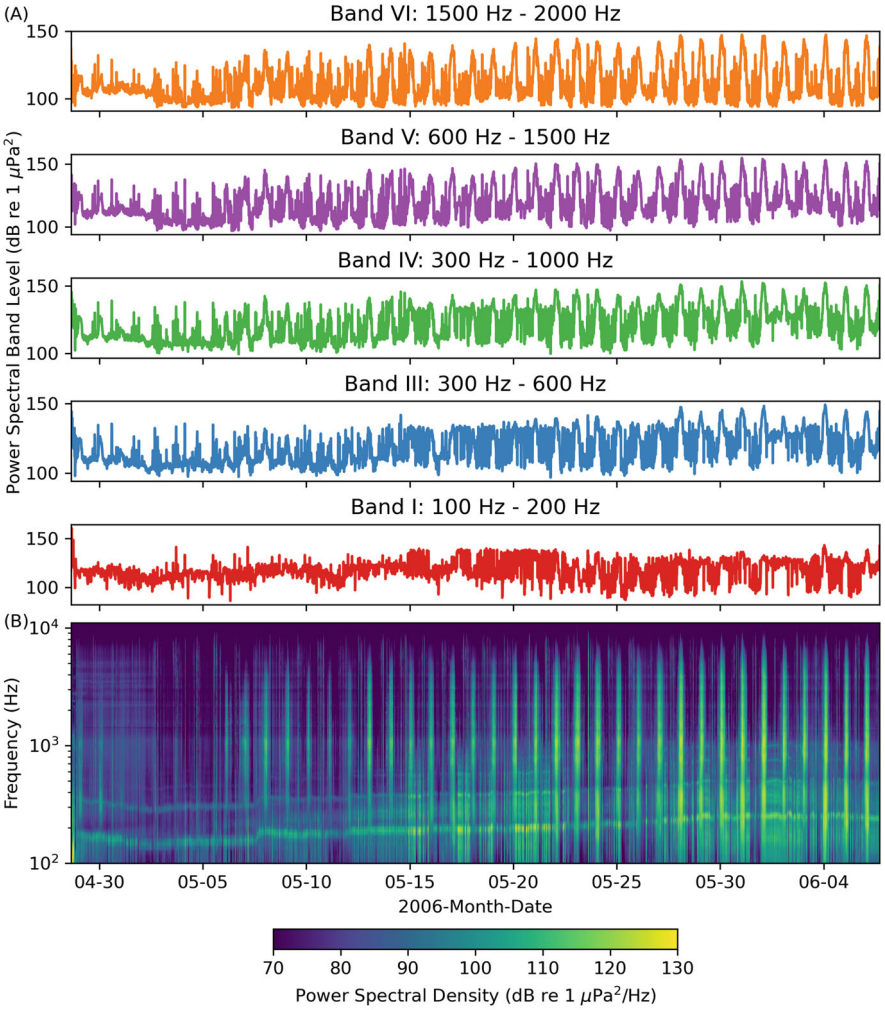

**Fig. 8** The PSB sums and composite spectrograms plotted over time from LARS recordings made between 29 April and 6 June 2006 in the Bay River grid. (**a**) PSB sums for frequency Bands I, III, IV, V, and VI associated with fish species in Table 2. (**b**) The composite spectrogram of the soundscape for this same period with frequency on a log scale (100 Hz–10 kHz) and color ramp scale. All PSD sums and color ramp units are given in dB re 1 μPa$^2$/Hz

600–1500 Hz) frequency band also showed this increase in temperature-associated calling activity, although this species was largely nocturnal in its calling activity. Increased PSB sum with increased water temperature can be seen as increased peaks in the Bands III, IV, and V and as broad spectral pulses (300–1500 Hz) in the composite spectrogram occurring each night (Fig. 8b); these nocturnal choruses became more intense at the end of May and the start of June. During July and August (Fig. 9), the nightly spotted seatrout chorus became less intense and no longer

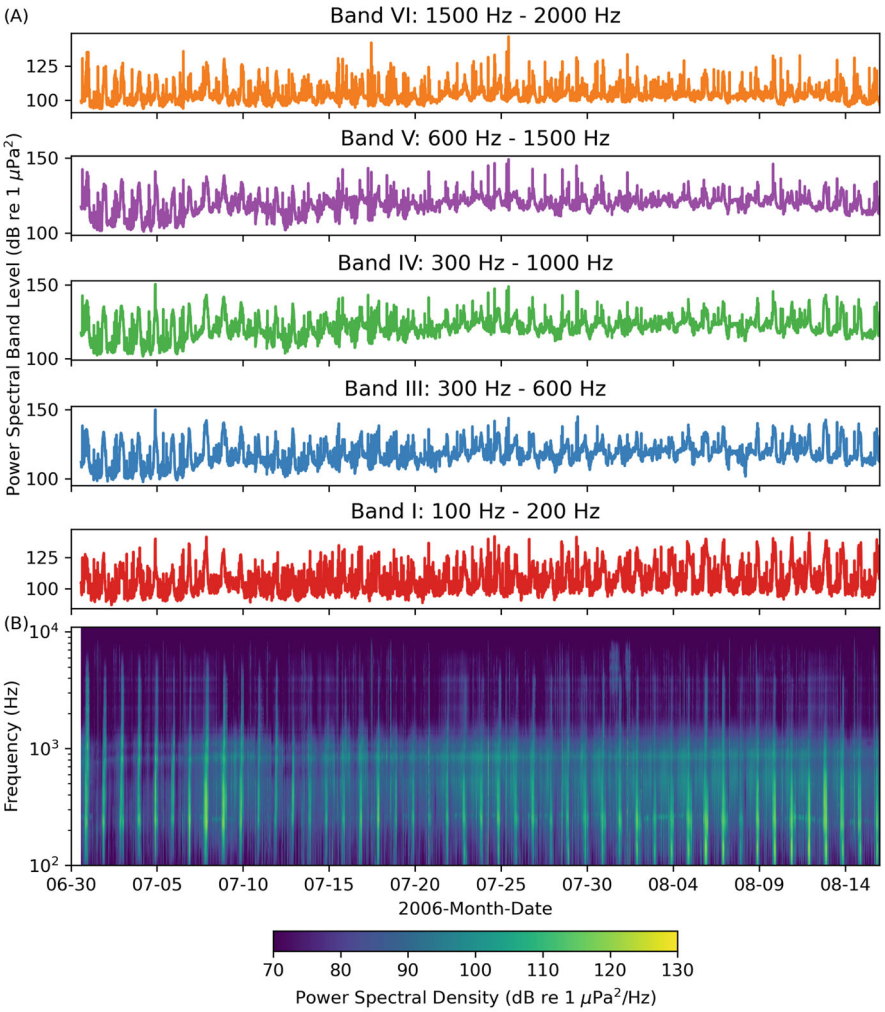

**Fig. 9** The PSB sums and composite spectrograms plotted over time from LARS recordings made between 30 June and 16 Aug 2006 in the Bay River grid. (**a**) PSB sums for frequency Bands I, III, IV, V, and VI associated with fish species in Table 2. (**b**) The composite spectrogram of the soundscape for this same period with frequency on a log scale (100 Hz–10 kHz) and color ramp scale. had the dominant frequency of 200 Hz during the daytime, as the oyster toadfish had ceased calling as much during the day. Instead, during this summer period, spotted seatrout grunts (Band III 300–600 Hz) and red drum knocking (Band I 100–200 Hz) can be heard in late August and September 2006 as part of the nightly mixed sciaenid chorus (Fig. 10). In addition, the nightly chorus at this time was dominated by the grunting of spotted seatrout (Fig. 10a, Band III, 300–600 Hz), which then dominated the soundscape nocturnally. By the end of September (24 Sep 2006), this seatrout

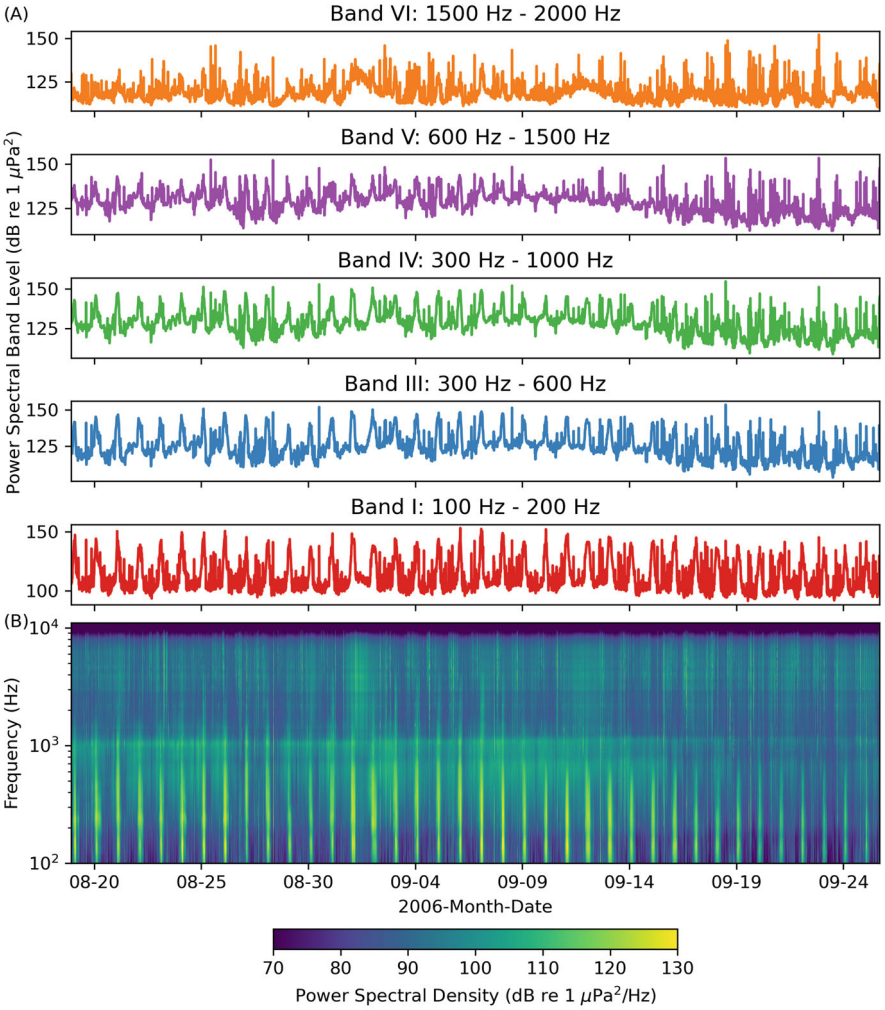

**Fig. 10** The PSB sums and composite spectrograms plotted over time from LARS recordings made between 20 Aug and 25 Sep 2006 in the Bay River grid. (**a**) PSB sums for frequency Bands I, III, IV, V, and VI associated with fish species in Table 2. (**b**) The composite spectrogram of the soundscape for this same period with frequency on a log scale (100 Hz–10 kHz) and color ramp scale. All PSD sums and color ramp units are given in dB re 1 μPa$^2$/Hz

chorus had become less dominant in the soundscape (Fig. 10b). A listener could also hear Atlantic croaker "popping" sounds in this period in Band IV (Fig. 10a), the sound of which overlaps with the *Cynoscion* grunts in Band III but has higher frequency components. In Fig. 11a, b, at the beginning of October, a shorter time window period (03 October through 11 October) was visualized in order to observe the diminished Sciaenidae chorus. (It is still dominated by the species above, spotted seatrout, red drum, and Atlantic croaker, but the chorus is greatly reduced in calling activity at the

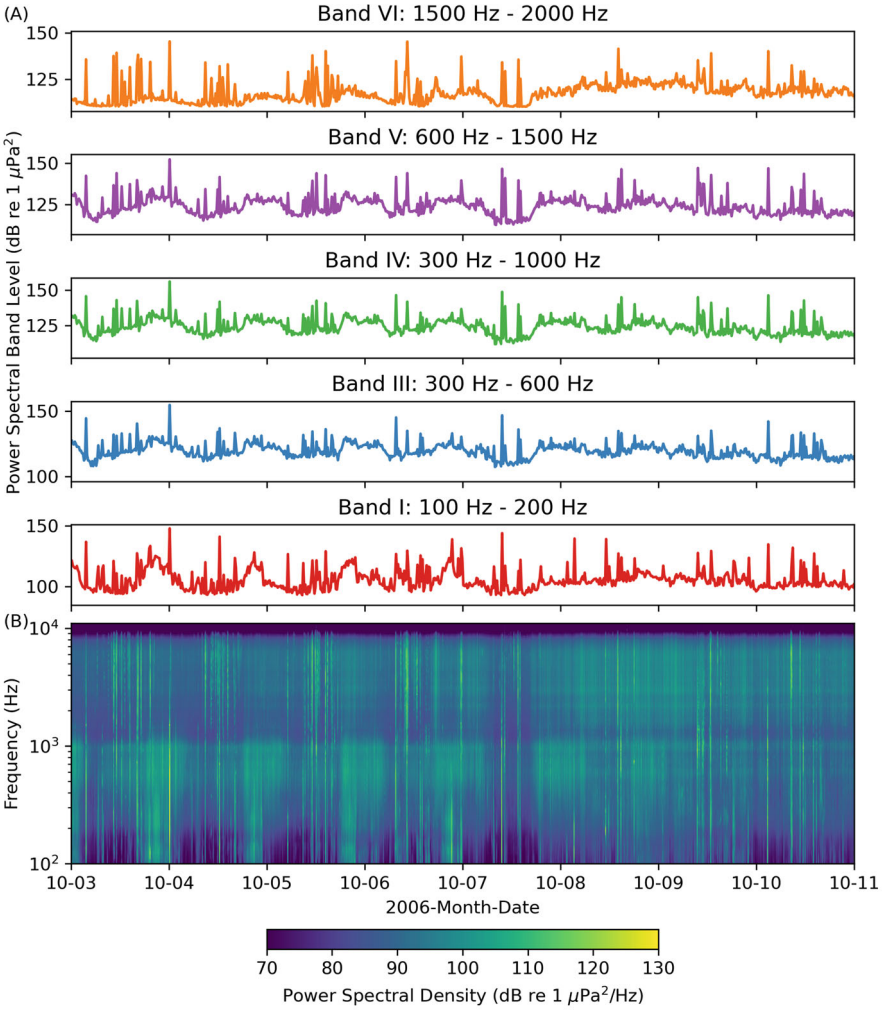

**Fig. 11** The PSB sums and composite spectrograms plotted over a short time window so the diminishing Sciaenidae chorusing can be observed from LARS recordings made between 3 Oct and 11 Oct 2006 in the Bay River grid. (**a**) PSB sums for frequency Bands I, III, IV, V, and VI associated with fish species in Table 2. (**b**) The composite spectrogram of the soundscape for this same period with frequency on a log scale (100 Hz–10 kHz) and color ramp scale. All PSD sums and color ramp units are given in dB re 1 μPa$^2$/Hz

end of this period.) These nightly Sciaenidae choruses persisted throughout October (PSB sums in Fig. 12a and in the spectrogram in Fig. 12b), but at a lower intensity of calling. This is due most likely to the shortening photoperiods, and colder water temperatures (water temperature dropped from 26 °C to 20 °C) at this time of year. By 9 November, the calling activity and fish chorusing is at a minimum, although it still occurs nocturnally, and most spawning activity has ceased (Fig. 12).

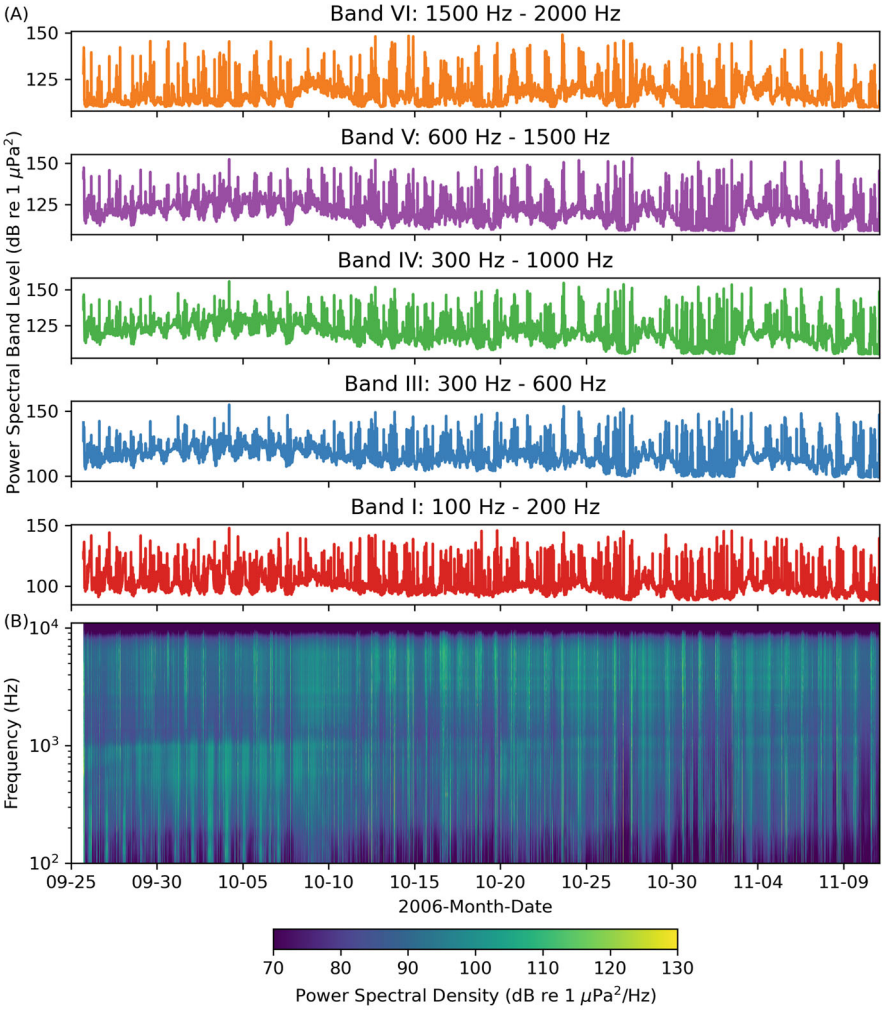

**Fig. 12** The PSB sums and composite spectrograms plotted over time from LARS recordings made between 25 Sep and 11 Nov 2006 in the Bay River grid. (**a**) PSB sums for frequency Bands I, III, IV, V, and VI associated with fish species in Table 2. (**b**) The composite spectrogram of the soundscape for this same period with frequency on a log scale (100 Hz–10 kHz) and color ramp scale. All PSD sums and color ramp units are given in dB re 1 μPa$^2$/Hz

## Interannual Variation in Soundscape

The Band I (red drum 100–200 Hz) PSB sum intensity over the years 2006–2018 at sites in the Bay River grid and on Brant Island Shoal was visualized in a composite spectrogram (Fig. 2). There was no reliable intercalibration possible for the ECU Sonobuoys used in 1998 due to reliability issues with old cassette decks, so these recordings were omitted in the interannual comparisons, limiting this to a 12-year

comparison (2006–2018). These measurements were restricted to the months of Aug–Oct, when red drum are actively calling and reproduction is occurring, effectively excluding any other species besides the red drum when examining Band 1. The icListen recording system was used as the comparative standard and transformed the LARS PSB sums to an equivalent level. Generally, these two recording systems responded similarly when tested in the pool and in air calibration tests to changes in the sound source frequencies and levels. This was especially true in Band 1, but a conversion factor (−0.7 dB LARS to icListen, with the LARS measuring slightly lower than the icListen in this frequency range based on the air and pool calibration tests) needed to be applied to standardize these systems' responses.

The result of the interannual comparison is shown in Fig. 13. There was a significant decline of 27.5 dB in PSB sum values associated with this Band 1 across the years (Table 3; ANOVA $F_{2,24} = 58.7$, $5.72 \times 10^{-10}$). The year with the greatest PSB sum for red drum was 2006, and this has declined over time so 2018 was the lowest year. The difference between 2006 and 2018 was the most significant (Table 3, Tukey's HSD P = 0.000001), although there was a significant decline of 19.4 dB between 2006 and 2017 as well. This suggests that a decline in the calling activity of red drum in the area around the Bay River has occurred over the period 2006–2018. This is a region well known to local fishermen that target the large spawning red drum aggregations for sport fishing. This soundscape measure of fish calling activity could be due to lower red drum population size perhaps due to increased sportfish harvest (prior to this observation period, between 2000 and 2006, red drum sport fish harvest averaged 823,991 fish per year ±18.17 Proportional

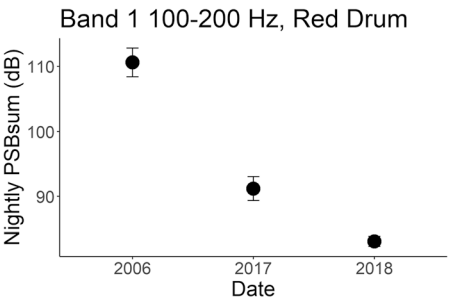

**Fig. 13** A plot of the mean nightly PSB sum during the months of Aug, Sep, and Oct over the years 2006 through 2018 for Band 1 (100–200 Hz), which is associated with red drum Sciaenops ocellatus calling activity. The means are dB ± 1SE (re 1 $\mu Pa^2/Hz$)

Standard Error (PSE) in North Carolina, whereas in 2017 and 2018, the sportfishing harvest had increased to 2,156,815 ± 18.62 PSE fish per year between 2014 and 2018; NOAA Marine Recreational Information program MRIP statistics, https://www.fisheries.noaa.gov/data-tools/recreational-fisheries-statistics-queries). Another possible cause in the soundscape associated with adult red drum might be due to migration away from this part of the ecosystem to avoid hypoxic stress in the low salinity regions from river runoff and nutrients input causing algal blooms at the river mouth, or some other factors as yet unknown. Water temperature alone is not likely to be responsible for this decline, because if anything, water temperatures have increased over this period.

## Summary

The soundscape in Pamlico Sound has become noticeably quieter in the frequency bands (<1 kHz) used by fishes after accounting for variation in the three recording systems used. There were significant changes in PSB Band I (red drum adults in the Sciaenidae), with a 27.5 dB decrease in PSB sum values. This acoustic soundscape metric (PSB sum) can be used to assess changes in the calling behavior of these fishes, which is closely tied to their spawning and reproductive activity and should be used as a proxy for the health of this Pamlico Sound red drum population. The observed decline in PSB Band I is an indication that the red drum spawning behavior is declining. The methods of soundscape measurements proposed here can be used as a long-term fishery assessment tool.

Introduction ..... 322
Methods ..... 322
References ..... 323

**Abstract**

The underwater acoustic coastal environment is presented in views of seasonal climatology and potential interactions of sound waves with mesoscale and submesoscale processes are examined. The sound speed profiles (SSPs) are computed from two-/three-dimensional underwater acoustic propagation models and observed conductivity-temperature-depth profiles, and submesoscale realistic numerical model outputs. The density profiles, multivariate regressed with a temporal mean, seasonal basis functions, and a linear trend are translated into the propagation and dissipation of the SSP. Moreover, the density profiles in the cross-shore direction are decomposed into a constant density profile in the cross-shore direction, and density profiles having mesoscale and submesoscale features using a band-pass filter in the frequency domain and wavenumber domain. In this chapter, the analysis method to evaluate the influence of submesoscale and mesoscale oceanic variability on the sound propagation is only presented.

## Introduction

Acoustic waves propagate through the compression and decompression of the medium, and propagation speed depends on the bulk modulus and density of the medium (e.g., Newton-Laplace equation) because wave propagation is directly proportional to stiffness (elasticity) and inversely proportional to the mass of inertia. In particular, the acoustic waves in water have been to study acoustic tomography, marine mammals, underwater communications, defense, and security (e.g., Forget et al. (2015), Johnson and Tyack (2003), and Munk et al. (2009)).

This chapter aims to examine the variability of underwater acoustic environments under seasonal density profiles and the modified acoustic wave propagations associated with interactions between acoustic waves and meso-/submeso-scale eddies, fronts, and internal tides in a coastal environment (e.g., Yoo et al. (2018)). Thus, the climatology of density vertical transects (e.g., time mean, amplitudes and phases at the annual, and semiannual frequencies) from Lee et al. (2019) are adopted and the two-dimensional wave propagation model to derive the underwater acoustic environments is applied. Then, the acoustic wave propagations under scenarios of meso-/submeso-scale eddies, fronts, and internal tides are examined. There are potential deflections (or reflection) of sound speed due to vertically modulated thermoclines associated with temporal variability of three-dimensional density structures in the intra-annual (i.e., seasonal superharmonic frequencies), seasonal, and inter-annual in inter-annual timescales. This work can provide the basic information on the acoustical ocean environments of underwater communication of subsurface oceanographic samplings and explorations (e.g., Send et al. (2012)).

## Methods

The sound speed profiles (SSP) in the cross-shore direction are decomposed into a constant SSP in the cross-shore direction and SSPs having mesoscale and submesoscale features:

$$c(r,z,t) = c_C(z) + c_M(r,z,t;|\sigma| \le \sigma_0) + c_S(r,z,t;|\sigma| > \sigma_0)$$

where a constant SSP ($c_C$) is computed with an average of the sound speed (SS) in time and cross-shore direction at each depth. The mesoscale SSPs ($c_M$) are estimated with first few modes of the spatial time series of SSPs longer than 10 days ($\sigma_0 = 0.1$ cycles per day (cpd)) in the depth and cross-shore direction. A low-pass filter ($|\sigma| \le \sigma_0$) can be applied to the demeaned spatial SSPs first, then the singular value decomposition (SVD) on the spatial time series of SSPs is applied to remove the submesoscale spatial structures. The first few modes accounting for 90% of the sum of entire singular values are only used. The submesoscale SSPs ($c_S$) are estimated with the rest of SSP by subtracting the constant SSP and mesoscale SSPs. Although statistical analysis using SVD may not isolate the dynamics of mesoscale and submesocale or the physical processes in their representing spatial

length scales [$O(100)$ km for mesoscale and $O(1–10)$ km for submesoscale], the low-pass filter takes care of most of decomposition.

As another way to isolate the mesoscale SSPs, a wavenumber-domain band-pass filter of the SSPs with a constant SSP removed at each depth can be applied:

$$c(r,z) = c_C(z) + c_M(r,z) + c_S(r,z)$$

where

$$c_M(r,z) = \sum_{0<k<k_0} \widehat{c}(k,z)e^{ikr}$$

$$c_S(r,z) = \sum_{k\geq k_0} \widehat{c}(k,z)e^{ikr}$$

and $k_0$ denotes a threshold wavenumber to delineate the mesoscale and submesoscale features. The horizontal wavenumber ($k$) is defined as the cross-shore distance at each depth,

$$k(z) = 2\pi\frac{m}{L_z}$$

which may not be identical for all cases because of the nonconstant continental shelf and bottom bathymetry ($m = 1, 2, \ldots M$). Thus, the wavenumber-domain can be defined differently at each depth and may not filter the data in a consistent way. This can lead the vertically discontinued or mismatched SS and generate unnecessary features of SS propagations.

Capacity of Fishes to Learn to Associate Ambient Sounds with Environmental Variables ..... 345
Conclusion ..... 345
References ..... 346

**Abstract**

In the field of fish bioacoustics, sounds other than conspecific communication sounds have generally been viewed as background noise interfering with the detection of communication signals. However, many fish species do not vocalize but still possess acute hearing, suggesting that fish hearing may have evolved, in part, to detect and extract information from the "ambient sounds" present in the environment. This chapter highlights some of the major sources of natural ambient sound and discusses how they function as sources of biologically relevant information. Some fishes can extract information about larval settlement sites, spawning events, food sources, and approaching predators from natural ambient sound. Instances where natural ambient sounds function as noise are also discussed. Ambient sound can mask hearing and some vocalizing fishes have been known to either produce louder vocalizations or change vocalization rates to cope with increases in ambient sound levels. Several species living in shallow water habitats vocalize at frequencies that coincide with a dip in acoustic energy in the local ambient sound spectrum. Data on the behavioral and physiological responses of fishes to natural ambient sounds remains scarce. Such information could be important for understanding how anthropogenic sounds affect the survival and reproduction of fishes.

## Introduction

The International Organization for Standardization, ISO 18405:2017 document defines ambient sound as "sound that would be present in the absence of a specified activity." "Specified activities" include the act of measuring sound, and the radiation of sound from specified sound sources. Ambient sound according to ISO is thus defined based on the perspective of a human experimenter measuring sound, where ambient sound represents the "background sound" from sources other than the one being measured.

Animals produce communication signals to convey information from one animal (sender) to another (receiver) in order to affect the behavior of the recipient (Seyfarth and Cheney 2003). A "signal" in the context of animal communication is defined as an action or behavior produced by a sender that has evolved to convey information and help the receiver make a decision, which, on average, is beneficial to both sender and receiver (Myrberg 1981; Bradbury and Vehrencamp 2011). In contrast, "cues"

also provide information to a receiver, but the content has not been shaped by natural selection in order to benefit both sender and receiver (Bradbury and Vehrencamp 2011). Since it is well established that receivers detect and interpret conspecific acoustic communication signals, any sound in the environment apart from conspecific acoustic signals can be considered as ambient or background sound and a potential source of cues for an animal. In this chapter, ambient sound is thus defined from an animal's perspective as "all the sounds impinging on the animal in a given environment apart from conspecific acoustic communication signals."

Underwater environments are bathed in ambient sound (Hildebrand 2009; Rountree et al. 2020). Before the invention of sound-producing steam ships in the early 1800s (Harris 2022), ambient sound in aquatic environments was predominantly composed of sounds generated by biotic sources such as invertebrates, fishes, and marine mammals (biophony), and abiotic sources such as wind, rainfall, and other environmental phenomena (geophony). Despite recent increases in anthropogenic sound in many aquatic environments, natural sounds still constitute a major component of the underwater ambient sound spectrum (Hildebrand 2009; Frisk 2012).

Actinopterygian or "ray-finned" fishes are the planet's largest and most diverse group of vertebrates (Nelson et al. 2016). At least a thousand species of ray-finned fishes (henceforth called "fishes" for brevity) have been known to actively produce sounds for communication (Looby et al. 2022), and there are likely many more vocal species. The "matched filter hypothesis" proposed by Capranica and Moffat (1983) maintains that the auditory systems of animals are tuned to detect the frequencies present in conspecific acoustic communication signals. According to this hypothesis, any sound other than that produced by a conspecific interferes with the detection of conspecific signals. However, the matched filter hypothesis does not explain why nonvocal fishes have specific tuning characteristics associated with their auditory system. The list of nonvocalizing species includes some species from families such as Cyprinidae (Jacobs and Tavolga 1967) and Mormyridae (Fletcher and Crawford 2001), which possess accessory hearing structures that improve auditory sensitivity and increase the bandwidth of hearing. Additionally, sound production is not an ancestral trait in fishes, evolving independently several times across multiple lineages (Rice et al. 2022). Therefore, since all fishes can hear (Popper et al. 2022), hearing in fishes likely evolved to detect and extract information from ambient sound in the environment.

Buckingham (1999) proposed the concept of "acoustic daylight" wherein similar to how cameras use daylight scattered from objects to form an image of the environment, ambient sound could theoretically be exploited to acoustically image the aquatic environment. Fay (2009) developed this concept in the context of fish hearing and proposed that fishes could potentially use ambient sound as acoustic daylight, extracting information about the surrounding environment. In other words, natural ambient sounds can function as "cues." Thus, natural ambient sounds can potentially provide important behaviorally relevant information that can inform the receiver and guide a particular behavior.

In certain situations, however, natural sources of ambient sound can act as noise, masking the detection of environmental sounds important to the receiver for survival and reproduction such as mating vocalizations, sounds made by approaching predators, etc. *Here, noise is defined as any sound which interferes with the detection and interpretation of biologically relevant signals and cues important for the animal.*

This chapter highlights the major natural sources of ambient sound in the context of how such sources could provide useful information to fishes. Examples from literature on how fishes use natural ambient sounds to extract beneficial information about the environment are summarized. Cases where natural ambient sounds function as noise, interfering with the detection of relevant signals and environmental cues, are also discussed. The chapter ends with a discussion of information gaps in our understanding of how natural ambient sounds affect the physiology and behavior of fishes, and how uncovering this information could provide a more nuanced understanding of the impacts of anthropogenic sounds on fishes.

## Major Sources of Natural Ambient Sounds and their Putative Biological Relevance

Natural ambient sounds can be generated by abiotic sources (geophony) and by animals (biophony). In this section, only those sources of natural ambient sound that fall within the hearing ranges of fishes will be discussed. Fishes are most sensitive to sounds below 1000 Hz, although certain fishes with hearing specializations such as ostariophysians can detect sounds up to 3 kHz (Ladich and Fay 2013), and some alosids can detect ultrasonic frequencies (30–150 kHz) (Plachta and Popper 2003). Prominent sound sources that have been omitted in the section are sounds generated by rainfall, which occur between 10–40 kHz (Scrimger et al. 1987), and sounds generated by the thermal agitation of water molecules (>50 kHz) (Hildebrand 2009). Most studies characterizing natural sources of ambient sound measure sound pressure, whereas fish ears are thought to primarily function as detectors of particle motion (Popper and Hawkins 2018). Therefore, using sound pressure data to infer how fishes extract information from natural ambient sounds likely has limitations.

### Geophony

Geophony that is within the audible range of fishes is primarily generated by: 1) weather events such as wind, 2) geological phenomena such as earthquakes, volcanoes, and release of water and smoke from hydrothermal vents, 3) sea ice, and 4) flowing and falling water (Table 1). To the best of the authors' knowledge, no data exists on the behavioral responses of fishes to geophony, and whether fishes extract information from these sound sources.

**Table 1** Major sources of geophony and hypothesized biologically relevant information contained in them. See the main text for more details

| Sound source | | Frequency content | Hypothesized biologically relevant information contained in these sounds |
|---|---|---|---|
| 1. | Wind-generated waves | ~ 0.5–50 kHz (Hildebrand 2009) | Depth along the water column; and distance from the shoreline. |
| 2. | Flowing water (rivers and brooks) | ~ 10–100 Hz (Vračar and Mijić 2011; Martin and Popper 2016) | Rate of water flow; identity of different habitats such as river stretches and branch points (Velde et al. 2022). |
| 3. | Waterfalls | < 1000 Hz (Lugli and Fine 2003)[a] | Location of jumping sites for migratory fishes such as salmon. |
| 4. | Sea ice | ~ 100–1000 Hz (Miksis-Olds et al. 2013) | – |
| 5. | Underwater earthquakes | ~ 5–35 Hz (Butler 2006) | Occurrence of earthquakes, which have been known to cause mortality in fishes. |
| 6. | Hydrothermal vents | ~ 10–250 Hz (Crone et al. 2006) | Location of hydrothermal vents. |
| 7. | Underwater volcanoes | < ~600 Hz (Chadwick Jr. et al. 2008) | Occurrence of volcanic eruptions, which have been known to cause mortality in fishes. |

[a]The authors characterized acoustic frequencies only up to 1000 Hz;, therefore it is possible that acoustic energy is contained at frequencies >1000 Hz

## Wind-Generated Waves

Breaking waves generated at the water's surface by winds are the primary source of geophony in the oceans, with a frequency range of ~0.5–50 kHz (Hildebrand 2009). There is a strong correlation between windspeed and sound pressure levels in marine environments, even at depths of 1000–2000 m (Kurahashi and Gratta 2008). The cues used by fishes to estimate water depth are not clearly understood, although recent research suggests that hydrostatic pressure may be an important cue (Davis et al. 2021). Since wind-generated sound decays with depth (Short 2005), the presence or absence of this sound might provide fishes with a rough estimate of their vertical position along the water column. This hypothesis requires that fishes possess an internal model of how ambient sound decays with depth. Alternatively, fishes could learn to associate the loudness and spectral content of ambient sound conditions with water depth. No data currently exists, however, to support this hypothesis.

Bardyshev et al. (1973) recorded ambient sound at various distances from the shoreline and found that the ambient sound was more pulsatile closer to the shore, with large increases and decreases in the amplitude of acoustic pressure. The distribution of pressure amplitude significantly differed from a gaussian distribution up to 600 m from the shore. Beyond this distance, the distribution of pressure amplitude of ambient sound resembled that of gaussian white noise, indistinguishable from ambient sound in the open ocean. Therefore, ambient sound from breaking waves could also potentially inform coastal fishes about their distance from the

shoreline. The exact nature of how ambient sound profiles change from the shore to open ocean will depend on conditions such as the slope of the seabed, the nature of the substrate, etc.

### Flowing Water (Rivers and Brooks)

Acoustic energy in rivers appears to be primarily distributed between 10–100 Hz (Vračar and Mijić 2011; Martin and Popper 2016), which falls within the range of hearing of most fishes. Vračar and Mijić (2011) found that, on average, sound pressure levels were higher in faster flowing rivers compared to two slow flowing rivers, suggesting that sound levels tend to increase with higher flow rates. Therefore, in addition to the lateral line system of fishes, which is known to sense flowing water and is important for rheotaxis (Montgomery et al. 2013), fishes might be able to obtain information about water flow rates from the loudness of the ambient sound environment.

A recent study revealed that the spectral signatures of large slow flowing rivers, small slow flowing rivers, and brooks were consistently different in sites across the Netherlands, suggesting that fishes may be able discriminate between these habitats using spectral cues (Velde et al. 2022). The study also revealed that frequency spectra differed between river stretches and branch points, suggesting that acoustic information could potentially be used by migrating fishes to locate branch points along rivers (Velde et al. 2022). Therefore, acoustic characteristics can potentially inform fishes about different habitats in flowing water.

### Waterfalls

Few studies have characterized the ambient sounds produced by waterfalls. Lugli and Fine (2003) measured low frequency sounds (0–1000 Hz) generated by waterfalls in a shallow freshwater habitat (<70 cm deep). Sound pressure levels decayed by 30 dB re 1μPa within two meters from the waterfall, suggesting that waterfalls can only be detected from close range in shallow water environments. Sounds emanating from waterfalls might be especially important for migrating fishes such as salmon, which are known to jump up waterfalls. Migrating sockeye salmon appear to have preferred locations to jump up waterfalls, which is dependent on the depth of the pool below the falls and the height of the falls (Lauritzen et al. 2005). Along with visual and hydrodynamic cues, the acoustic signature of the pool, especially the particle motion characteristics, might be important for selecting suitable locations by particle motion-sensitive salmon for jumping up waterfalls. Studies that measure the acoustic characteristics of jumping and non-jumping sites need to be carried out to determine if the ambient sound is consistently different in these two environments, which could potentially be used by migrating salmon to find suitable jumping sites.

### Sea Ice

In Antarctic and Artic waters, ambient sounds are generated by a combination of geophysical phenomenon such as thermal cracking of ice, glacial calving, and glacial waterfalls (Tegowski et al. 2011). Ambient sounds in habitats occupied by sea ice have been shown to be highly dependent on the amount of ice cover in the area, with

maximum acoustic energy in the 100–1000 Hz spectral band (Miksis-Olds et al. 2013). To the best of the authors' knowledge, no studies have been conducted to determine whether sounds emanating from sea ice provide cues about relevant environmental variables such as the location of feeding and breeding sites to fishes.

### Underwater Earthquakes

Earthquakes generate underwater acoustic waves called T waves, which can propagate for thousands of kilometers (Fox et al. 2001). At the seabed, T waves travel as seismoacoustic polarized interface waves (known as *Ti* waves). Frequencies below ~5 Hz propagate along the sediment bed and frequencies above ~5 Hz propagate as acoustic waves in the water above the seabed. The acoustic aspect of the *Ti* waves contain energy primarily between 5 Hz and 35 Hz (Butler 2006), which falls withing the hearing range of fishes (Sand and Karlsen 1986). Frohlich and Buskirk (1980) calculated the theoretical sound pressure levels of sounds generated by earthquakes and found that the levels are generally above the hearing thresholds of grunts (*Haernulon* species) and Atlantic cod (*Gadus morhua*). This suggests that these, and other fish species, can potentially detect underwater earthquakes. Earthquakes can cause underwater landslides, which can kill fishes and destroy habitat (Zimmerman et al. 2008). Thus, the ability to detect the sounds preceding earthquakes may potentially be adaptive to fishes, allowing them to escape the area before the earthquake strikes. More research is needed to confirm whether fishes detect and behaviorally respond to the low frequency sound waves generated by earthquakes.

### Hydrothermal Vents

Hydrothermal vents produce sounds with acoustic energy primarily distributed between ~0.5 kHz and 3 kHz (Italiano et al. 2011), although majority of the energy appears to be located between ~10 Hz and 250 Hz (Crone et al. 2006). Crone et al. (2006) also found that sound pressure levels in the 0–500 Hz band measured 0.1–0.3 m from the opening of a hydrothermal vent were ~ 10–30 dB re 1μPa louder than the ambient sound in the surrounding water. The authors of this study estimated that sound pressure levels of sounds generated by vents can rise above background sound pressure levels up to ~5–15 m away from the vent opening. They suggest that hydrothermal vent sounds might function as a cue informing marine organisms about the presence of vents. Most vents are greater than 2 km deep (Baker and German 2004). Therefore, deep sea fishes may use sounds emanating from hydrothermal vents to either avoid hot fumes that are extruded from the vents or to locate prey that live close to vents. Further studies are required to explore this question.

### Underwater Volcanoes

Sounds generated from underwater volcanoes are variable in nature. Some eruptions can create harmonic sounds, containing energies at integral multiples of a fundamental frequency. Other eruptions can produce more broadband sounds with acoustic energy distributed across a range of frequencies. Acoustic energy is primarily of low frequency (<~600 Hz) and explosive volcanic bursts can increase local ambient sound pressure levels by ~50 dB re 1μPa, between 10 Hz and 50 Hz (Chadwick

Jr. et al. 2008). Little is known about the responses of fishes to sounds generated by volcanoes. Like earthquakes, volcanic eruptions can cause fish mortality (Caballero et al. 2023). Thus, it might be adaptive for fishes to detect sounds produced by volcanic eruptions, but such a hypothesis remains to be investigated further.

## Biophony

The primary biotic sources of natural ambient sound are invertebrates such as snapping shrimp and hard-shelled invertebrates, fishes, and marine mammals (Table 2). Compared to sources of geophony, more data exists on how fishes extract

**Table 2** Major sources of biophony, evidence for fishes extracting biologically relevant information from these sources of biophony, and additional hypothesized biologically relevant information contained in these sounds. See the main text for more details

| Sound source | | Frequency content | Examples of fishes extracting biologically relevant information | Additional hypothesized biologically-relevant information |

biologically relevant information from biophony. However, studies characterizing the particle motion aspect of various sources of biophony are still scarce.

### Invertebrates

Many invertebrate species either actively vocalize or produce sounds passively while moving or eating. Sounds generated by invertebrates encompass a wide frequency band, ranging from ~0.04 kHz to 115 kHz (Duarte et al. 2021). Snapping shrimps are usually the dominant biotic source of ambient sound in shallow tropical and subtropical marine environments. They produce broadband clicks with frequencies ranging primarily between 2 kHz and 20 kHz, with peak frequencies falling from 2 kHz to 5 kHz. Snapping shrimp sounds can increase local sound pressure levels by 20 dB re 1μPa, and habitats occupied by them can be as loud as 140–150 dB re 1μPa (Cato and Bell, 1992). However, since the frequencies of best hearing are usually below 1000 Hz in most fishes (Popper et al. 2019), loud sounds made by snapping shrimp are unlikely to cause hearing damage or negatively affect fish behavior. In fact, playbacks of reef sounds dominated by snapping shrimp vocalizations have been demonstrated to attract fish larvae, suggesting that snapping shrimp sounds are important cues for reef localization for larvae of coral-reef fishes (Leis et al. 2003).

Grating sounds made due to the movement and feeding of hard-shelled invertebrates can also contribute to local ambient sound. Sea urchin feeding creates sounds with acoustic energy between 800 Hz and 2800 Hz, in the coastal waters of New Zealand (Radford et al. 2008). These sounds fall within the hearing range of fishes and could possibly be used by predatory fishes to locate urchins and other prey items associated with reefs. Thus, sounds produced by invertebrates could potentially be acoustic cues for locating important habitats such as coral reefs. Whether fishes use sounds from invertebrates for other purposes remains to be further investigated.

### Fishes

Fish choruses are a major source of ambient sound in shallow habitats such as coral reefs (McWilliam et al. 2017), and intertidal habitats (Halliday et al. 2018). The collective ambient sound from chorusing fishes could potentially be used by heterospecific fishes to locate habitats such as reefs and tidal estuaries. Fish vocalizations are generally major components of the playbacks of reef sounds in studies that demonstrate the attraction of fish larvae to reef sounds (e.g., Tolimieri et al. 2004), suggesting that in coral reef environments, fish sounds can serve as important spatial cues to locate settlement sites on reefs.

Besides vocalizations, fishes also extract information about the environment from the sounds produced passively by other fishes while eating and moving. Sounds produced during feeding can inform conspecifics about the presence of food (Wang et al. 2021). Some fishes are repelled by infrasound (<20 Hz) (Sand et al. 2000; Bui et al. 2013), which is thought to be a predator avoidance response since large swimming fishes can generate infrasound (Bleckmann et al. 1991). In contrast, predatory fishes are often attracted to low frequency pulsatile sounds (Richard 1968), which are often associated with wounded or struggling prey. Thus, sounds

produced passively by fishes could inform other fishes about the presence of food, predators, and prey.

### Mammals

Various marine mammal groups such as cetaceans, phocids, and otariids produce underwater vocalizations in the range of 10 Hz to approximately 340 kHz depending on the species (Duarte et al. 2021). Some fishes have evolved behavioral responses to the sounds produced by predatory marine mammals, which likely reduces predation risk. Vocal activity in the Gulf toadfish (*Opsanus beta*) (Remage-Healey et al. 2006) and silver perch (Luczkovich et al. 2000) is greatly reduced when exposed to playbacks of dolphin vocalizations, but not other control sounds. Furthermore, certain members of the order Clupeiformes such as the American shad (*Alosa sapidosomma*) can detect ultrasound and at relatively high intensities can elicit an acoustic startle response by these fishes. Such a response is believed to be an antipredator adaptation to avoid echolocating odontocetes (Plachta and Popper 2003). Thus, there is evidence that fishes can obtain information about the presence of predatory mammals from their vocalizations.

## Natural Ambient Sounds as Sources of Biologically Relevant Information

Few studies have been conducted on whether fishes use ambient natural sounds to extract information useful for survival and reproduction. The goldfish (*Carassius auratus*) has been shown to conduct "auditory scene analysis," which is the ability to identify and segregate the multiples sources of sound that the animal experiences at a given moment This suggests that the goldfish and possibly other fish species may be able to identify and segregate the various sources of sound in the ambient sound spectrum and extract useful information from them. Known cases where fishes extract information about the environment from ambient sound are described in the following sections (summarized in Table 3).

### Location of Larval Settlement Sites

Fish larvae have been shown to be attracted to playbacks of sounds recorded from coral reefs, suggesting that fish larvae use sounds emanating from coral reefs to locate them and choose settlement sites (Montgomery et al. 2006). There is variability among taxa in the spectral components of the ambient sound spectrum preferred for settlement. Most species are preferentially attracted to the component of coral reef ambient sound spectrum primarily generated by invertebrates (>570 Hz), but other fish species demonstrate no preference for the high or low frequency components of the coral reef sound spectrum (Simpson et al. 2005, 2008).

The acoustic characteristics of different coral reef ecosystems appear to show consistent differences, which could potentially be exploited by coral fish larvae to

**Table 3** List of examples of fishes extracting biologically relevant information from natural ambient sounds. Examples where the responses of fishes to acoustic stimuli resembling certain natural ambient sounds suggest that they have the capability to extract biologically relevant information from these natural ambient sounds have been included under "Putative examples." See the main text for more details

| Types of biologically relevant information extracted | | Examples | Putative examples |
|---|---|---|---|
| 1. | Location of larval settlement sites | • Larval fishes attracted to recordings of ambient reef sounds (Simpson et al. 2005, 2008; Montgomery et al. 2006).<br>• Larval fishes attracted to sounds from specific coral reef habitats where they normally settle in but not sounds from other coral reef habitats (Radford et al. 2011).<br>• Some larval species avoid sounds from habitats they do not generally settle in (Radford et al. 2011). | – |
| 2. | Location of spawning conspecifics | Playbacks of sounds made by chubs shaking their tails while spawning attracted conspecifics (Wang et al. 2022) | – |
| 3. | Detection of food sources | Flower fish attracted to playbacks of worm feeding sounds (Wang et al. 2021) | • Cyprinids attracted to playbacks of sounds made while pebbles are dislodged, which may uncover hidden invertebrate prey (Holt and Johnston 2011).<br>• Some predatory fishes attracted to low frequency pulsed sounds, thought to be produced by swimming or struggling prey (Richard 1968). |
| 4. | Detection of predators | Some fishes reduce vocalization rates during playbacks of predatory dolphin vocalizations (Luczkovich et al. 2000; Remage-Healey et al. 2006) | • Certain fishes are repelled by infrasound (<20 Hz), thought to be generated by swimming movements of approaching predators (Sand et al. 2000).<br>• Ultrasound evokes a startle responses in some Clupeiform fishes, which is likely an adaptation to escape predatory odontocetes (Plachta and Popper 2003). |
| 5. | Detection of fishes possessing swim bladders | – | Goldfish (*Carassius auratus*) conditioned to detect sounds resembling scattered ambient sounds by fish swim bladders (Lewis 1994) |

locate preferred habitats (Radford et al. 2010). In fact, larvae of some fish species are known to demonstrate strong preferences for sounds emanating from specific coral reef environments such as lagoons or fringing reefs, suggesting that larvae not only obtain directional information from reef sounds but also use these sounds for habitat identification (Radford et al. 2011). Parmentier et al. (2015) studied the responses of coral fish larvae of 20 fish species belonging to 10 families to ambient sound recorded from different coral reef habitats. The authors observed interspecific differences in larval attraction to playbacks of sounds recorded from the different habitats. Some species were also repulsed by sounds emanating from certain habitats. Thus, in addition to locating favorable environments, coral reef larvae also appear to be able to use ambient sound to avoid settling in specific habitats.

The acoustic environment can vary locally in a coral reef. Kennedy et al. (2010) found that the sound environment was correlated with factors such as the local density and biomass of fishes, as well as the diversity of coral and fish species. It is possible that larval fishes select different microhabitats for settlement based on their acoustic profiles, and further research on this topic is warranted.

The specific acoustic cues used to locate the sources of reef sounds remain poorly understood. Coral fish larvae could be using particle motion vectors as cues to guide them to the reef, similar to how adult female plainfin midshipman (*Porichthys notatus*) localize mating calls produced by males (Zeddies et al. 2010). In Zeddies et al. (2010), female plainfin midshipman localized a sound source ~1 m away from the animal. It has been speculated that larval fishes can localize reefs located at distances of up to 1 km from the animal (Mann et al. 2007). It is unknown if acoustic particle motion fields around coral reefs provide directional information about the location of reefs, which fish larvae could utilize to locate the reef from large distances. Alternatively, larval fishes could be climbing up intensity gradients in sound pressure, or particle motion variables (displacement, velocity, or acceleration; see Sisneros and Rogers (2016)). More research is required on the acoustic cues used by larval fishes, and how acoustic cues could be combined with other cues such as chemical cues (Atema et al. 2002) to locate reefs.

## Location of Spawning Conspecifics

In several freshwater fish species, which spawn in riverbeds, both males and females are known to vigorously shake their tails while mating. This tail-shaking behavior displaces sand and gravel, and helps bury the eggs (Katano 1992b; Chuang et al. 2006). Playbacks of recorded "collision" sounds made by two species of chubs (*Opsariichthys evolans* and *Zacco platypus*) while shaking their tails during spawning, attracted more chubs of both species compared to control speakers either playing music or recorded ambient sound (Wang et al. 2022). Chubs attracted to spawning events generally tend to be satellite males or conspecifics, which cannibalize eggs (Katano 1992a, b). Thus, the presence of collision sounds in the ambient

sound environment appears to provide satellite males and conspecific egg-eating chubs with information about the location of spawning pairs. Future studies should investigate if the attraction to collision sounds is present in other freshwater species which spawn in riverbeds.

## Detection of Food Sources

Sounds produced during feeding can inform conspecifics about the presence of food. A few species in the family Cyprinidae are known to be attracted to playbacks of sounds that are associated with the dislodgement of pebbles during feeding in their native shallow freshwater habitat (Holt and Johnston 2011). Holt and Johnston (2011) suggest that since dislodged pebbles tend to expose hidden invertebrate prey items, the attraction of cyprinid fishes to sounds produced by pebble movement might be an adaptative or learned response for finding prey. Playbacks of sounds produced by flower fish feeding on worms attracted conspecifics (Wang et al. 2021) demonstrating that this species also obtains information about the presence of food from feeding sounds. The ability to locate food by listening to the feeding sounds made by conspecifics/heterospecifics may be present in other species and requires further investigation.

Bleckmann et al. (1991) measured the frequency content of sounds generated by the movement of five fish species: convict cichlid *Cichlasoma nigrofasciatum*, black ghost knifefish *Apteronotus albifrons*, Mexican tetra *Astyanax fasciatus mexican*us, striped panchax *Aplocheilus lineatus*, and rainbow trout *Salmo gairdneri*, when moving freely or startled. The frequencies of sounds produced when these fishes were tethered and struggling to escape the tether were also recorded. A fish struggling to escape from a tether resembles a naturalistic situation when a fish struggles to escape the jaws of a predator. Sounds produced by moving, tethered, and struggling fishes were primarily below 100 Hz. Predatory reef fishes such as groupers (*Epinephelus striatus, Mycteroperca venenosa,* and *Mycteroperca bonaci*), snappers (*Lutjanus analis, and Ocyurus chrysurus*), and the white margate (*Haemulon album*) have been shown to be attracted to playbacks of low frequency (25–50 Hz) pulsatile sounds (Richard 1968). The attraction of predatory reef fishes to these low frequency sounds suggests that predatory fishes can possibly detect and localize the sounds produced by swimming prey, as well as prey that are struggling to escape capture by a predator. Further studies are required to test this hypothesis.

## Detection of Predators

Infrasound (<20 Hz) has been known to trigger an avoidance response in juvenile and adult salmonids, and eels (Sand et al. 2000; Bui et al. 2013). This repulsion of some fish species to infrasound has been proposed to be an adaptation to avoid

predators, as approaching predators likely produce low frequency hydrodynamic sounds while swimming (Bleckmann et al. 1991). The avoidance response of species such as salmon to infrasound occur only when the fish are close to the speakers (< 2 m) (Knudsen et al. 1992), suggesting that animals only detect infrasound from sources a few body lengths away. Therefore, a sudden increase in low frequency sounds in the ambient sound environment could inform smaller prey fishes that a large animal is in close proximity to the individual.

Some vocalizing fish species appear to detect predatory dolphin vocalizations and behaviorally respond by reducing vocal activity, which presumably reduces their chances of being detected by dolphins in the natural environment (Luczkovich et al. 2000; Remage-Healey et al. 2006). Certain species of Clupeiform fishes can detect ultrasound, which is believed to be an adaptation to detect the sounds generated by predatory odontocetes during echolocation (Plachta and Popper 2003). Thus, some fishes have the ability to acquire information about the presence of predators in the environment by detecting their vocalizations in the ambient sound environment.

### Detection of Fishes Possessing a Swim Bladder

Goldfish may be able to sense the presence of other individuals by detecting ambient sound scattered by the swim bladder of a nearby fish. Lewis (1994) simultaneously exposed tethered goldfish to white noise played via a speaker, as well as sound resembling scattered white noise from a fish's swim bladder, generated by a piezoelectric transducer. This experimental setup mimics a situation where another fish with a swim bladder (which scatters sound) is close to the "receiver" goldfish, while the "receiver" is experiencing white noise. Goldfish can learn to recognize the scattered white noise. Thus, the presence of ambient sound may help goldfish and possibly other fishes sense the presence of nearby fishes that possess a swim bladder, or other gas-filled chambers, especially when the fish is in a shoal of fishes that possess swim bladders. It should be noted that in the conditioning experiments carried out by Lewis (1994), the speaker relaying white noise was close to the goldfish (distance to goldfish = 36 cm) and therefore the white noise experienced by the animal was likely very different from ambient sound in a natural setting. The sound levels of ambient sound scattered by swim bladders is likely to be very low in natural environments, and it remains to be seen if goldfish and other fishes could detect the ambient sound scattered by swim bladders in natural settings.

## Natural Ambient Sounds as Noise

Not all natural ambient sounds are relevant to fish survival and reproduction and such sounds are likely to be species-specific and context-specific. Below, we document cases where natural sounds have been shown to function as noise, interfering with the detection of relevant acoustic signals and cues (Table 4).

**Table 4** List of examples where natural ambient sounds function as noise. Examples where the responses of fishes to nonnatural sounds suggest that increased levels of natural ambient sound could function as noise have been included under "Putative examples." Also included under the putative examples column are cases where fishes change vocal activity in responses to events, which are known to increase ambient sound levels (such as increases in wind speeds and storms). See the main text for more details

| The ways in which natural ambient sounds function as noise | | Examples | Putative examples |
|---|---|---|---|
| 1. | Masking | • Hearing thresholds of cods (*Gadus morhua*) for pure tones increased with increased levels of natural ambient sound (Chapman and Hawkins 1973).<br>• Auditory sensitivity to pure tones masked by playbacks of recorded ambient natural sound (Ladich 2013). | – |
| 2. | Vocalization frequencies match "quiet windows" in the ambient sound spectrum | Peak frequency of vocalizations of several shallow water fishes lies close to ~100 Hz. This coincides with a dip in acoustic energy at ~100 Hz in the ambient sound spectra in these habitats (Lugli 2010) | – |
| 3. | Increase in loudness of vocalizations during periods of elevated ambient sound levels | – | Blacktail shiners (*Cyprinella venusta*) increased the loudness of vocalizations of vocalizations under playbacks of white noise (Holt and Johnston 2014). |
| 4. | Changes in vocal activity during periods of elevated ambient sound levels | – | • Brown meagre (*Sciaena umbra*) (Picciulin et al. 2012) and oyster toadfish (Luczkovich et al. 2016) increase and decrease their vocal activity respectively during increased levels of anthropogenic sound.<br>• Pomacentrids increased calling activity during increased wind speeds, known to be correlated with ambient sound levels (Munger et al. 2022).<br>• Calling activity of some fishes increased and others decreased during tropical storms (Locascio and Mann 2005; Boyd et al. 2021). |

## Masking

The presence of ambient natural sound can mask the hearing of pure tones in fishes. Chapman and Hawkins (1973) measured behavioral hearing thresholds of the cod to pure tones in the fish's natural marine environment. Hearing thresholds were dependent on the sound pressure levels of ambient sound, with thresholds increasing with increasing sound pressure levels. During the experimental period, ambient sound was primarily generated by natural sources: wind and rain. This is the only study that measured the effect of natural ambient sound on hearing in a fish's native environment.

Other studies have measured the masking effect of ambient sound on the peripheral auditory system of fishes by using the auditory evoked potential (AEP) technique. Experiments have shown that the sound levels required to generate a detectable auditory evoked potential (auditory thresholds) at the level of the peripheral auditory system for pure tones increase when recorded ambient natural sounds are simultaneously played on underwater speakers (For example, see Amoser and Ladich 2005). AEP studies on freshwater fishes have demonstrated that the physiological auditory sensitivity to pure tones is more masked (resulting in increases in auditory thresholds) in species, which possess accessory hearing structures compared to species that lack them (Ladich 2013). In contrast, the physiological auditory sensitivity (i.e., AEP thresholds) to pure tones was minimally masked in fishes that do not have hearing specializations (Vasconcelos et al. 2007; Codarin et al. 2009). Studies suggest that accessory hearing structures tend to improve physiological auditory sensitivity in fishes, especially at higher frequencies ($>$ 1 kHz) (e.g., see Ladich 2000). Thus, it is not surprising that the generally more sensitive auditory system of fishes with accessory hearing structures appear to be more masked by increased levels of ambient sound. These results suggest that fishes with accessory hearing structures might be more susceptible to underwater noise, masking sounds important of survival (such as the sounds produced by approaching predators).

It has been pointed out that AEP techniques likely only measure the physiological auditory sensitivity of the peripheral auditory system (i.e., hair cells and auditory afferents) (Popper and Hawkins 2021). It is possible that even if sounds do not generate a detectable AEP, central processing in the brain may still allow fishes to hear these sounds. It is not known if the increased masking of the peripheral auditory system by ambient sound in fishes with accessory hearing structures translates to increased masking of hearing. More studies of hearing thresholds measured via behavioral methods under increasing levels of ambient underwater sound (such as in Chapman and Hawkins 1973) need to be performed to address this question.

While masking of pure tones by ambient sound is informative, especially for understanding the auditory physiology of the animal, it is difficult to interpret the ecological significance of these experiments. The frequency content of fish communication sounds can either be broadband, with acoustic power distributed across a large frequency range, or harmonic containing acoustic power at integral multiples of a fundamental frequency (Kaatz et al. 2017). Thus, for acoustically communicating species that use harmonic sounds as part of their communication repertoire,

masking studies of pure tones by natural ambient sound could help determine how detection of conspecific communication sounds is impeded under increased levels of ambient sound. It is harder to interpret the results of masking studies for fishes, which do not communicate acoustically, or which produce more broadband communication sounds. More nuanced studies that investigate how the presence of certain kinds of environmental sounds impede the detection of sounds important for survival and reproduction (such as courtship sounds, sounds made by approaching predators, etc.) are required.

## Vocalization Frequencies Match "Quiet Windows" in the Ambient Sound Spectrum

Acoustic communication in several species living in shallow water environments appear to have evolved to increase signal detectability in the presence of local ambient sound. Lugli (2010) characterized the ambient sound spectra of the habitats occupied by nine species of goby. The habitats were classified into four categories: stony stream, spring, brackish lagoon, and rocky seashore. The peak frequency range and bandwidth of the vocalizations produced by each species coincided with the frequencies of the ambient sound spectrum that contained the least amount of energy ("quiet windows") in the fish's native habitat. This suggests that each species has evolved to maximize acoustic signal transmission in its native acoustic environment. Lugli (2010) also showed that the dominant frequencies of vocalizations produced by several fishes living in nearshore marine habitats, stony rivers and creeks, coincided with the quiet windows in the ambient sound spectra in all three habitats. The quiet window was centered around 100 Hz. Lugli (2010) hypothesized that the major reason for several shallow water fish species evolving low-frequency acoustic communication (~100 Hz) may have been to take advantage of this quiet window in ambient sound.

More studies are required to confirm if acoustic communication frequencies of shallow water species have evolved to take advantage of a quite window in the ambient sound environment, and whether such quite windows exist in different shallow water environments. In Lugli (2010), two arbitrary spectra from two specific locations were used to demonstrate that quiet windows in nearshore marine and stony river/creek habitats occur at around 100 Hz. It remains to be seen if these quiet windows occur in other shallow water locations and if they exist near 100 Hz. Additionally, fish ears are thought to primarily function as detectors of particle motion (Popper and Hawkins 2018). The spectral content of sound pressure and particle motion can differ in aquatic environments, especially in shallow water habitats (Banner 1968; Jesus et al. 2020). Since particle motion was not measured in the study by Lugli (2010), it is unclear if the frequency spectrum of the particle motion aspect of the ambient sound environment in shallow water habitats has a dip in energy close to 100 Hz.

The overlap between the dominant frequencies of fish vocalizations and quite windows in the ambient sound spectrum may not be a universal phenomenon. Coers

et al. (2008) measured the ambient sound in the intertidal habitat of the rock-pool blenny (*Parablennius parvicornis*) and found the ambient sound spectrum to be dominated by frequencies below 250 Hz, which overlaps with the communication calls of the goby. Thus, more research is required to determine if frequencies of fish vocalizations coincide with quiet windows in local ambient sound.

## Increase in Loudness of Vocalizations during Periods of Elevated Ambient Sound Levels

Vocal fish species appear to have evolved behavioral adaptations that can potentially increase the transmission and interpretability of communication signals in noisy environments. The involuntary tendency of a sender to increase vocal effort that can include increases in loudness, frequency, rate, and duration of a signal to compensate for increases in ambient sound levels is termed the Lombard effect or Lombard reflex (Summers et al. 1988). The Lombard effect has been documented in some fishes. Blacktail shiners (*Cyprinella venusta*) demonstrated an increase in the sound pressure levels of vocalizations under playbacks of white noise (Holt and Johnston 2014). Oyster toadfish (*Opsanus tau*) increased sound levels by 7 and 9 dB re 1μPa during and after passages of vessels, which temporarily increased the loudness of ambient sound (Luczkovich et al. 2016). Although fishes were exposed to nonnatural sounds in these experiments (white noise and boat sounds), the fact that fishes demonstrate the Lombard effect when exposed to these sounds suggests that the ability of fish to actively increase the sound pressure levels of their signals may have evolved to increase signal transmission under increased levels of natural ambient sound. It remains to be seen whether fishes can modulate the loudness of vocalizations to improve signal transmission when the ambient sound increases in loudness due to natural causes.

## Changes in Vocal Activity during Periods of Elevated Ambient Sound Levels

Data on fish vocal responses to increases in the loudness of ambient sound due to natural causes is scarce. Boyd et al. (2021) documented that during a tropical storm, underwater ambient sound levels due to abiotic sources such as wind increased at frequencies below 500 Hz. The calling rates of some fish species increased during the storm, whereas the calling rates of other species decreased. Other environmental variables such as water level and temperature also changed during the storm, and therefore it is possible that the change in vocal activity could be driven by these other factors rather than the increase in loudness of ambient sound. Similarly, sound pressure levels of a fish chorus increased during and after a hurricane (Locascio and Mann 2005). The authors attribute the increased sound pressure levels to

increased vocal activity. Munger et al. (2022) found a correlation between vocal activity of pomacentrids and wind speeds. Since ambient sound levels are known to increase with wind speed, it is possible that these fish increased vocal activity in response to increased ambient sound levels.

Fishes also appear to either increase (Picciulin et al. 2012) or reduce (Luczkovich et al. 2016) vocal activity in response to increased levels of anthropogenic sound. Thus, some fishes are capable of modulating their vocal activity to cope with increased levels of ambient sound. This increase and decrease in vocal activity has been shown in two different species, brown meagre (*Sciaena umbra*) (Picciulin et al. 2012), and oyster toadfish (Luczkovich et al. 2016), respectively. However, it is not known whether a given species can both increase or decrease their vocal activity in response to increased levels of ambient sound. Reducing vocal activity may help conserve energy for quieter periods when the probability of masking is lower. Alternatively, increasing vocal activity can likely improve signal detectability. The durations and frequencies of ambient sounds impinging on the animal may determine how fishes modify vocal activity, which needs to be investigated further.

## Information Gaps on the Effect of Ambient Sounds on Fishes

This chapter summarizes the major sources of natural ambient sounds in aquatic environments and discusses how they could provide information about the environment to fishes as well as function as noise, interfering with the detection of relevant signals and cues. Existing studies likely represent a small subset of the ways in which natural ambient sounds affect fishes. Some information gaps on the biological relevance of natural ambient sounds to fishes are highlighted below.

### Defining Ambient Sound from an Animal Perspective

Despite the numerous studies that characterize ambient sound, few studies have defined ambient sound from the perspective of animals. One of the few documented definitions of ambient sound from ISO 18405:2017 defines it from the perspective of a human experimenter measuring sound: any sound in the background other than the sound being quantified is considered ambient sound. However, since it is difficult to pinpoint the sounds an animal is focusing on/paying attention to in the sound environment versus the "background" sound that an animal is not focusing on, translating the ISO definition from an animal's perspective is challenging. The only exception to this is likely conspecific communication signals, which are known to be beneficial to the sender as well as the receiver (Bradbury and Vehrencamp 2011), and therefore by definition the receiver is obligated to "pay attention" to these sounds. Therefore, in this review, all sounds impinging on an animal except conspecific communication sounds have been considered ambient

sound. It is necessary to come to a consensus on a working definition of ambient sound from an animal's perspective to limit confusion about what the term "ambient sound" entails across the bioacoustics community.

## Particle Motion Content of Natural Sound Environments

Most studies that characterize ambient sound environments and the responses of fishes to ambient sound measure sound pressure and not particle motion. Particle motion is considered the primary stimulus for hearing in most fishes (Popper and Hawkins 2021). Using sound pressure to characterize sounds can still inform researchers about the temporal structure of sounds, such as, for example, the calling rates of fishes. Sound pressure data can also be used to determine the bandwidth or frequency content of sounds. However, measuring particle motion is still preferable for estimating the frequency bandwidths of ambient sounds in the context of fish hearing because the frequency content of pressure and particle motion can differ slightly in some underwater environments (For example, see Figs. 13 and 15 in Jesus et al. 2020). Hence, to better understand how fishes extract information from natural ambient sound, ambient sounds need to be characterized via particle motion (displacement, velocity, acceleration, etc.) because this is what the fish inner ear is designed to detect.

## The Use of Natural Ambient Sounds as Cues

Little is known about how natural sounds function as sources of biologically relevant information, with coral fish larvae being attracted to reef sounds being the best documented evidence of fishes using natural sounds as cues. However, there is much still to be uncovered even in this domain such as the acoustic cues used by larvae to localize reefs. To determine if a natural ambient sound source functions as a source of biologically relevant information, a correlation needs to be established between the sound and specific environments or situations. A correlation would demonstrate that the sound provides reliable information about the environment or situation, which could potentially be used by fishes. The next step would be to demonstrate a behavioral response to playbacks of these sounds, demonstrating that fishes use these sounds to guide certain behaviors. Natural sounds should be characterized as completely as possible by measuring sound pressure, particle motion (displacement, velocity, or acceleration), and other measures that define the attributes of natural sounds in a given environment such as skew, kurtosis, etc. (reviewed in detail in Wilford et al. 2021)), to determine the acoustic features of ambient sound that may provide biological relevant information about the environment. Understanding how fishes use natural ambient sounds as cues is required to predict how various sources of anthropogenic sounds such as those produced from shipping, air guns, etc., disrupt the detection of these cues and thereby disrupt behavior important for the long-term survival and reproduction of fishes.

### Natural Ambient Sounds as Noise

Natural ambient sounds can also disrupt the detection of important cues and signals. Little is known about how certain natural ambient sounds can mask hearing of other biologically relevant sounds to fishes, and if fishes adjust their behavior to cope with increased levels of natural ambient sound. This information could be important for identifying anthropogenic sounds that are particularly disruptive to fishes, and the capacity of fishes to cope with anthropogenic sound.

### Fish Responses to Sudden Changes in the Natural Ambient Sound Environment

Few data exist on how fish behavior is modified during periods of increased ambient sound due to natural causes such as storms or other weather-related events. Although calling activity of different fish species have been documented to change during storms (e.g., see Locascio and Mann 2005), it is difficult to rule out the effect of other variables in these studies. More studies are needed to determine if increases in natural ambient sound disrupt important behaviors such as locating mates, finding food, escaping from predators, etc.

### Capacity of Fishes to Learn to Associate Ambient Sounds with Environmental Variables

It is well established that fishes can be trained to associate acoustic stimuli with positive rewards (Yan and Popper 1991) as well as aversive stimuli, such as an electric shock (Tavolga and Wodinsky 1963). The ability of fishes to associate acoustic cues with environmental variables suggests that fishes may possess the ability to learn how to extract information from natural ambient sounds that are useful for survival, such as the sounds produced by predators, sounds associated with feeding grounds, etc. More studies are required to further investigate this area of research.

## Conclusion

The matched filter hypothesis by Capranica and Moffat (1983) maintains that the auditory systems of animals such as ray-finned fishes evolved to detect conspecific communication signals. This hypothesis treats any sound besides a conspecific communication sound as part of the background noise, interfering with the detection of communication sounds. This review focuses on cases where these non-communication sounds or "ambient sounds" have been shown to provide useful biologically relevant information to fishes. Fishes are known to extract information about larval settlement sites, location of spawning conspecifics, food sources, and

approaching predators, from natural ambient sounds. In some instances, however, ambient sounds can also function as noise, interfering with the detection of signals and cues, matching the predictions of Capranica and Moffat (1983). Natural ambient sounds can mask hearing, and certain vocalizing species increase their loudness or change their rate of vocalizations to cope with increases in ambient sound levels. Several species living in shallow water habitats vocalize at frequencies that coincide with a dip in acoustic energy in the local ambient sound spectrum, suggesting that these species have adapted to such environments by increasing the signal to noise ratio of communication sounds. The effect of natural ambient sounds on fishes remains an understudied topic. It is important to determine how ambient sounds function as cues to better understand how anthropogenic sounds could potentially disrupt these cues. Additionally, investigating whether natural ambient sounds function as noise could provide insights into the types of anthropogenic sounds that might be most disruptive to fish survival and reproduction.

**Acknowledgments** We thank the organizers of the International Conference on the Effects of Noise on Aquatic Life, Berlin, 2022 for providing funding to Sujay Balebail to present this review at the conference. We thank the editor Dr. Arthur Popper for his constructive feedback on the initial version and subsequent revisions of this review, which considerably improved the quality of the final version. We also thank Dr. Ian Jones for an insightful discussion on how the frequency content of sound pressure and particle motion can be different. This review is dedicated to the memory of the late Dr. Richard R. Fay whose thoughts on how fishes may use ambient sounds as "acoustic daylight" inspired us to write this review.

**Abstract**

In the Patagonian Fjords (Chile), an explosive development of salmon aquaculture has occurred, making Chile the second largest salmon producer in the world. Several environmental impacts of this industry on marine ecosystems have been identified. However, descriptions of the underwater soundscape near the sea-based salmon installations are scarce. A continuous recording of ~45 h was conducted using a calibrated hydrophone (0.02–60 kHz) anchored at 20 m depth (2 m from bottom) and 250 m from a salmon net pen. Thirteen noises were identified (particle motion metrics were not included). The dominant noise had a

peak frequency of ~80 Hz, probably due to electric generators ($SPL_{RMS}$ ~ 120 dBre1μPa). The second dominant was ~2500 Hz, probably from automatic feeding systems or well boats in use ($SPL_{RMS}$ ~ 142 dBre1μPa). Outboard motor noises were also present ($SPL_{RMS}$ ~ 130 dBre1μPa). During only 1 h, anthropogenic noises were absent ($SPL_{RMS}$ ~ 100 dBre1μPa), where snapping shrimps and fish sounds were found. Therefore, the soundscape was strongly dominated by anthrophony from the salmon net pen with 97% of the total time and ~ 40 dBre1μPa higher than natural sounds. Moreover, the highest noise might be roughly 175 dBre1μPa at 1 m from the net pen (regarding the simple geometric spreading loss model). Consequently, it is raising the necessity to evaluate the effects of these noises on the marine fauna.

## Introduction

The increasing noise emitted by human activities in the marine environment is generating scientific concern regarding noise impacts on this ecosystem (Ellison et al. 2012). Facing this problem, the use of passive acoustic sensors provides useful information on the composition of the soundscape. The soundscape is the combination of sounds in a particular location and time, and it can be decomposed as biophony, geophony, and anthropophony regarding their source of origin (Farina 2014). In order to control, or to reduce, the impacts of the anthropophony on the marine ecosystem, it is necessary to identify and characterize the sources of noise and its metrics (sound pressure levels, particle motion, and frequency), in conjunction with the identification of its ecological effects on different marine species (Wale et al. 2021). Therefore, in the present study, a description of the soundscape of a fjord from the Northern Chilean Patagonia was conducted, considering the rapid increase of the aquaculture industry (Molinet et al. 2018) and also considering that this is an area with high ecosystem importance for marine mammals (Hucke-Gaete et al. 2004, 2013).

The ocean is an acoustic environment where sound travels about 4.3 times faster than in air (Stojanovic and Preisig 2009). There is a wide range of sounds in the ocean that can be described by their sound pressure level (in pascals or micropascals), particle motion (meter, meter per second, or meter per square second), and their frequency (Hetz). All fishes and several invertebrates detect and use particle motion generated by underwater sounds, but it is still difficult to measure it in the field because of difficulty in obtaining adequate instrumentation (Popper and Hawkins 2019). Herein, we will focus only on pressure levels and frequency. Several marine species from invertebrates to big mammals use acoustic signals for different ecological processes as communication (Whitehead and Weilgart 1991; McCauley and Cato 2000; Wysocki and Ladich 2001), reproduction (Lobel 2002), and defense

(Versluis et al. 2000; Patek and Caldwell 2006; Buscaino et al. 2011), and some fish and invertebrate larvae use acoustics signals as cues during settlement processes (Mann et al. 2007; Lillis et al. 2013; Hinojosa et al. 2016).

Human activities such as shipping, construction, and exploration (e.g., seismic air guns), among other activities, have added several sounds (or noises) into aquatic environments, and consequently this has generated concern regarding their effects on marine life (Popper and Hawkins 2016; Southall et al. 2019; Wale et al. 2021). In order to inform public policies that tackle underwater noise, it is imperative to understand the full range of physiological and behavioral impacts that noise has on marine life (Southall et al. 2019; Popper and Hawkins 2019), but also, as a first step, it is key to identify the anthropogenic noise sources in a particular area.

The Northern Chilean Patagonian Fjords has seen an explosive development of salmon aquaculture (Atlantic salmon-*Salmo salar*, Pacific salmons-*Oncorhynchus* spp., and Rainbow trout-*Oncorhynchus mykiss*) over the last 30 years (Tecklin 2016; FAO 2018). Consequently, scientific concern about the impact that this industry generates in marine ecosystems has received special attention (Poblete et al. 2019). For example, an increase of the nutrients at the seafloor close to fish cages (Carroll et al. 2003), as well as the introduction of chemical substances into the water column (Miranda and Zemelman 2002), has been described. There is also evidence demonstrating the introduction of these farmed exotic species to the natural environment (Correa and Gross 2008; Figueroa-Muñoz et al. 2022), and the introduction of large amounts of floating plastics to this low human populated region (Hinojosa and Thiel 2009; Ahrendt et al. 2021).

However, the description of the underwater soundscape near salmon farm (net pens) installations are scarce. The salmon industry operation at the sea has the potential to introduce sound signals from low to high frequency as a result of its multiple daily functions, such as transportation, electricity production, and feeding processes. Recent descriptions from other parts of the world have shown that salmon net pens are emitting noises of considerable intensity ($SPL_{RMS}$ ~ 110 dB re 1μPa) (Radford and Slater 2019). Additionally, these authors suggest that the noise from higher frequencies (1–2 kHz) come from engines, blowers, and pumps, whereas the noises from lower frequencies (<1 kHz) come from water flows and vibrations. In the Northern Chilean Patagonian Fjords, there is no available noise data from the field regarding salmon farm noises, other than that Vester and Timme (2010) accidentally recorded salmon farm noise in this area as they were recording cetacean sound signals. Therefore, the objective of this chapter is to describe the underwater soundscape of a salmon farm (net pen) in operation in a Northern Chilean Patagonian Fjord.

## Methods

A calibrated hydrophone SoundTrap 300 STD (Oceaninstruments.nz; 0.02–60 kHz) was used to obtain underwater sound recordings. Continuous recordings were made with a sample rate of 96 kHz at the "Comau" Fjord, "Los Lagos" Chilean Region (Fig. 1). The recordings were made from the ~19th hour of November 18 to the

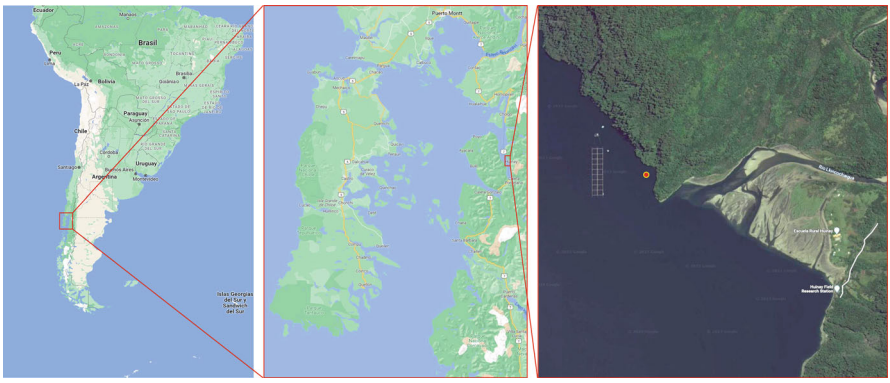

**Fig. 1** Comau Fjord in Los Lagos Region, Chile. Red dot indicates the hydrophone position (42°22′23‘‘S; 72°25′43’‘W), anchored at 20 m depth (2 m from bottom) and 250 m from a salmon farm structure. (Images from Goggle Maps)

~16th hour of November 20 (~45 h). The hydrophone was anchored at 20 m depth (2 m from bottom) and 250 m from the salmon structures (Fig. 1).

The acoustic data analysis was examined using the RavenPro program (V1.5) with a Hamming window, 8.192 samples, 90% overlap, and a sampling frequency of 4.096 Hz. For this investigation, all anthropogenic noises associated with the net pen were characterized in peak frequency (Hz) and duration (h). Anthropogenic noise was defined as any acoustic signal not associated with biological or geophysical sounds. Additionally, the noise metrics as Sound Pressure Levels ($SPL_{RMS}$ and percentiles) and the Cumulative Distribution Function (CDF) were calculated in R with the package PAMguide (Merchant et al. 2015) and using the software dBWav (©Marshall Day Acoustics).

## Results

Total 13 types of anthropogenic noises from variable sources and silence intervals were detected in a ~45-h period of recording (Table 1). For this study, silence was considered as the absence of anthropogenic noise. Additionally, in the absence of anthropogenic noise, sporadic biological sounds such as fish vocalizations and Alpheidae shrimp clicks were identified.

The lowest detected frequency peak was 70.3 Hz, corresponding to type 3 noise associated with a motorboat, while the maximum frequency peak is given by type 11 noise at 2953 Hz from an unknown source. All the noises detected during the ~45 h of recording presented unequal duration. However, there were some types of sounds that were more frequent than others (see Fig. 2).

The noise most dominant in time was type 2, characterized with a low frequency (80 Hz, $SPL_{RMS}$ ~ 120 dB re 1μPa), with a total duration of 23 h and probably associated with noise from an electric generator (Fig. 3). The second most prominent

**Table 1** The different types of noises recorded at the Comau Fjord, Los Lagos Region, Chile

| Noise type | Total duration (h) | Peak (Hz) |
|---|---|---|
| 1 | 12:15:25 | 2718.8 |
| 2 | 23:38:19 | 82.0 |
| 3 | 0:03:40 | 70.3 |

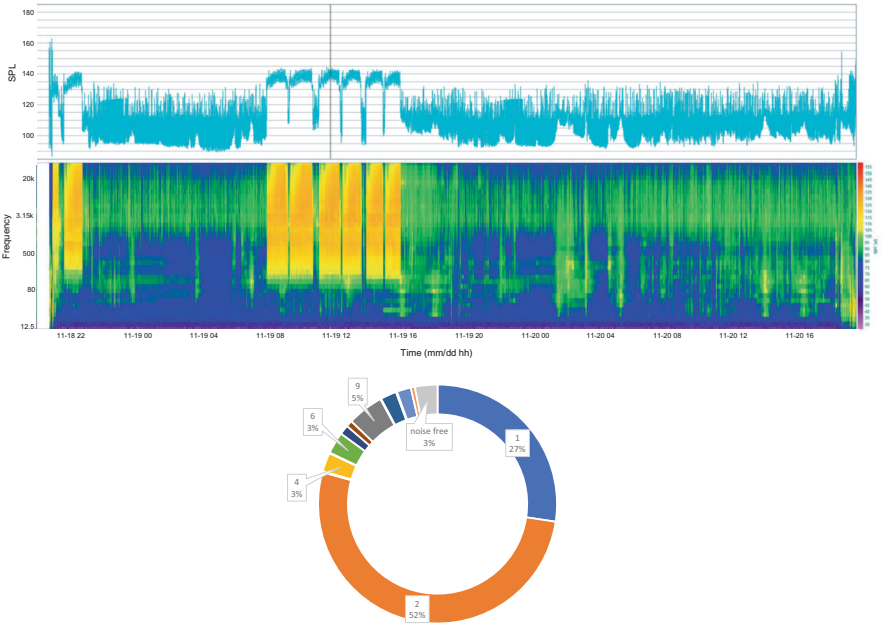

**Fig. 2** Sound Pressure Level ($SPL_{RMS}$, upper graph) and a long-term spectrogram (middle graph) over ~45 h, where the color scale (coldest to hottest) represents the $SPL_{RMS}$. The pie chart at the bottom represents the percentual occurrence of the different types of anthropogenic noise, where only the most common noises were indicated (Type 1, 2, 4, 6, 9, and noise-free). The hydrophone was situated at 250 m from a salmon farm (net pen) in the Comau fjord, Los Lagos Region, Chile

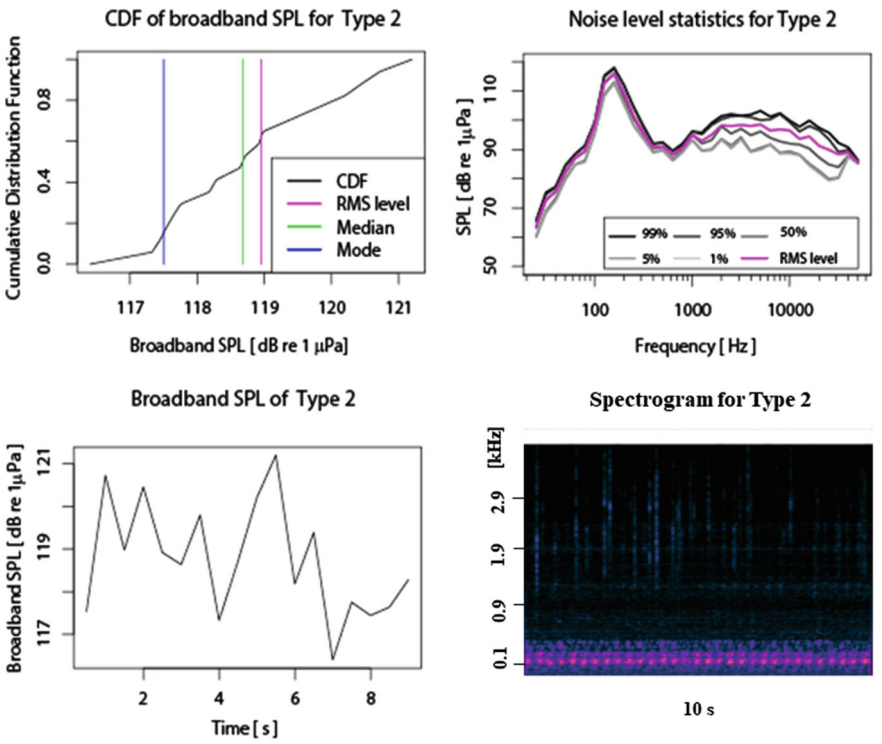

**Fig. 3** Noise metrics from type 2 noise. The graph on the upper left shows the Cumulative Distribution Function (CDF) of broadband SPL, where the RMS levels, the median, and the mode were represented. The upper right graph shows the noise level (SPL) statistics per frequency. The lower left graph shows the broadband SPL variation over time. The graph on the lower right shows the spectrogram where hottest colors represent higher SPL

noise corresponds to type 1. This is relatively high frequency (2500 Hz, $SPL_{RMS}$ ~ 142 dB re 1µPa) and most likely associated with the automatic feeding system or the operation of a well boat (Fig. 4).

During most of the total of recording, the passage of different boats was detected, where there were noises of type 4, 6, and 9, in a frequency range of 70–269 Hz ($SPL_{RMS}$ ~ 110–140 dB re 1µPa), with a total of 3.5 h of presence (Figs. 5, 6, and 7).

Anthropogenic noise-free moments ($SPL_{RMS}$ <100 dB re 1µPa) generally occurred when the most dominant noises (type 1 and type 2) disappeared and, coincidentally, no boats passed by (Fig. 8). In these periods, it is possible to identify the clicks of snapping shrimp and sporadic fish vocalizations. Of the 2 days of recording (~45 h), there were periods free of anthropogenic noise only for approximately 1.5 h.

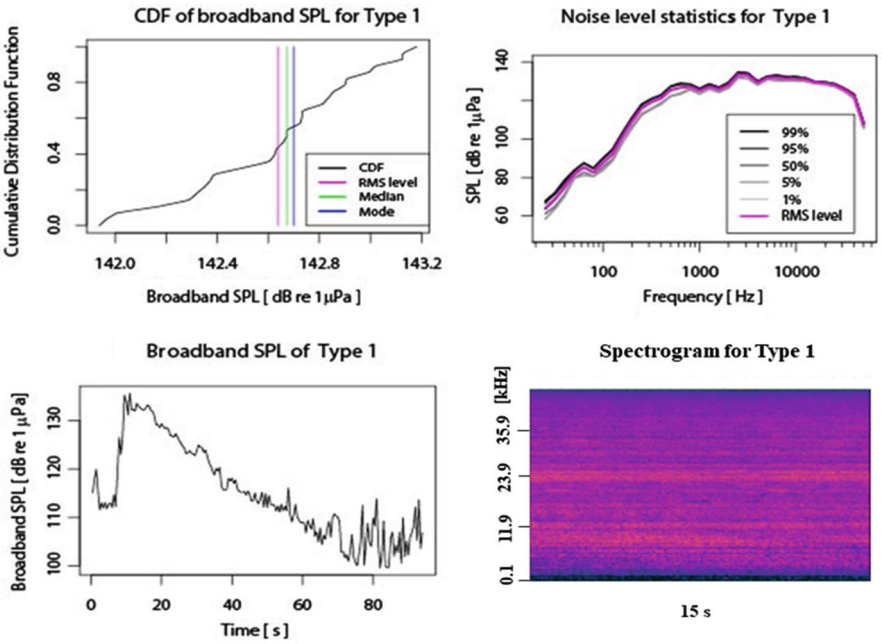

**Fig. 4** Noise metrics from type 1 noise. The graph on the upper left shows the Cumulative Distribution Function (CDF) of broadband SPL, where the RMS levels, the median, and the mode were represented. The upper right graph shows the noise level (SPL) statistics per frequency. The lower left graph shows the broadband SPL variation over time. The graph on the lower right shows the spectrogram where hottest colors represent higher SPL

## Discussion

Although anthropogenic underwater noise has become a global issue (Williams et al. 2015), in Chile it is still considered an emerging problem and even more so, considering it is mostly unknown for the Patagonian Fjords. In general, the variety and intensity of anthropogenic noises in the ocean are related to the associated use, such as marine traffic areas, military training areas, fishing and industrial activities, etc. (Hildebrand 2009). Due to the expansive industrialization in aquatic areas, anthropogenic noise is becoming more prevalent and the natural soundscape is increasingly disrupted. Here, in ~45 h of recording, 13 types of noise from anthropogenic sources were detected in a normal operation of a salmon farm (pen net) in Northern Patagonia. These noises are related to automatic power systems, electricity generators, and traffic boats of different types, the noises from boats being the most diverse in frequency and duration, and notoriously contributing to the composition of the anthropogenic soundscape of a salmon farm.

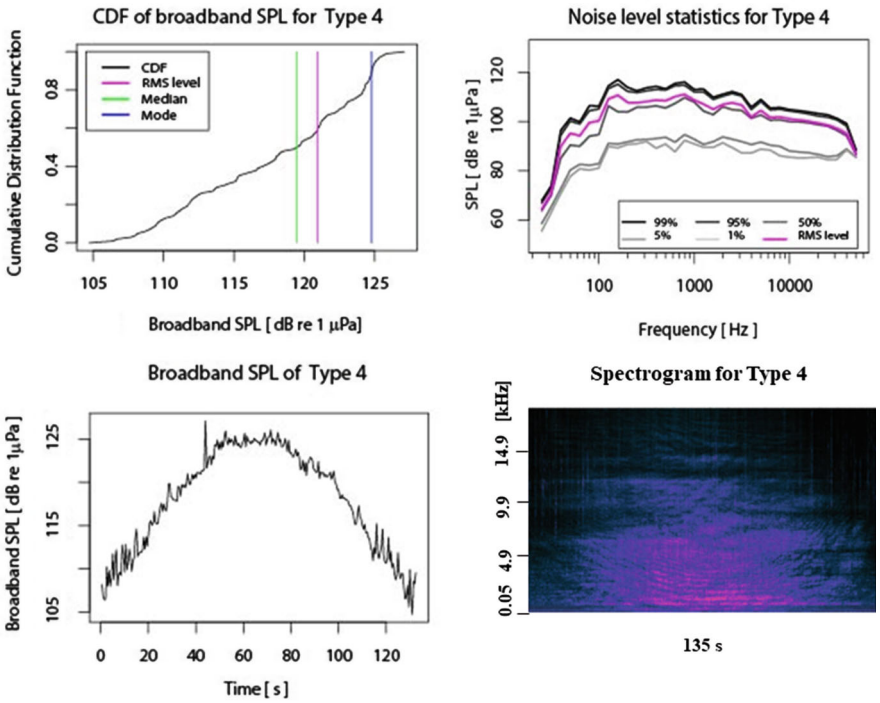

**Fig. 5** Noise metrics from type 4 noise. The graph on the upper left shows the Cumulative Distribution Function (CDF) of broadband SPL, where the RMS levels, the median, and the mode were represented. The upper right graph shows the noise level (SPL) statistics per frequency. The lower left graph shows the broadband SPL variation over time. The graph on the lower right shows the spectrogram where hottest colors represent higher SPL

The masking effect of anthropogenic noise on biological communication by sounds has been extensively investigated in cetaceans (Erbe et al. 2016, 2018; Williams et al. 2020; Branstetter and Sills 2022), and it is probable that vocalizations of these species in the northern Patagonia may be masked by anthropogenic noises from the salmon aquaculture industry (Liu et al. 2013). Our examination of the recorded files revealed the presence of biological sounds (some fish vocalizations and shrimp clicks), so the masking effects generated by net pen noises may also occur over species other than cetacean. Moreover, the spectrum visualization sometimes becomes confusing at low frequencies because the anthropogenic noise was masking all the potential biological sound signals. Type 2 noise was visible in the spectrum for long periods of time but is masked by other higher-frequency noises, so it is possible that it was present in much of the recording except for the rare periods of silence (noise absence). In the case of type 1 noise, which corresponds to the second noise with the highest presence, it is possible that, due to its cyclicity, they may be the feeding periods or another farming process as fish suction for bath cleaning (use of well boats) that occurs regularly and during the daylight. Type

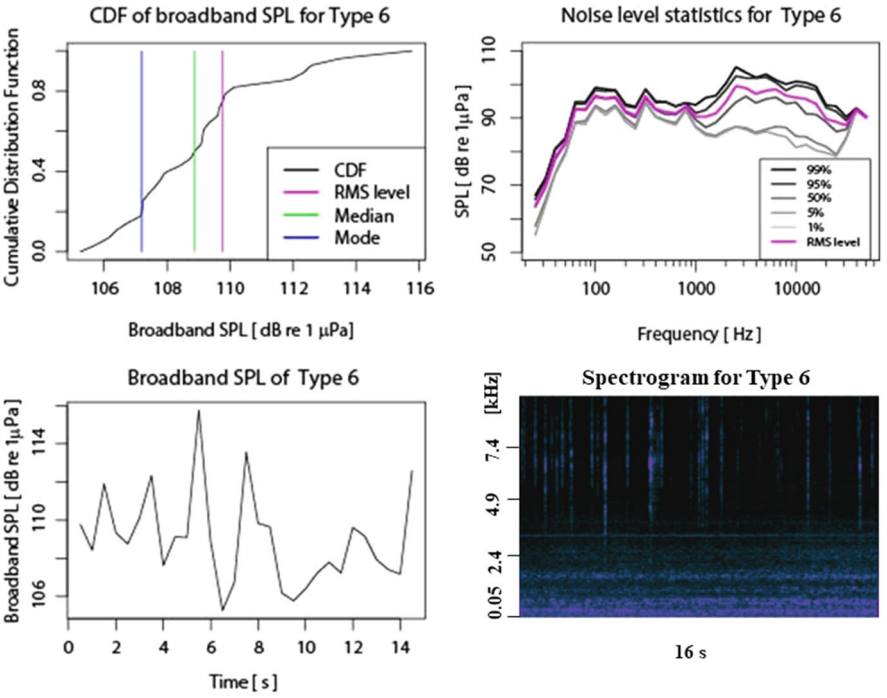

**Fig. 6** Noise metrics from type 6 noise. The graph on the upper left shows the Cumulative Distribution Function (CDF) of broadband SPL, where the RMS levels, the median, and the mode were represented. The upper right graph shows the noise level (SPL) statistics per frequency. The lower left graph shows the broadband SPL variation over time. 1 noise was the noise with the higher intensity ($SPL_{RMS}$ ~ 142 re 1 µPa; $SPL_{Peak}$ ~ 170 re 1 µPa; and SEL ~173 dB re 1 $\mu Pa^2s$). Considering a rough and simple spherical transmission loss model, type 1 noise was generated at around 190 dB re 1 µPa at 1 meter from the source which was similar to the noise used for sea lion-deterrent bombs (205 dB re 1 µPa) in some countries (Hildebrand 2009), probably generating some impacts on the fish farmed and also over the surrounding ecosystem (considering a cylindrical transmission loss model, it is 166 dB re 1 µPa at 1 m, and with a combined spreading loss model, it is 176 dB re 1 µPa at 1 meter from de source). Solé et al. (2021) determined that noise at relatively lower frequencies (350 Hz and 500 Hz), and SEL around 190 dB re 1 $\mu Pa^2s$, which is used as acoustic treatment against lice infestation, did not present any risks to the hearing of farmed salmon. However, it is necessary to determine if farmed fish show any behavioral changes when they are exposed to chronic noise of higher intensity as detected in this study. The results of this research indicate that the marine ecosystem surrounding the farm in the Comau Fjord is exposed to anthropogenic noise for around 97% of the examined time, where only 3% of this time was without the presence of any

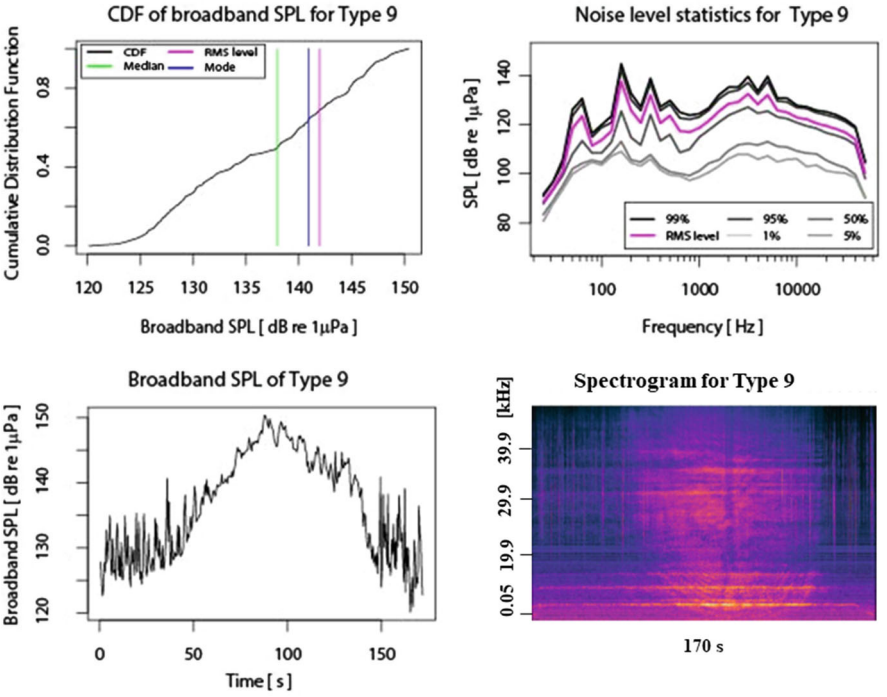

**Fig. 7** Noise metrics from type 9 noise. The graph on the upper left shows the Cumulative Distribution Function (CDF) of broadband SPL, where the RMS levels, the median, and the mode were represented. anthropogenic noise, leaving only few moments for biological acoustic signals which may be important for the ecological processes of a large number of species (Lillis et al. 2013; Hinojosa et al. 2016; Gordon et al. 2019).

Fjords, channels, and estuaries are ecosystems with higher biological productivity and play a very important role in the carbon cycle (Liu et al. 2010). The fjords from the Northern Patagonia are also considered important feeding ground for humpback whales, and feeding and nursery ground for blue whales (Hucke-Gaete et al. 2013; Buchan and Quiñones 2016). The Comau Fjord is considered to be of great importance to shallow cold-water coral formations (Häussermann and Försterra 2007). This area is one of the three fjords in the world that form large banks of the coral species *Desmophyllum dianthus* at shallow depths. In this area, there have been events of massive mortality of this coral due to collateral effects of the microalgal proliferation enhanced by the eutrophication that the salmon farms generate (Försterra et al. 2014). The increasing incorporation of new farming centers may greatly affect the water column (Poblete et al. 2019) and also, as was shown by this study, will introduce different types of noises with higher intensities that may affect

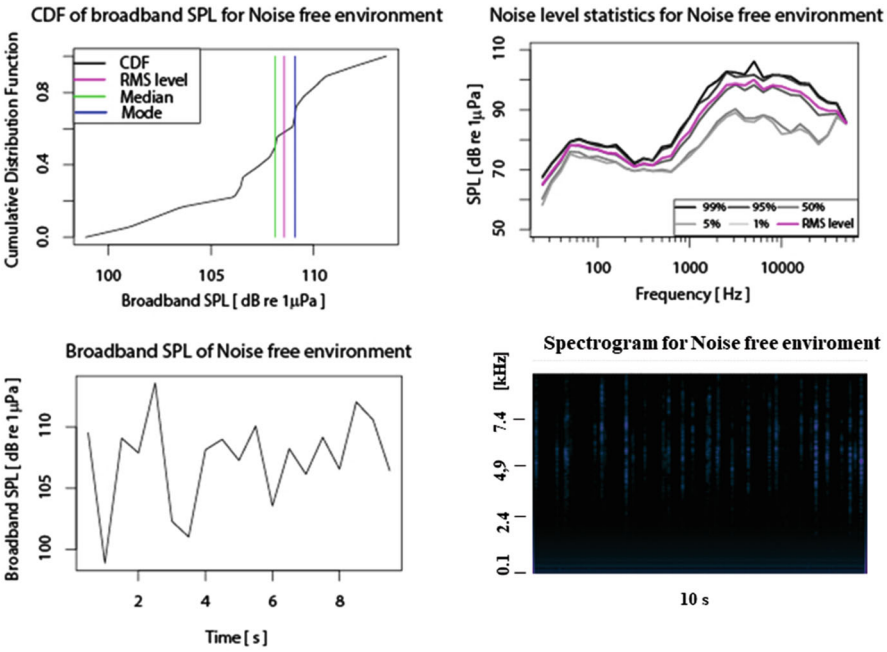

**Fig. 8** Noise metrics from the noise-free environment. The graph on the upper left shows the Cumulative Distribution Function (CDF) of broadband SPL, where the RMS levels, the median, and the mode were represented. The upper right graph shows the noise level (SPL) statistics per frequency. The lower left graph shows the broadband SPL variation over time. The graph on the lower right shows the spectrogram where hottest colors represent higher SPL

the species that inhabit it. Therefore, efforts must be focused on more studies addressing the effects of these noises from the aquaculture industry on the Chilean fjord-land. Therefore, it will help to reformulate environmental regulations when allowing the installation of farming centers in places of ecosystem importance. In addition, detailed environmental impact studies are needed to better understand the biodiversity of these areas, with great population dynamics as they also receive migratory species that would be exposed to chronic anthropogenic noise.

**Acknowledgments** This manuscript was a poster presentation in the conference "The effect of noise on aquatic life" conducted in Berlin, Germany, from 10 to 15 July. The funding for IHT to assist to the conference was provided by COPAS COASTAL ANID FB210021.

**Abstract**

Freshwater ecosystems such as rivers and lakes are heavily threatened by a multitude of stressors, including noise pollution by human activities. Noisy activities on and in the water, such as the prominent use of motorized boats, may alter natural underwater soundscapes. Traffic noise and sound from other human activities on land may also penetrate into the water, especially through bridges. Natural soundscapes vary with hydro-morphological variation among river types and sections and with the heterogeneity in local diversity of sound-producing animals and plants. Natural soundscapes may play an important role in orientation and navigation, in particular for migratory fishes, but still very little is known. It is clear that anthropogenic noise may deter, disturb, distract, and mask natural soundscapes, but few studies have addressed the extent of potential masking impact in freshwater systems. Many rivers flow through urban areas, where typically many bridges provide crossing opportunity to noisy road traffic. Weeklong underwater recordings reveal diurnal and weekly fluctuations of sound pressure levels (SPLs) in underwater soundscapes, likely related to road traffic over urban bridges, in a Dutch lowland river system. Weekdays and weekends

## Introduction

Underwater soundscapes reflect underwater habitat features and locally audible biodiversity (Alcocer et al. 2022; Desjonqueres et al. 2015; Gottesman et al. 2020). A soundscape refers to all sounds audible at a particular location and is determined by the presence of sound sources and propagation properties of the waterbody (Mullet et al. 2017). Sound sources include natural sources of abiotic (wind, waves, water currents and turbulence, running sediment), biotic (animals, plants) origin (Hildebrand 2009; Fine and Parmentier 2015; Geay et al. 2017; Freeman et al. 2018), and anthropogenic sources of human activities making sound purposefully (sonar, airguns) or as a by-product (vessel, construction, and piling noise, and sounds from weirs, locks, and pumping stations). These environmental sounds are also referred to as geophony, biophony, and anthrophony (Mullet et al. 2017; Pijanowski et al. 2011). Sounds attenuate over a distance because of spherical spread, and high frequencies fade at a faster rate than low frequencies, except in shallow waters, in which wave length and water column height determine a low-frequency cut-off for wave lengths that do not fit the depth (Forrest et al. 1993; Larsen and Radford 2018; Rogers and Cox 1988; Urick 1975).

Habitat-associated soundscapes determined by the acoustic presence of aquatic animals have often been reported for marine environments (Kaplan and Solomon 2016; Kennedy et al. 2010; Lin et al. 2021). Furthermore, acoustic monitoring has been successfully applied to assess fluctuations in habitat quality, for example, for tropical and temperate reefs (Bertucci et al. 2016; Harris et al. 2016). Also, freshwater soundscapes consist of a wide variety and potentially habitat-dependent sound sources with diverse spectral characteristics (Desjonqueres et al. 2015; Gottesman et al. 2020; Martin and Popper 2016). Biotic sounds include fish calls (Colleye et al. 2013; Cott et al. 2014; Parmentier and Fine 2016), aquatic invertebrate chorusing (Desjonqueres 2016; Greenhalgh et al. 2021), amphibian and bird calls (Narins et al. 2007; te Velde et al., n.d.), and even aquatic plant respiration (Kratochvil and Pollirer 2017; van der Lee et al. 2020). These biotic sound sources typically co-occur with abiotic sound sources, and the mixture of sounds is filtered by environment-specific propagation features, which can all provide critical information about the environment to aquatic animals (Fay 2009; Slabbekoorn et al. 2010).

Habitat-associated soundscapes determined by hydro-morphological features have been investigated in particular for freshwater systems. Wysocki et al. (2007) and Amoser and Ladich (2010) revealed, for example, habitat-associated soundscape diversity as well as year-round soundscape diversity in Austria. Most pronounced

were the differences between quiet stagnant waters and loud fast-flowing waters (Amoser and Ladich 2010; Wysocki et al. 2007). Tonolla et al. (2010, 2011) studied the relationship between physical river features with soundscapes in more detail for high-elevation fast-flowing rivers in Switzerland (Tonolla et al. 2010, 2011). He found considerable temporal variation in spectral profiles, but this was exceeded by spatial variation associated with distinct river sections, such as pool, riffle, and running sediment. Kacem et al. (2020) had similar correlative results in Canadian rivers and additionally found brook trout (*Salvelinus fontinalis*) densities associated with both physical features of river sections and variation in sound levels therein (Kacem et al. 2020). Different sections of a relatively slow-flowing Dutch river system, with relatively low-amplitude SPLs, also varied spectrally with several hydro-morphological features (te Velde et al. unpublished manuscript).

Human activities on, in, and near waterbodies introduce anthropogenic noise in natural soundscapes. Habitat-dependent soundscapes that may provide cues to aquatic animals may thereby be disturbed or masked (Duarte et al. 2021; Mickle and Higgs 2018; Popper and Hawkins 2019; Slabbekoorn et al. 2010). Boat noise is generally composed of a broadband component and a set of tonal sounds that are generally high in amplitude compared to natural soundscapes (Hildebrand 2009; Jansen and De Jong 2017). Traffic noise outside the water, on nearby roads or bridges, can also affect underwater soundscapes, especially for the low-frequency ranges (Holt and Johnston 2015; Martin and Popper 2016; te Velde et al. unpublished manuscript; Zang et al. 2019). However, still only a few studies report spatial and temporal variation in underwater sounds that originate from human activities on land (Martin and Popper 2016; Rountree et al. 2020). Furthermore, while there is increasing attention toward anthropogenic noise and soundscape deterioration in marine systems (Havlik et al. 2022), river systems remain largely overlooked.

In the current study, temporal patterns are investigated in a weeklong underwater recordings at urban bridges and at more quiet rural areas, with more and less nearby road traffic, respectively, in a Dutch lowland river system. With the aim to answer the following questions: Are diurnal and weekly fluctuations of road traffic density reflected in patterns of sound pressure levels (SPLs) of underwater soundscapes? Are urban bridge sites more noisy in overall underwater SPLs than rural quiet sites, and are relatively quiet, nighttime periods shorter within than outside the city? Is there significant variation among different days of the week, and can weekdays and weekends acoustically be distinguished in underwater soundscape profiles? Answers to these questions should provide insight into the potential for noise pollution impact on migratory fishes and other aquatic animals that rely on natural soundscapes for daily survival and reaching reproduction sites and life stages.

## Methods

Continuous one-week recordings were made synchronously at four bridges twice at two cities, at high- and low traffic-density sites, in the Valleikanaal-Eem river system in the Netherlands (te Velde et al. unpublished manuscript). As a reference for traffic density, sound level values were extracted from an in-air traffic noise map made by

the "RIVM atlas voor de leefomgeving" (RIVM 2021) (Fig. 1). In this map, sound level was predicted from data on hourly motorized vehicle passages, and is expressed in Lden (Level Day-Evening-Night), which yields a mean dB re 20 uPa level per 24 hours, where evening and night have a higher weighting than daytime levels. Samples were taken in the relatively small, slow-flowing river Valleikanaal, within and outside the city of Veenendaal, and in the relatively large, slow-flowing river Eem, within and outside the city of Amersfoort. In March 2022, four Soundtraps were deployed to get a weeklong, continuous recordings, simultaneously at two high traffic-density sites (under bridges) and two low traffic-density sites (rural area). This was carried out in the cities of Veenendaal (8–16 March 2022) and Amersfoort (22–31 March 2022) (Fig. 1). This resulted in 4 one-week recordings at high traffic-density sites and 4 one-week recordings at low traffic-density sites.

Four Soundtrap 300 STD hydrophones (Ocean Instruments, NZ, Acoustic Monitoring Systems) were used, suspended between an anchor and a sub-surface buoy to prevent surface motion, in the middle of the river, 30 cm above the riverbed and 1.50 m below the water surface. The soundtraps were set at a sampling frequency of 96 kHz, high PreAmp gain, and with the high-pass filter turned off. Spectrograms were generated of the weeklong recordings with a temporal resolution of 1 minute,

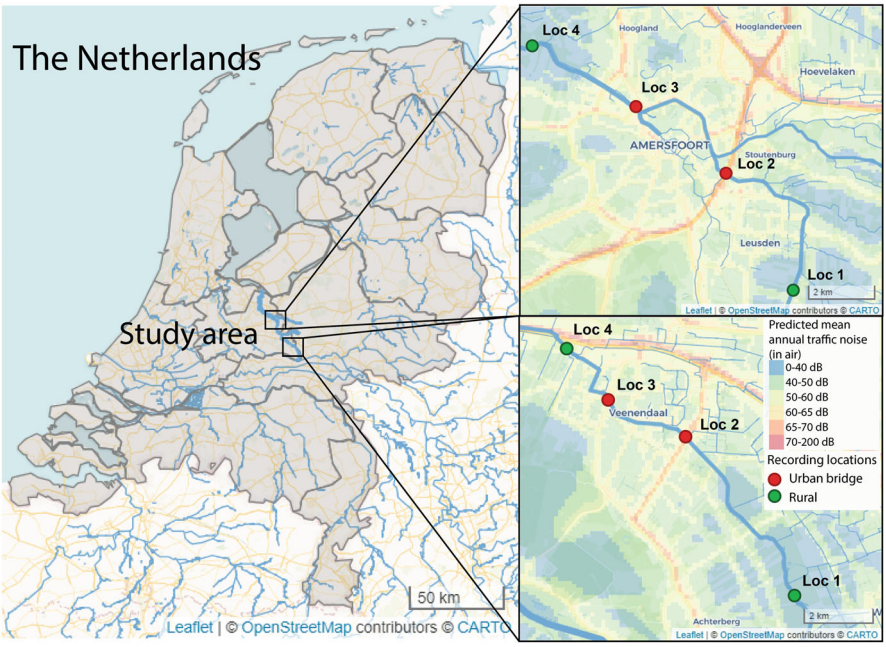

**Fig. 1** Recording locations in the Valleikanaal-Eem river system in and around the cities of Amersfoort and Veenendaal with predicted in air sound map from traffic noise. The traffic noise map was adapted from the RIVM atlas leefomgeving. Sound in the map was predicted from data on hourly motorized vehicle passages, and is expressed in Lden (Level Day-Evening-Night) which is a mean dB re 20 uPa per 24 hours, where evening and night have a higher weighting than day levels

and a frequency resolution of 1 Hz, to explore temporal and spectral patterns in the river soundscapes (te Velde et al. unpublished manuscript) (see Fig. 2 for example spectrograms of two locations). Any patterns that stood out from the long-term spectrogram were inspected further through visual inspection of 2-hour

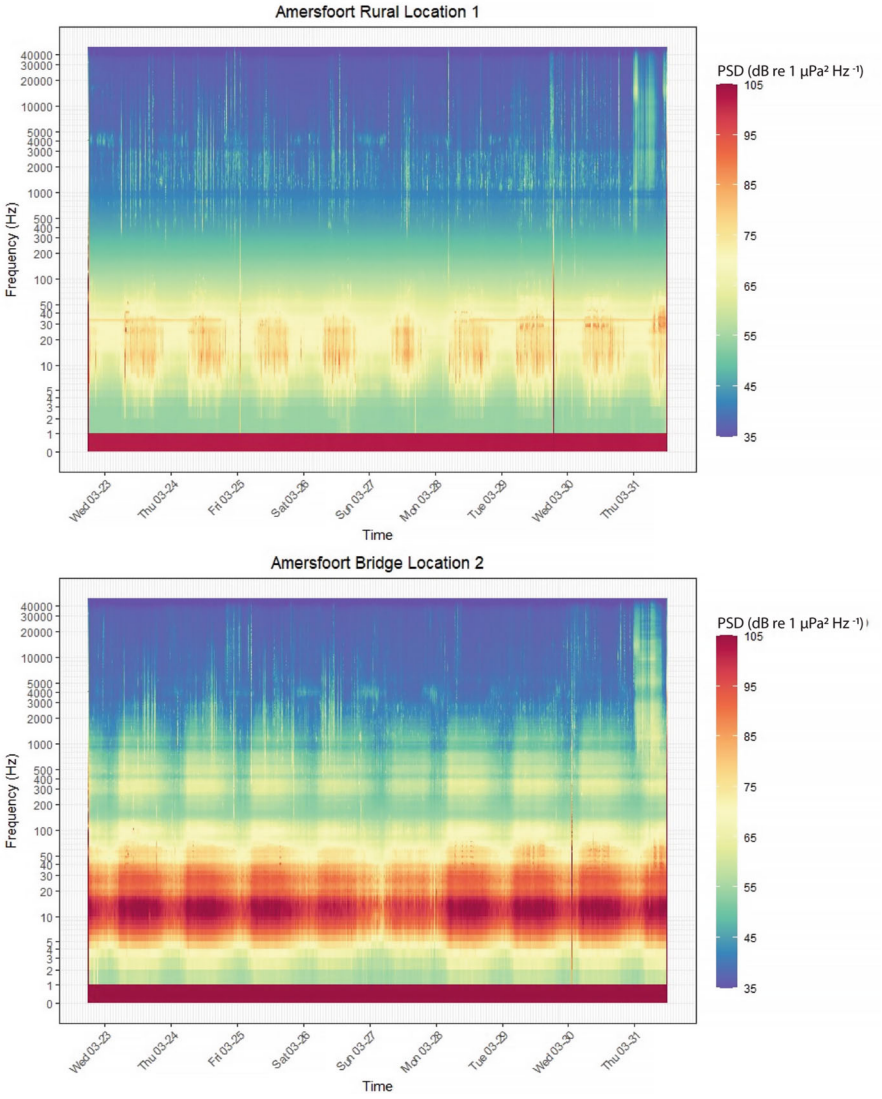

**Fig. 2** One-week spectrogram examples of one of the rural and urban Bridge recording locations in and around Amersfoort. Sound energy between 10 and 50 HZ is likely largely attributable to daily fluctuations in traffic noise levels. At 4000 Hz, repeated presence of water boatmen in the evenings is visible for both sites. Also present on the last day for both sites: rain sound across the full bandwidth, especially visible in the highest frequencies (300–40,000 Hz)

spectrograms with a higher temporal resolution in the audio program Audacity™. The window length settings were often adjusted to achieve a desired temporal and spectral resolution depending on recording conditions.

Temporal variation in sound levels was investigated, over the day and throughout the week, by depicting sound pressure level (SPL, in dB re 1 μPa), per hour, separately for each day of the week. Sound energy for the 10–50 Hz frequency band was selected, which should capture road traffic related noise presence well (te Velde et al. unpublished manuscript; Holt and Johnston 2015; Zang et al. 2019; Song et al. 2020; note that soundtraps only gradually provide accurate data in the range up to 20 Hz, which calls for some caution in comparing absolute levels among studies, but the frequency range of 10–50 Hz provides well comparable level within this study). Whether there was significant variation in SPL between urban bridge locations and rural quiet sites, and whether there was significant variation among days was tested. This was done using two-way repeated measures ANOVA, followed by a post-hoc pairwise comparison using the Estimated Marginal Means (EMMs) with Tukey adjustment. The period of relatively quiet night time (between 19:00 and 7:00) was measured, at the arbitrary threshold of 75 dB re 1 μPa, and again tested whether there was significant variation in quiet night duration between urban bridge locations and rural quiet sites, and whether there was significant variation among days. This was also done using two-way repeated measures ANOVA, followed by a post-hoc pairwise comparison using the Estimated Marginal Means (EMMs) with Tukey adjustment.

## Results

All amplitude patterns showed a distinct day-night pattern over the day (Fig. 3), with higher daytime than nighttime SPLs. Typically, sound levels rose sharply between 5:00 and 7:00 in the morning, to reach a plateau for the day, to level off gradually again over a long period, between 15:00 in the afternoon and 3:00 the next morning. The rural nights had a longer quiet night period than the urban bridge sites, roughly centered between 23:00 and 4:00. The urban bridge sites had weekday plateaus at 88 and 90 dB re 1 μPa in Veenendaal and 90 and 95 dB re 1 μPa in Amersfoort. The rural quiet sites had weekday plateaus at 68–70 and 75 dB re 1 μPa in Veenendaal and 73–75 and 72–74 dB re 1 μPa in Amersfoort. The urban bridge sites were significantly more noisy than the quiet rural sites ($F(1, 6) = 44.43$, $p < 0.001$). The difference between daytime high and nighttime low ranged from 15 to 35 dB at urban bridges, while this was around 5 dB for the rural sites. There also was significant variation among days ($F(6, 36) = 22.993$, $p < 0.001$), with weekend days in particular being more quiet than weekdays at the urban bridge sites (see Fig. 4 for pairwise significance).

The duration of relatively quiet nighttime periods (Fig. 5) varied significantly between urban bridge and rural quiet sites ($F(1, 6) = 103.2$, $p < 0.00001$), there was no significant difference in quiet hours among nights. The sound level did not get

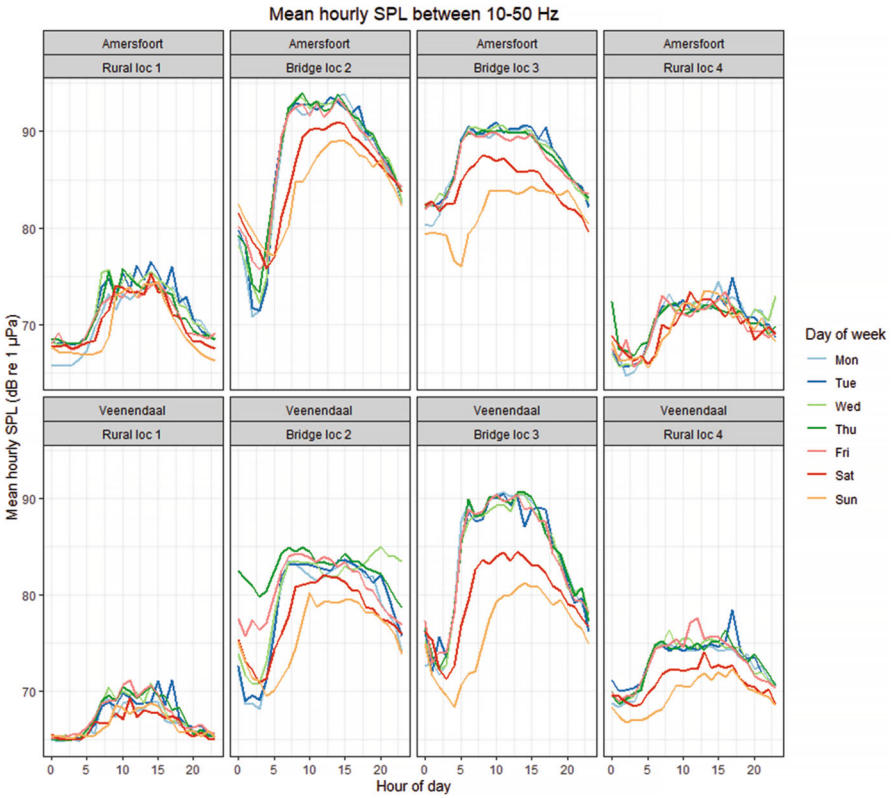

**Fig. 3** Mean hourly Sound Pressure Levels (SPL) between 10 and 50 Hz at each recording location, colored lines indicate the days of the week

above the arbitrary threshold of 75 dB re 1 µPa at rural sites 1 and 4 of Veenendaal, and not below at the urban bridge site 3 in Amersfoort.

## Discussion

Diurnal and weekly fluctuations of road traffic density were found, reflected in patterns of sound pressure levels (SPLs) of underwater soundscapes from these Dutch lowland river sites. Urban bridge sites were noisier in underwater SPLs than rural quiet sites, and relatively quiet, nighttime periods were significantly shorter within than outside the city. Also, significant variation was found among different days of the week, and weekdays could acoustically be distinguished from Saturday to Sunday, in particular for the urban bridge sites of both Veenendaal and Amersfoort. How these findings provide insight into the potential for noise pollution impact on migratory fishes and other aquatic animals will be addressed below.

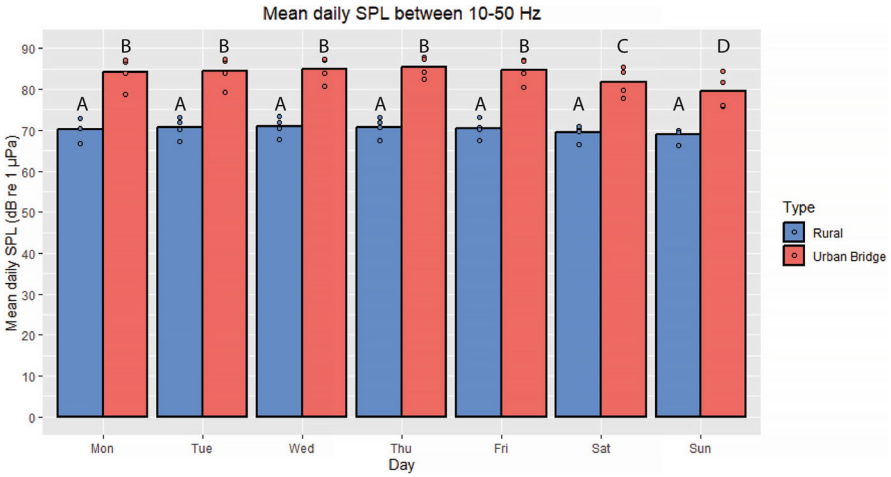

**Fig. 4** Mean daily SPL between 10 and 50 Hz of rural and urban bridge recording sites. Dots represent the mean daily SPL of each separate recording location. Letters indicate pairwise significance, showing that rural is significantly different from urban bridge, and Saturday and Sunday in the city are significantly different from other days in the city

## Human Presence in Underwater Soundscapes

The patterns in underwater sound pressure level results suggest large differences between day and night and between urban bridges and rural sites. Also at the rural sites, differences were seen between day and night, but also sound traces on the sonograms that were very similar in frequency, shape, and pattern to the road traffic related sounds for the urban bridge sites (also see Holt and Johnston 2015; Martin and Popper 2016; Zang et al. 2019; Song et al. 2020; te Velde et al. unpublished manuscript)). So, it is not certain whether any of the diurnal fluctuations are related to natural fluctuations at the rural sites, but for the urban bridges it is clear that traffic noise causes strong elevations of daytime sound pressure levels and shortening or complete absence of relatively quiet nighttime periods. Martin and Popper (2016) also found SPL differences under a large bridge over the Hudson River (USA) between weekends and weekdays, summer and fall, and peaks during rush hours. The variation in underwater sound levels between weekdays and weekends implies that impact could also have a weekly cycle. Such variable impact was found for free-ranging mulloways (*Argyrosomus japonicus*) related to higher boat activity in weekends (Payne et al. 2014). Individual fish were less active and inhabited deeper waters during the weekend, and they had less full stomachs and fewer fish in their diet over the weekend.

The road traffic related elevation of sound pressure levels is most prominent up to 100 Hz but is visible on the sonograms up to 3000 Hz and is typically at its high end from 7:00 to 15:00, after which sound levels only gradually decline throughout the afternoon and evening. In contrast with Martin and Popper (2016), the current study does not show significant SPL peaks at rush hours. Fish and other aquatic animals

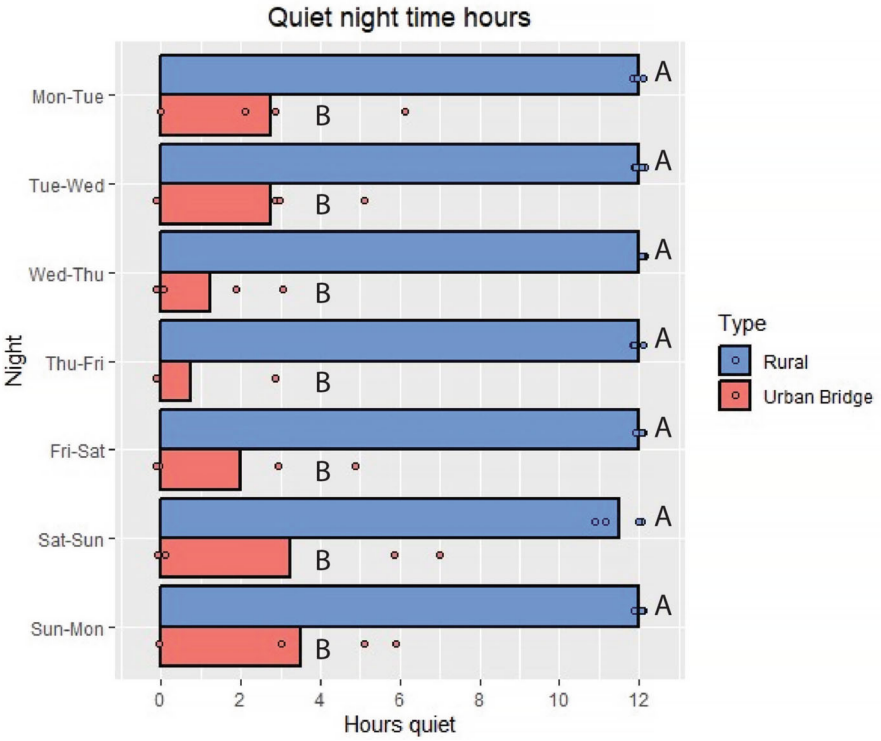

**Fig. 5** Number of "quiet" hours per night (between 19.00 and 7.00), in which SPL between 10 and 50 Hz is below 75 dB re 1 µPa. Dots represent hours per day of each separate recording location. Letters indicate pairwise significance

are expected to be able to detect particle motion, and some fish and invertebrate species can detect sound pressure, due to the presence of a gas-filled bladder or bubble, depending on its size and distance from the ear (Amorim et al. 2015; Fine and Parmentier 2015; Ladich 2015; Popper et al. 2019). Particle motion levels are not the same as sound pressure levels, especially not close to water-air or water-substrate boundaries. The frequency range of most interest for communication and environmental cues for fish and aquatic animals is typically only up to a few hundred Hz or maximally up to a few thousand Hz, depending on the species. Little is known about diurnal activity patterns or fluctuations in relative importance of audibility of the natural soundscape, but many fish species migrate or spawn in the evening and at night (Brönmark et al. 2014; Lucas and Baras 2008; Northcote 1984), invertebrate species are also known to chorus in the evening and at night (te Velde et al. unpublished manuscript), and light conditions obviously make vision less useful overnight. The presence of anthropogenic noise in the Dutch river system, especially in the urban environments at bridges, seems therefore likely a potentially detrimental masker for relevant sounds and can limit animal access to important acoustic information (Codarin et al. 2009; Popper and Hawkins 2019).

## Conservation Implications

Freshwater ecosystems are among the most vulnerable in the world (Reid et al. 2013; Deinet et al. 2020; Tickner et al. 2020), typically threatened by a multitude of stressors (Parrish et al. 1998). These stressors include: blockage of routes for migratory species, overfishing, water quality and quantity changes, and riverbed deterioration (Allan et al. 2005; Belletti et al. 2020; Brevé et al. 2014; Forseth et al. 2017; Grill et al. 2019; Tamario et al. 2019). Anthropogenic noise may add up to these stressors, through acoustic deterrence, disturbance, distraction, and masking. Although the surface has just been scratched about variation in natural soundscapes, the importance of sound to aquatic animals has become sufficiently clear, as is the associated threat by noise pollution (Cox et al. 2016; Duarte et al. 2021; Fay 2009; Slabbekoorn et al. 2010; Slabbekoorn and Bouton 2008). A few examples of anthropogenic noise-related activity level, swimming patterns, and foraging efficiency, already indicate that sound may indeed have fitness consequences for fish (Payne et al. 2014; van der Knaap et al. 2021).

Noise pollution may especially affect migratory fish. Migratory fish are constantly faced with challenges on their way and continuously need to take decisions based on the environmental information available to them. They thereby depend on external stimuli with critical information about their surroundings, such as habitat suitability, predator presence, potential mate quality, and food availability. External stimuli can be detected through a variety of senses: taste/smell, sight, touch, and hearing (Lucas and Baras 2008), but the latter is so far little investigated and underrated or overlooked. Several studies have shown that fish species use sound in orientation and habitat selection, especially in low-visibility conditions of murky waters and during dark nights (Gordon et al. 2018, 2019; Holles et al. 2013; Huijbers et al. 2012; Montgomery et al. 2006; Radford et al. 2011; Slabbekoorn and Bouton 2008). This supports the idea that migratory fish may use the spatial heterogeneity of sounds to gain information about their surroundings. This also implies that masking by anthropogenic noise of the natural soundscapes and acoustic cues in lowland rivers may mean trouble for the animals in this already heavily impacted ecosystem.

## Conclusions

Rivers of high and low elevation, fast- and slow-flowing vary in absolute underwater sound levels. All river types and sections have more or less locally distinct soundscapes related to hydro-morphological features and the local sound-producing biodiversity. Traffic noise in urban areas, over bridges, and even on roads near waterbodies transmits diurnal and weekly activity cycles acoustically to the underwater world. The disparity between the relatively quiet natural soundscapes and the relatively loud presence of anthropogenic noise for large parts of the day suggests another stressor of serious concern for this already threatened ecosystem. Still, little is known about the importance of natural soundscapes for aquatic animals and migratory fish in particular. Therefore, more studies are needed that explore spatial and temporal

variation in soundscapes and the impact of these soundscapes on the distribution and welfare of aquatic animals. Special focus should be put toward the acoustic ecology of migratory fish and to what extent their natural auditorily driven behavior is affected by anthropogenic noise from boats on the water and road traffic near the water.

**Abstract**

Baseline information on underwater ambient sound levels is poorly available for the Mediterranean Sea. The SOUNDSCAPE project filled this knowledge gap, developing a basin-scale, cross-national acoustic monitoring in the Northern Adriatic Sea. Data were collected from March 2020 to June 2021, including the full lockdown period related to the COVID-19 pandemic, at nine stations covering different natural conditions and anthropogenic pressures. Soundscape was monitored continuously 24 h a day by using calibrated stationary recorders (44.1 kHz sampling rate, 16-bit resolution). The entire dataset was analyzed to 20-second

averaged sound pressure levels (SPLs) in all the one-third octave frequency bands (base 10). Noise levels for the 63 Hz and 125 Hz one-third octave bans were described, in compliance with the descriptor 11.2 of the EU-Marine Strategy Framework Directive. A difference of about 30–33 dB was found in these frequencies between the quietest and the noisiest monitoring stations, indicating a high spatial variability. Higher SPL median levels were observed where shipping activity was dominant. The SOUNDSCAPE dataset establishes baseline levels for the assessment of future trends in the Northern Adriatic Sea.

## Introduction

Since the nineteenth century, marine soundscapes have been progressively altered by the sound generated by human activities, such as maritime traffic, coastal construction, seismic surveys, etc. Nowadays, underwater sound has been demonstrated as a potential threat to marine life and as an emerging pollutant (Duarte et al. 2021). To determine the degree of threat requires monitoring and mitigation measures. Adopted by the European Union in 2008, the Marine Strategy Framework Directive (MSFD) is currently the only one example of legislation which directly addresses this source of pollution (Merchant et al. 2022). In a larger context, the MSFD asks Member States of the European Union to attain a good environmental status (GES) by defining eleven qualitative descriptors. Descriptor 11 focuses on introduction of energy (including underwater noise) into the marine environment. Descriptor 11 refers both to impulsive sound in water (Descriptor 11.C1) and continuous low-frequency sound in water (Descriptor 11.C2). Originally D11.C2 implied the monitoring of trends in continuous underwater sound in marine waters but more recently, "levels of anthropogenic continuous low-frequency sound that do not adversely affect population of marine animals" have been requested by the European Commission Decision of 2017 (Comm. Dec. 2017).

Following MSFD guidance, several joint international UN monitoring programs have been developed in European Seas (reviewed by Merchant et al. 2022). In this framework, the Italy-Croatia SOUNDSCAPE project, funded by EU within the Interreg (European Territorial Cooperation) instrument, developed the only basin-scale, cross-national underwater acoustic monitoring run so far in the Mediterranean Sea, with special regard to the Northern Adriatic Sea.

The Adriatic Sea is the northern part of the Mediterranean Sea (Fig. 1), extending as far north as 45°47' N. It is an elongated, landlocked narrow basin that covers an area of about 138,000 km$^2$. The North Adriatic Sea (NAS) includes the northern part, from the Gulf of Trieste to the Middle Adriatic Pit; a transect southeast from Split, Croatia (MS8), to northwest from Ancona, Italy (MS3), was considered for defining the SOUNDSCAPE study area. NAS is characterized by

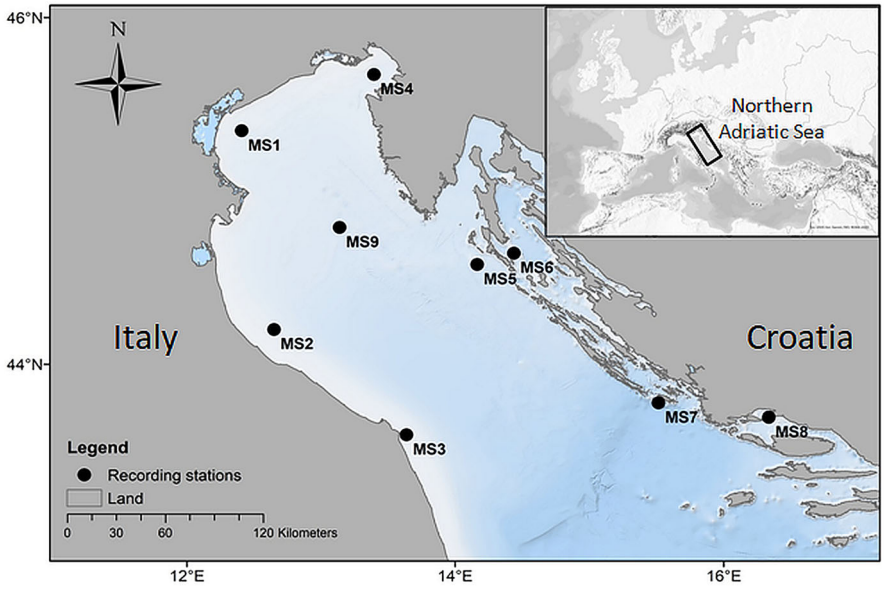

**Fig. 1** Hydrophones positioning in North Adriatic Sea; MS1, Venice (Italy); MS2, Rimini (Italy); MS3, Ancona (Italy); MS4, Trieste (Italy); MS5, Susak Lošinj (Croatia); MS6, Lošinj (Croatia); MS7, Žirje (Croatia); MS8, Split (Croatia); MS9, Ivana D (Croatia). relatively shallow waters, starting with a depth of 15 m along the Venice-Trieste coastline, increasing slowly southward, and then sharply reaching about 270 m in the basin central part. The northern and western coasts are generally sandy-muddy; in contrast, the eastern coast is mountainous, including numerous islands, bays, and coves (Artegiani et al. 1997; Marini et al. 2008). NAS presents strong seasonal variability in vertical temperature and salinity profiles, which could possibly be reflected in seasonal variability in the underwater noise levels. Surface temperature ranges from 4 °C (in extreme winters in the shallow NAS) to 29 °C (during warm and dry summers). Salinity values range from near zero near the mouths of rivers to a maximum of about 39.2 psu (practical salinity unit) on the east part of the area (Mihanović et al. 2013, 2021).

Further, while having a very vulnerable biodiversity including endangered and threatened marine species (Coll et al. 2010), NAS is highly impacted by human-generated activities due to a high concentration of harbors and by many anthropogenic activities including fisheries, mussel, and fish farms, as well as commercial, urban, and touristic activities (Maglio et al. 2016).

The heavy shipping activity that characterizes the NAS, combined with the shallow and stratified waters and the strong seasonality typical for the area, create a unique acoustic environment for a case study.

SOUNDSCAPE started in February 2020. This project created a scientific and institutional cooperation between eight institutional partners, leading to: (i) monitoring the underwater soundscape; (ii) evaluating possible impact on marine biological resources; and (iii) developing and implementing a planning tool for straightforward management. This chapter specifically focuses on the underwater ambient sound monitoring results.

## Underwater Ambient Sound Monitoring in the Northern Adriatic Sea

Nine acoustic monitoring stations were implemented along the Italian and Croatian shallow waters (Fig. 1). Their locations were determined after analysis, considering expected anthropogenic noise pressures, deployment and servicing complexity, soundscape modeling requirements, and cost. All the stations were provided with a calibrated autonomous passive underwater acoustic recorder (hereafter APUAR) Sono.Vault by Develogic Subsea Systems GmbH (Hamburg, Germany), featured with an omnidirectional broadband Neptune Sonar D60 Hydrophone(−192.7 dB re 1 V/μPa sensitivity; flat frequency response: 10 Hz–20 kHz ± 3 dB). Further, the same mooring setup was used in all the monitoring stations. This allowed the data collected to be compatible and comparable between stations. Image and scheme of the Sono.Vault APUAR equipment and accessories are presented in Fig. 2 APUARS were set to record continuously at a sampling rate of 44.1 kHz, providing a recording bandwidth of 22 kHz (16-bit resolution).

Data were collected from March 2020 to June 2021, including the full lockdown period related to the COVID-19 pandemic (i.e., March–April 2020). A subset of data encompassing one calendar year (1/4/2020–31/3/2021) was analyzed in detail.

Processing and visualizing tools based on Python code were specifically developed for SOUNDSCAPE by the University of Gdansk and CNR-ISMAR in accord to Betke et al. (2015). The Jupyter Notebook interactive document for data post-processing is now freely available in ROHub, the research object management platform (Petrizzo et al. 2022a). Metrics used are sound pressure levels (SPLs) in one-third octave frequency bands (hereafter TOBs) (base 10) in units of dB re 1 $\mu Pa_{rms}$. During data analysis, a 20 second temporal observation window was applied. Percentiles values (10th, 50th, and 90th percentiles) obtained per each TOB have been here used as metric, employing the median rather than the arithmetic mean as measure of tendency in the dataset. This is in accord with the most recent recommendations from the Technical Group on Underwater Noise (Sigray et al. 2021). The complete dataset of 20 seconds averaged SPLs output files was recently released by Petrizzo et al. (2022b, 2023).

The SOUNDSCAPE project dealt specifically with monitoring continuous low-frequency sound pressure as requested by the MSFD Descriptor 11.C2. Considering the sound emitted by shipping and the hearing ability of different marine species, frequencies suggested for this descriptor are one-third octave bands centered at 63 and 125 Hz. Therefore, TOB's centered frequencies of 63 and 125 Hz (re 1 $\mu Pa_{rms}$) were the primary focus of the data processing within SOUNDSCAPE, although the sound

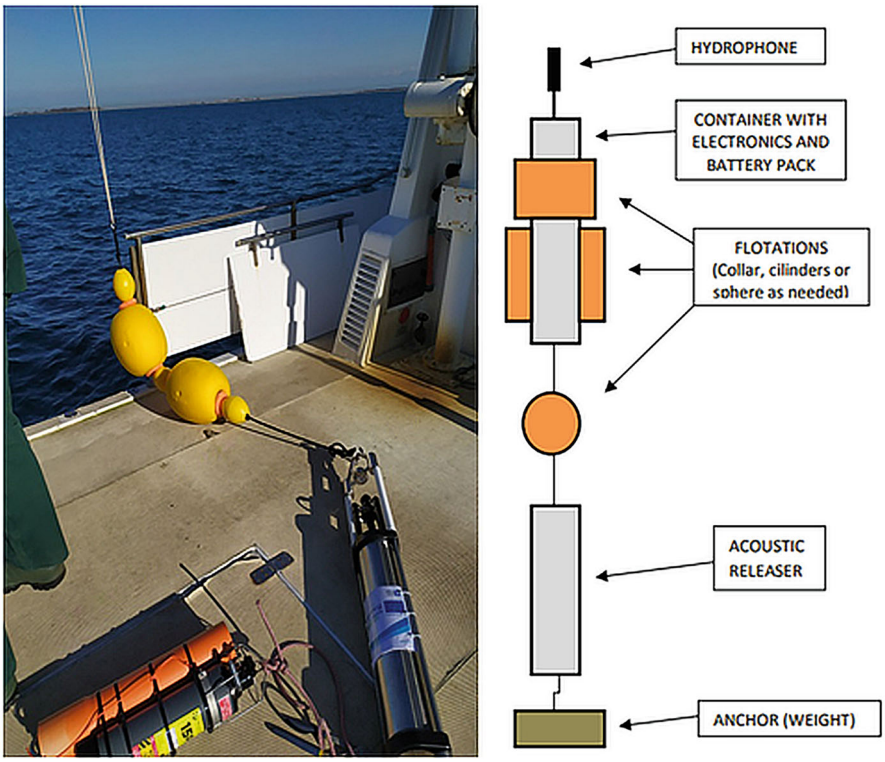

**Fig. 2** Equipment picture (left) and scheme of the autonomous passive underwater acoustic recorder (APUAR) mooring (right); the rig design includes an anchor, an acoustic releaser, the APUAR itself is secured with ropes, and flotations that assure a positive buoyancy at about three meters above the sea bottom. For a detailed APUAR description, please refer to Petrizzo et al. (2023)

measurements themselves covered a wider frequency range (10 Hz–20 kHz). Interestingly, these bands already proved to be predictive of local predominant ship type over time (Picciulin et al. 2015). Two other bands were specifically defined within the project: the 250 Hz and the 4 kHz TOBs, based on two target species identified by the SOUNDSCAPE project. The 250 Hz TOB has been chosen because it falls in the acoustic sensitivity of the target species loggerhead sea turtle (*Caretta caretta*): Its best hearing range falls between 100 and 400 Hz (Martin et al. 2012). The 250 Hz band also falls in the hearing sensitivity of range of most fish species (Ladich and Fay 2013); consequently, it was considered a good proxy to evaluate possible impact on non-mammalian marine species that are relevant for fisheries in NAS. Finally, 250 Hz TOB was found to contain a greater amount of the noise from small vessels, that are highly diffusive in coastal areas, being, at the same time, responsive to noise exposure from large vessels as the 125 Hz band (Merchant et al. 2014).

The bottlenose dolphin (*Tursiops truncatus*) was the other target species identified by the SOUNDSCAPE project. Its hearing sensitivity peaks between 15 and

130 kHz but has a lower but still present acoustic sensitivity between 1 and 10 kHz (Lawson et al. 2001). In the context of SOUNDSCAPE, 4 kHz TOB frequency was chosen as proxy for possible human-generated sound effect on the species. This accords with Jensen et al. (2009) that estimated the potential masking impacts on bottlenose dolphin communication by considering five TOBs with centered frequencies from 4–10 kHz.

Yearly SPL values collected at basin scale are presented here in compliance with the requests of the EU-MSFD. Figure 3 represents the nine NA monitoring stations as circles with different diameter, sized according to their median value (50th percentile) calculated for the 63 Hz, 125 Hz, 250 Hz, and 4 kHz TOBs. These maps graphically indicate those values that are exceeded for the 50% of the recording time.

Overall, for the MSFD frequencies (63 Hz and 125 Hz TOBs), the stations MS3 (Ancona), MS6 (Losinj), and MS1 (Venice) show lower median annual SPLs (63 Hz and 125 Hz TOBs) compared to the other stations, whereas MS2 (Rimini), MS4 (Trieste), MS8 (Split), and MS9 (Ivana) were the noisiest locations. A difference of about 30 decibels is found in the medians between the quietest and the noisiest monitoring stations; in its turn, this confirms the spatial variability in the NAS underwater sound levels.

Figures 4 and 5 show the 10th and 90th percentiles SPLs: for the 10% of time underwater noise values NAS recordings reach values up to 112–115 dB re 1 μPa, mostly accounting the human-made noise contributes for the total noise budget in these frequencies. If 250 Hz TOB median SPLs distribution largely reflects the one

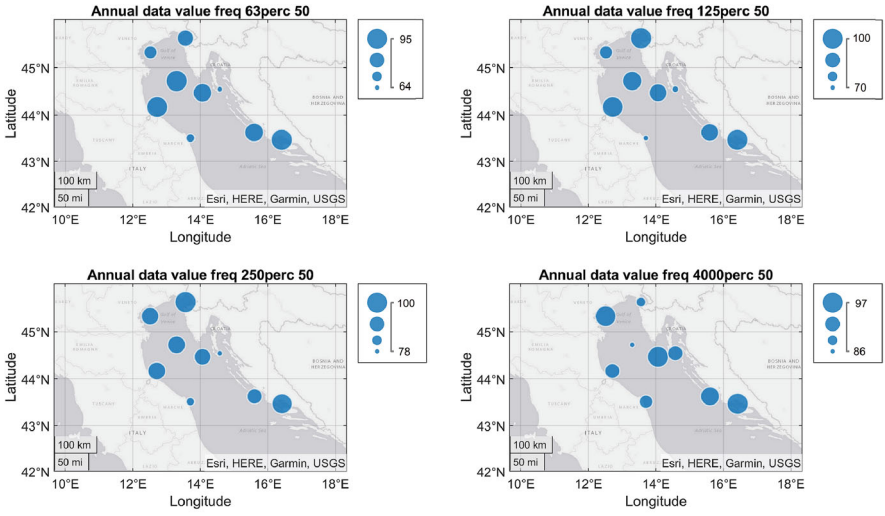

**Fig. 3** Representation of nine NA monitoring stations as circles with different diameters that are sized according to their total 50th percentile (dB re 1 μPa) calculated for the TOBs centered at 63 Hz and 125 Hz over one year of continuous recordings

observed for the case of 63 Hz and 125 Hz TOBs, the same is not true for the 4 kHz TOB, whose highest SPLs are found in MS8 (Split) but also in MS1 (Venice) and MS5 (Susak-Losinj¸ Fig. 4).

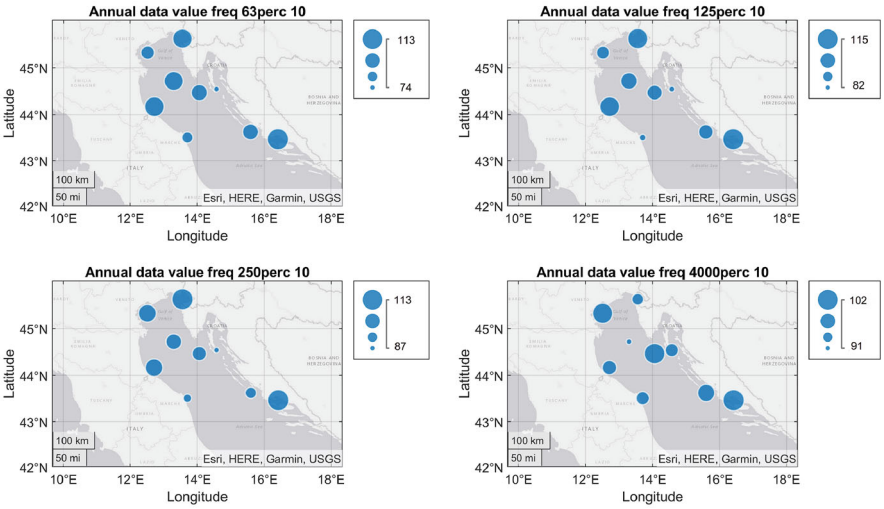

**Fig. 4** Representation of nine NA monitoring stations as circle with different diameter, sized according to their total 10th percentile (dB re 1 μPa) calculated for TOBs centered at 63 Hz and 125 Hz on one year of continuous recordings

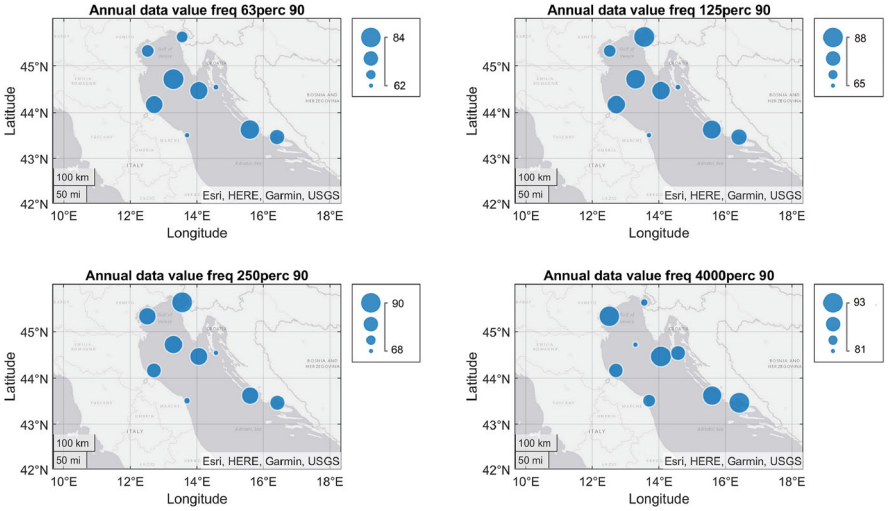

**Fig. 5** Representation of nine NA monitoring stations as circle with different diameter, sized according to their total 90th percentile (dB re 1 μPa) calculated for TOBs centered at 63 Hz and 125 Hz on one year of continuous recordings

## Conclusions

SOUNDSCAPE Interreg project developed an underwater sound monitoring project run at the basin scale in the Northern Adriatic Sea. The acoustic evaluation was expanded into uncovered areas by including the development of sound modeled maps (see Ghezzo et al. present issue). Higher levels in the 63 and 125 Hz TOBs were found where shipping activity was dominant, such as close to ports for MS4 (Trieste) and MS8 (Split) and along shipping lines, as MS9 (Ivana). This suggests that the observed heterogeneity was mainly driven by identifiable sources of human activity. Such a conclusion is further confirmed by the maximum values in the 10th percentile, being lower for the 4 kHz than the 63 and 125 Hz TOBs, the latter having been chosen as proxy of shipping activities. The SOUNDSCAPE dataset establishes baseline levels for the assessment of future trends in the Northern Adriatic Sea, which is particularly relevant since the commercial marine traffic of NAS ports is expected to grow in the next decade (Kocian 2014). The data here presented suggests for the need of mitigation measures in the NAS areas: These areas are relevant for environmental and species conservation and the underwater noise can potentially harm marine organisms in a variety of ways (Duarte et al. 2021).

**Acknowledgments** This work was financed through the project SOUNDSCAPE, funded by the EU Interreg V-A Italy-Croatia CBC Program 2014–2020 (Project ID: 10043643) and endorsed by the RELIANCE project, funded under call "Implementing the European Open Science Cloud" (H2020-INFRAEOSC-2018-2020). **Abstract**

The measured changes in northeast (NE) Pacific Ocean ambient sound levels in the 63–125 Hz bands are explained by the contribution from shipping to the sound energy budget using a globally averaged sound energy model. The energy model fails to identify the dominant source of sound in the 32 and 40 Hz bands because its estimates deviate from the measured levels. More research is required to resolve this discrepancy. Ships in cold deep water contribute more to ambient sound than in warm shallow water. This suggests a potential mitigation action for the NE Pacific Ocean soundscape that would involve avoiding cold deep routes where a warmer or shallower route is available.

## Introduction

### Eightfold Increase in Global Fleet Tonnage: 1964–2017

The amount of sound energy in the ocean associated with a given type of source is proportional to the number of such sources and the mean sound power radiated by each. While one can assign a value, $M$, to the number of ships and estimate their power based on existing measurements, it is problematic to do the same for other man-made sources (e.g., airgun arrays) and natural sources (e.g., marine animals, breaking waves, seismic activity). To analyze non-shipping contributions, empirical ambient sound measurements can be considered instead.

Apart from a small decline in the 1980s, the global commercial shipping fleet size increased monotonically between 1955 and 2017 (Fig. 1). During the 1964–2017 period, the number of vessels increased by a factor 3; the average tonnage of each ship also increased, such that the global tonnage increased by a factor of 8 in the same period (Ainslie et al. 2021; Table 1).

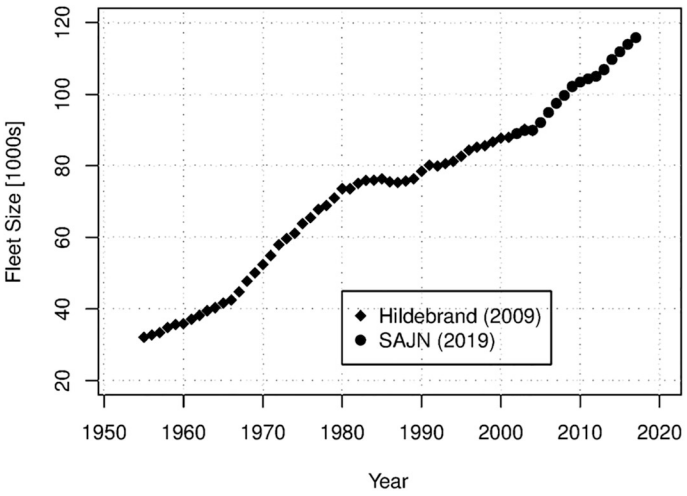

**Fig. 1** Based on Hildebrand (2009) and Shipbuilders' Association of Japan (SAJN) (2019), the global fleet size nearly quadrupled between 1955 and 2017 (Source: Ainslie et al. (2021))

**Table 1** Properties of global shipping fleet since 1964 (see section "Global Average Sound Field") (Based on Ainslie et al. (2021))

| Input | 1964 | 1998 | 2017 |
|---|---|---|---|
| Number of vessels $(M_0)/10^3$ | 40 | 86 | 116 |
| Source depth $(d)$/m | 4.24 | 5.00 | 6.05 |
| Total gross tonnage $(G)/10^9$ | 0.15 | 0.53 | 1.29 |
| Average gross tonnage per ship $(g)/10^3$ | 3.71 | 6.19 | 11.14 |
| Low-frequency level increase since 1964, in decibels, estimated as $10\log_{10}\frac{M_0\ d^2}{(M_0\ d^2)_{1964}}$ | 0 | 4.7 | 7.7 |
| $10\log_{10}\frac{G\ g^{-1/3}}{(G\ g^{-1/3})_{1964}}$ | 0 | 4.7 | 7.8 |
| $10\log_{10}\frac{G}{(G)_{1964}}$ | 0 | 5.5 | 9.3 |

## Observed 3–12 dB Increase in Sound Pressure Level: 1964–1998

Measurements at Point Sur in the northeast (NE) Pacific Ocean (Andrew et al. 2002) show an increase in sound pressure level (SPL) of 3–12 dB in the 10–400 Hz frequency range between the mid-1960s and late 1990s. The largest increase (8–12 dB, corresponding to a rate of 0.24–0.35 dB/a, where "a" is the international standard symbol for year (ISO 80000-3)) occurred in the 10–50 Hz frequency range. Similar increases in the second half of the twentieth century are reported by Ross (2005), McDonald et al. (2006), Andrew et al. (2011), and Chapman and Price (2011). Andrew et al. (2002) present measurements for four sites in the 16–100 Hz decidecade frequency bands (Fig. 2). (Here and throughout, decidecade bands are identified by their nominal center frequencies, in this case 16, 20, 32, 40, 50, 63,

80, and 100 Hz.) The increase in the power-averaged level over the four sites is 2–9 dB (Fig. 3).

Ships are known to radiate sound (Ross 1976), and according to Wenz (1962), the 10–100 Hz "ambient noise" frequency band is dominated by "oceanic traffic."

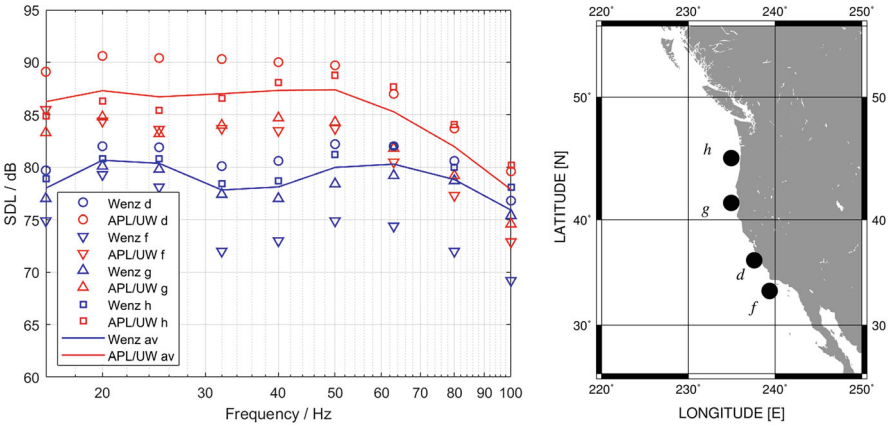

**Fig. 2** Left: Decidecade band power spectral density level (SDL; re 1 μPa$^2$/Hz) versus decidecade band center frequency for 1963–1965 ("Wenz") and 1994–2001 ("APL/UW") averaged over four measurement stations (d: Point Sur, California; f: San Nicolas Island, California; g: southern Oregon; h: southern Washington) in the NE Pacific Ocean. Right: Location of the measurement stations (Right-hand figure reproduced from Andrew et al. (2011) with permission)

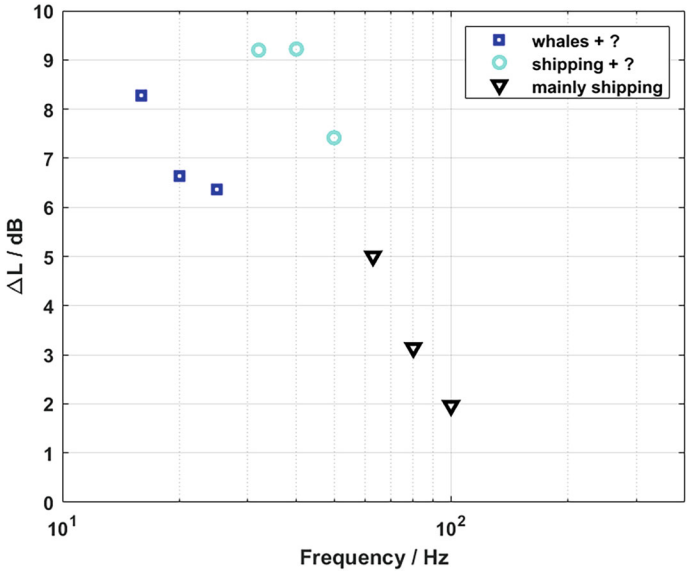

**Fig. 3** Increase in the level versus decidecade band center frequency from 1963–1965 ("Wenz") to 1994–2001 ("APL/UW") averaged over the four sites (d, f, g, and h)

Perhaps for this reason, increases in the 10–100 Hz frequency range are sometimes attributed to shipping traffic (Ross 1993; Erbe et al. 2019). However, while there is strong evidence that the 63–125 Hz decidecade bands are dominated by sound from ships (Ainslie et al. 2021), baleen whale calls make important contributions to other decidecade bands, especially those centered at 16 and 20 Hz (Curtis et al. 1999; Burtenshaw et al. 2004; McDonald et al. 2006). Because whales are known to dominate ocean sound at frequencies between 15 and 25 Hz during some seasons in the NE Pacific Ocean, these frequencies are labeled "whales + ?" in Fig. 3.

## Claimed 15–20 dB Increase in the Sound Pressure Level

According to Hildebrand (2009), available data "provide evidence for an overall increase of at least 20 dB in low-frequency ambient noise from preindustrial conditions to the present," while Frisk (2012) and Duarte et al. (2021) claim increases of 19 dB (1950–2007) and 15 dB (in 50 years), respectively.

The statements of Hildebrand (2009) and Frisk (2012) are partly based on Ross (2005), who demonstrated an increasing trend at 50 Hz of about 11 dB in a 20-year period between the 1950s and 1970s. More precisely, Ross's Fig. 5 provides evidence of an average increase of 0.55 dB/a from 1954 to 1974. On this basis, it seems reasonable to assume a 7.7 dB average increase from 1950 to 1964 at 50 Hz. At the same frequency, there was a subsequent increase of 7.3 dB from 1964 to 1998 (Fig. 3). The total is 15.0 dB in the 48 years from 1950 to 1998, corresponding to an average rate of 0.31 dB/a at 50 Hz. There is also an 11 dB increase at San Nicolas at 16 Hz (Andrew et al. 2011), a band contributed to by baleen whale calls (Table 2, Fig. 5). Finally, Fig. 3 shows an average increase of 2–5 dB in 34 years (1964–1998) in the frequency range corresponding to the 63–100 Hz decidecade bands.

The possibility of larger increases cannot be ruled out, but a careful search revealed no evidence to support claims of an average increase exceeding 15 dB over any time period. The observations in the Pacific Ocean are consistent with an

**Table 2** Changes in SPL in the 16–125 Hz decidecade bands during a period of approximately 34 years (nominally 1964–1998) in the coastal NE Pacific Ocean

| Frequency range/Hz | ΔL/dB | Rate of increase/(dB $a^{-1}$) | Notes |
|---|---|---|---|
| 16–25 | 6.4–8.3 | 0.19–0.24 | Baleen whale calls (Curtis et al. 1999; Burtenshaw et al. 2004; McDonald et al. 2006; Andrew et al. 2011); possibly some shipping |
| 32–50 | 7.4–9.2 | 0.22–0.27 | Some shipping (Andrew et al. 2011); some baleen whale calls (Burtenshaw et al. 2004; McDonald et al. 2006; Andrew et al. 2011);<br>the increases were highest in the 32 and 40 Hz bands, for which the level is overestimated by the global energy model with the Wales-Heitmeyer source level (Ainslie et al. 2021) |
| 63–125 | 2.0–5.0 | 0.06–0.15 | Mainly shipping (Ainslie et al. 2021) |

increase of 0.2–0.3 dB/a in decidecade bands centered between 16 and 50 Hz (Table 2). They do not support a claim of an average increase exceeding 15 dB increase in 50 years and are also not compatible with large increases across the 10–100 Hz frequency range (increases exceeding 5 dB have only been reported for frequencies up to 50 Hz).

## Contribution to Ambient Sound from Ships

Shipping provides a ubiquitous contribution to the soundscape in the NE Pacific (Curtis et al. 1999), with ambient sound levels varying as a functional of seasonal changes in sound propagation. In the 80 Hz decidecade band, the levels reach a maximum in March (Fig. 4), and SPL tracks sea surface temperature (SST) in a mechanism closely related to the afternoon effect (Ainslie et al. 2021). The pattern is repeated over 12 years, especially at site h, and in all bands between 63 and 125 Hz, consistent with a continuously radiating source of sound close to the sea surface (a shipping lane), indicating that ships dominate the coastal NE Pacific Ocean soundscape in this frequency range (Ainslie et al. 2021).

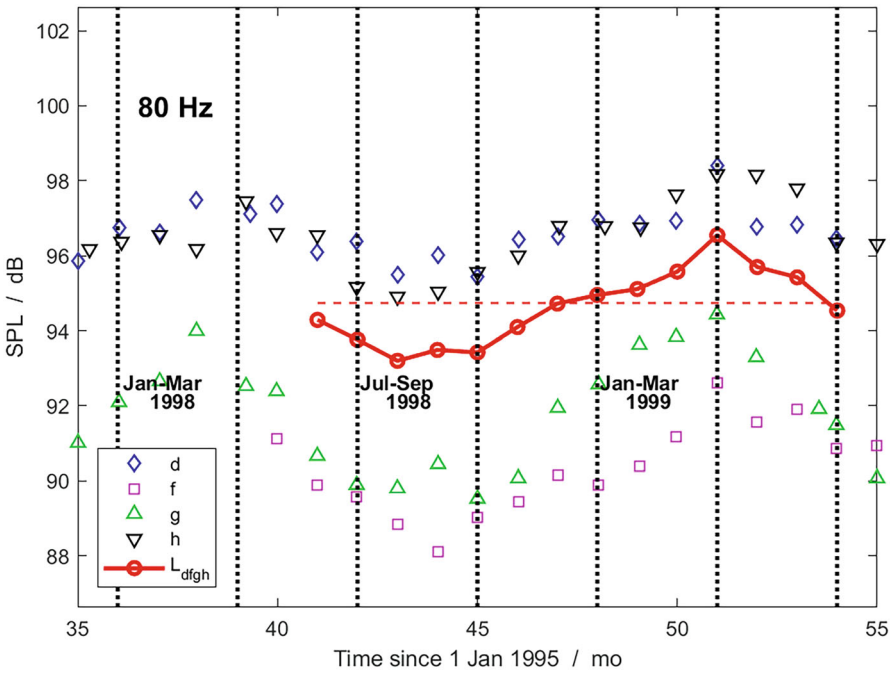

**Fig. 4** Time series of monthly medians of decidecade band SPL (re 1 μPa$^2$) for each of the four sites (d, f, g, and h) versus time in the 80 Hz decidecade band. The red curve is averaged over all four sites. This plot shows 14 months from May 1998 to June 1999, inclusive (Reproduced from Ainslie et al. (2021) with permission)

## Contribution to Ambient Sound from Baleen Whales

McDonald et al. (2009) and Burtenshaw et al. (2004) point out that during the period covered in Fig. 5, fin and blue whales in the NE Pacific Ocean had a spectral peak at 16–18 Hz with blue whale harmonics in the 32, 50, and 63 Hz decidecade bands. McDonald et al. (2009) point out the spectral peak from blue whales decreased from around 22.5 Hz in 1964–1965 to 16 Hz by the early 2000s. Some of the sound in the 16 Hz decidecade band (Fig. 5) undoubtedly originates from whales, and perhaps most of it, but the possibility of a contribution from some other (natural or anthropogenic) source or local effect on sound propagation that also peaks in August–December cannot be ruled out.

Fin whales are present year round at coastal sites in the NE Pacific Ocean (Curtis et al. 1999; Burtenshaw et al. 2004). They transmit a pulse at 15–20 Hz, with low energy in harmonics. Other fin whale calls also have energy in the 40 and 80 Hz bands (Buchan et al. 2019; Wiggins and Hildebrand 2020). Thus, baleen whales contribute to all decidecade bands from 16 to 80 Hz.

Blue whale calls are recorded at the four recording sites mainly between August and December (Curtis et al. 1999; Burtenshaw et al. 2004; McDonald et al. 2006).

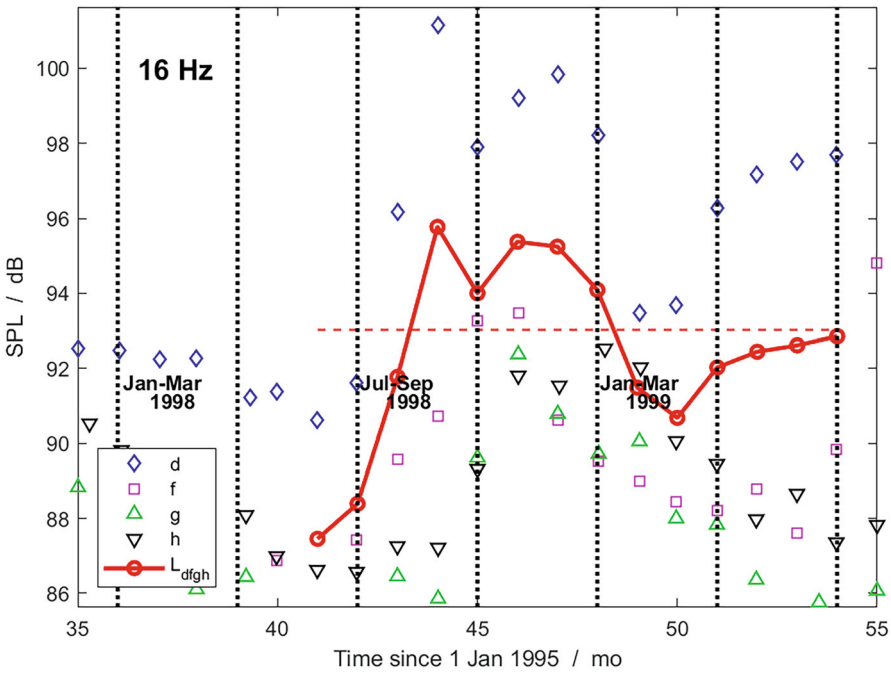

**Fig. 5** Time series of monthly medians of decidecade band SPL (re 1 μPa$^2$) for each of the four sites (d, f, g, and h) versus time in the 16 Hz decidecade band. The red curve is averaged over all four sites. This plot shows 14 months from May 1998 to June 1999, inclusive (Reproduced from Ainslie et al. (2021) with permission)

The 16 Hz decidecade band, which corresponds to a dominant frequency of blue and fin whale calls during the recording period and locations covered in Fig. 5, also has a strong seasonal peak (roughly from August to December; Fig. 5), corresponding to the blue whale calling season off the Californian coast (Curtis et al. 1999; Burtenshaw et al. 2004). The blue whale signal is present at all four sites and is most prominent at sites d and f (Ainslie et al. 2021). The whales arrive later in a northern habitat, and the calling season extends from October to February off the Washington coast (Burtenshaw et al. 2004).

## Motivation for a Global Sound Energy Budget

Managing the risk of underwater sound to wildlife requires understanding what doses of sound cause adverse responses, and measurements of where sound levels may cause adverse effects in areas where sensitive species are found (Tyack et al. 2022) or to which access by sensitive species is prevented. Once adverse effects are observed or expected, mitigation requires understanding of which sound sources contribute to the problem. Management actions to reduce sound enough to reduce the risk require information on how much the main human sources contribute to causing these effects.

Unweighted sound exposure (a physical quantity, the definition of which is independent of any biological receiver) is proportional to average sound energy density. The source contributing the highest average amount of energy to the sound field in each frequency band therefore contributes the largest sound exposure in that band (Ainslie and Dekeling 2011). Thus, a ranking of source types from highest to the lowest sound energy (in joules) facilitates appropriate mitigation measures by targeting those sources making the largest contribution to the sound exposure. Successful risk management and mitigation rely on identifying the source correctly (Hatch et al. 2008).

Shipping noise has the potential to disrupt marine life in multiple ways. The contribution from shipping to the sound energy budget is estimated in the 30–500 Hz frequency range, and much concern about effects of shipping noise focuses on baleen whales, which specialize in low-frequency hearing and communication. Around September each year, North Atlantic right whales transition from their foraging season and prepare for migration. Therefore, the expectation is for stress hormone levels to be elevated by late September. However, after the shipping noise decreased in the North Atlantic following attacks on 11 September 2001 (“9/11”), samples taken from North Atlantic right whales after 9/11 unexpectedly showed *lower* levels of stress hormones relative to earlier in that year. The decrease in stress hormones during the period when noise levels decreased suggests that normal shipping noise levels could be chronically elevating stress in this species (Rolland et al. 2012). Several modeling efforts suggest that shipping noise decreases communication range in baleen whales because of the overlap in the frequency range of the whale calls and shipping noise (e.g., Hatch et al. 2012; Putland et al. 2018; Cholewiak et al. 2018). Baleen whales have mechanisms to compensate for the risk that noise will mask signals, including calling louder, shifting call frequencies out of the noise range, and repeating or lengthening calls (Tyack 2008). Models of

masking that do not account for these compensation mechanisms will overestimate masking effects (Tennessen and Parks 2016). However, there are limitations to these adaptations as they reach a biological limit, e.g., in how loudly an animal can call.

Vessel noise can also harm fishes and marine invertebrates. Reduced reproductive output in a species of coral reef fish was observed at SPL (re 1 $\mu Pa^2$; in the frequency band 108–2046 Hz) of 123 dB or sound particle acceleration level (PAL re 1 $\mu m^2/s^4$, in the same frequency band) of 93 dB (Nedelec et al. 2017), and in a marine invertebrate at SPL of 90 dB or PAL of 73 dB (Nedelec et al. 2014). Vasconcelos et al. (2007), Slabbekoorn et al. (2010), Stanley et al. (2017), and Putland et al. (2018) suggest that shipping noise decreases communication range in fishes because of the overlap in the frequency range of the fish hearing and shipping noise. Rogers et al. (2021) point out that masking can occur when anthropogenic noise overlaps with signals in time, frequency, and direction. The global extent of shipping activity is such that most species of marine fishes and invertebrates that can detect sound are likely to be able to detect ship sound.

According to Erbe et al. (2019), increased shipping is "responsible for the steady rise in ambient noise at low frequencies (10–100 Hz) in many ocean regions." However, large increases occur in bands containing clearly identifiable contributions from baleen whale vocalizations (Curtis et al. 1999; McDonald et al. 2006; Andrew et al. 2011), especially the 16 and 20 Hz decidecade bands (Fig. 3, Table 2), implying that part of the increase in these bands might be caused by increasing baleen whale populations. If this is true, then incorrect identification of the origin of, for example, the observed 8–9 dB increase in the 16–50 Hz decidecade bands may lead to poor management decisions and unexpected results. If the increase in one or more of these bands is caused primarily by an increase in the baleen whale population, then reduction of shipping noise may have less of a quieting effect than expected.

## Sound Energy Budget

Wherever there is sound, there is sound energy. For a medium of density $\rho$ and sound speed $c$, the energy density, $H_V$, is proportional to the mean-square sound pressure, $\overline{p^2}$,

$$H_V = \frac{1}{\rho c^2}\overline{p^2} \tag{1}$$

or mean-square sound particle velocity, $\overline{u^2}$,

$$H_V = \rho\overline{u^2}. \tag{2}$$

Integrating the energy density over all space results in the total sound energy (cf. Eq. 12),

$$H_{\text{tot}}(f) = \int H_V \, \mathrm{d}V, \tag{3}$$

which is related to the globally averaged mean-square sound pressure (Ainslie et al. 2021).

## Purpose and Scope

The purpose of this chapter is to establish a firm foundation for further research by quantifying the contribution from shipping to the global sound energy spectrum in the 30–500 Hz frequency range (delimited by validity of Wales and Heitmeyer (2002) at low frequency and the presence of wind-generated sound at high frequency) and correcting misconceptions arising from observed increases in the level in the frequency range 10–100 Hz.

## Terminology

Acoustical terminology follows ISO 18405:2017. Standard one-tenth decade (i.e., decidecade) frequency bands (IEC 61260-1:2014) are identified by their nominal center frequencies. International standard unit symbols are used for decibel (dB), neper (Np), and year (a) (ISO 80000).

# Methods

## Modeling

### Transfer Function

The quantity of interest (the modeling output) is the total sound energy in the sea (symbol $H_{\text{tot}}$), which is related to the total source power (symbol $W_{\text{tot}}$) up to the sea surface critical angle (symbol $\psi$). The role of the surface critical angle is to determine the amount of sound energy trapped in the water column (steeper paths lose energy on reflection from the seabed and do not contribute to the global sound budget in the frequency range of interest). The transfer function $\tau$ is defined as the ratio of output to input, i.e.,

$$\tau(f) \equiv \frac{H_{\text{tot}}(f)}{W_{\text{tot}}(f)}. \tag{4}$$

the total energy is therefore

$$H_{\text{tot}}(f) = \tau(f) W_{\text{tot}}(f), \tag{5}$$

where for $M_i$ sources of type $i$, each radiating power $W_i$

$$W_{\text{tot}}(f) = \sum M_i W_i(f) \tag{6}$$

and for sources of effective depth $d_i$ and source factor $S_i$ (Ainslie et al. 2021)

$$W_i(f) = \frac{4\pi S_i(f)\sin\psi}{\rho c}\left(1 - \frac{\sin 2k(f)d_i\sin\psi}{2k(f)d_i\sin\psi}\right) \tag{7}$$

where $k$ is the acoustic wavenumber $2\pi f/c$. The transfer function is inversely proportional to the absorption coefficient $\alpha$ (Ainslie et al. 2021)

$$\tau(f) = \frac{1}{2\alpha(f)c}. \tag{8}$$

## Global Average Sound Field

It follows from Eqs. 1 and 5 (using Eqs. 4 and 7) that

$$\langle P_f \rangle = \frac{2\pi}{V_{\text{tot}}}\sum\frac{M_i S_{f,i}(f)\sin\psi}{\alpha(f)}\left(1 - \frac{\sin 2k(f)d_i\sin\psi}{2k(f)d_i\sin\psi}\right), \tag{9}$$

where $V_{\text{tot}}$ is the total volume of all the world's oceans; $P_f$ and $S_f$ are the spectral densities of the mean-square sound pressure, $\overline{p^2}$, and source factor, $S$, respectively; and $<>$ indicates a global average. Equation 9 is a function of six variables, three of which ($S_f$, $kd$, $M$) are properties of the sources (ships) and the other three ($V_{\text{tot}}$, $\psi$, $\alpha$) are properties of the propagation medium. At low frequency ($2kd\sin\psi \ll 1$), it simplifies to

$$\langle P_f \rangle = \frac{4\pi}{3V_{\text{tot}}}\sum M_i \cdot (kd_i)^2 \cdot \sin^3\psi \cdot \frac{S_{f,i}(f)}{\alpha(f)}. \tag{10}$$

The low-frequency dependence on tonnage (Table 1) arises from Eq. 10 by noting that the factor $Md^2$ is approximately proportional to $G/g^{1/3}$. As observed by McDonald et al. (2006), the use of $10\log_{10}G$ would predict an increase of about 6 dB in the last three decennia of the twentieth century, similar to the 5 dB increase predicted by $10\log_{10}G\ g^{-1/3}$ (Ainslie et al. 2021). By contrast, the $10\log_{10}G^2$ dependence assumed by Frisk (2012) would overestimate the observed increase in 63–125 Hz decidecade bands (dominated by shipping) by about 8 dB.

The proportionality with $\sin^3\psi$ in Eq. 10 leads to a seasonal dependence because the critical angle decreases monotonically with increasing SST. A 4 °C temperature difference between summer and winter thereby leads to 2.4 dB higher SPL in the winter for the same shipping traffic (Ainslie et al. 2021). The same proportionality leads to a dependence on water depth because the critical angle increases with increasing water depth in deep water.

## Source Factor and Absorption Coefficient

Following Ainslie et al. (2021), the Wales-Heitmeyer (Wales and Heitmeyer 2002) formula is used for $S_f$ (Fig. 6) (increased by between 1.1 and 3.2 dB, depending on frequency, to account for the difference between the mean value of a level and the level of a mean value), and assume the absorption coefficient $\alpha(f)$ takes the form

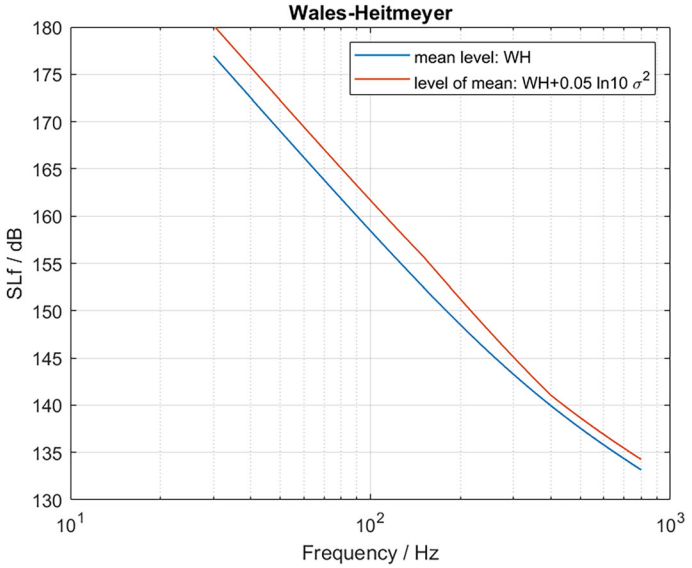

**Fig. 6** Wales-Heitmeyer source spectral density level (re 1 μPa$^2$ m$^2$/Hz) versus frequency calculated as mean level (blue) and level of mean source spectral density (red)

$$\alpha(f) = \alpha_{\min} + \alpha_0(f), \tag{11}$$

where $\alpha_0$ is the contribution from molecular relaxations (mainly boron) and $\alpha_{\min}$ is an empirical constant to be determined, possibly in the 0.2–0.4 Np/Mm range for the North Pacific Ocean (Kibblewhite 1989).

## Measurement

The model described in section "Modeling" (Eq. 9) predicts the globally averaged mean-square sound pressure

$$\langle P_f \rangle = \frac{1}{V_{\text{tot}}} \int P_f \mathrm{d}V. \tag{12}$$

To test the prediction, one needs a measurement of this global average. The ideal solution would be to employ a global network of hydrophones, for example, using the Comprehensive Nuclear-Test-Ban Treaty Organization network (Robinson 2021; Gibbons 2022) or Argo floats (Gould 2005). However, in practice this work is limited by the data available to the authors at the time of writing, at four sites in the NE Pacific Ocean (Andrew et al. 2011). Following Ainslie et al. (2021), an average over these four stations is used as a proxy for a global average.

## Results

The global energy expression (Eq. 10) requires an average low-frequency absorption coefficient. Predicted SPL for multiple values of the low-frequency absorption coefficient (0.05 Np/Mm $< \alpha_{\min} <$ 8 Np/Mm) is compared with measurements in Fig. 7. For each $\alpha_{\min}$, the proportion of the global shipping fleet traversing over deep ocean (denoted $x$) is adjusted to match the measurement at 80 Hz. Different spectral slopes are associated with different low-frequency absorptions $\alpha_{\min}$ (the lower $\alpha_{\min}$, the greater the slope). The value of $\alpha_{\min}$ that best matches the slope in the range 50–100 Hz is 0.05 Np/Mm, but this value is outside the expected range of 0.2–0.4 Np/Mm. Additional hindcasts are made for the years 1964 and 2017 using $\alpha_{\min} = 0.2$ Np/Mm and $x = 0.31$ (corresponding to 31 % of the global fleet operating in deep water and $x/\alpha_{\min} = 1.6$ Mm/Np; Table 3) in Fig. 8.

Figures 7 and 8 demonstrate that the level and spectral slope in the 63–125 Hz decidecade bands (and the 1964–1998 increase in level) are explained by Eq. 10 with the Wales-Heitmeyer source-level spectrum, strengthening further the case for identifying these bands as dominated by shipping (Ainslie et al. 2021).

The theory also explains the 50 Hz decidecade band level, but it overestimates the 32 and 40 Hz band levels and underestimates the level increase at 32 and 40 Hz. Thus, the dominant source type for these decidecade bands remains unidentified.

The same information can be converted back to energy (Fig. 8 right) using

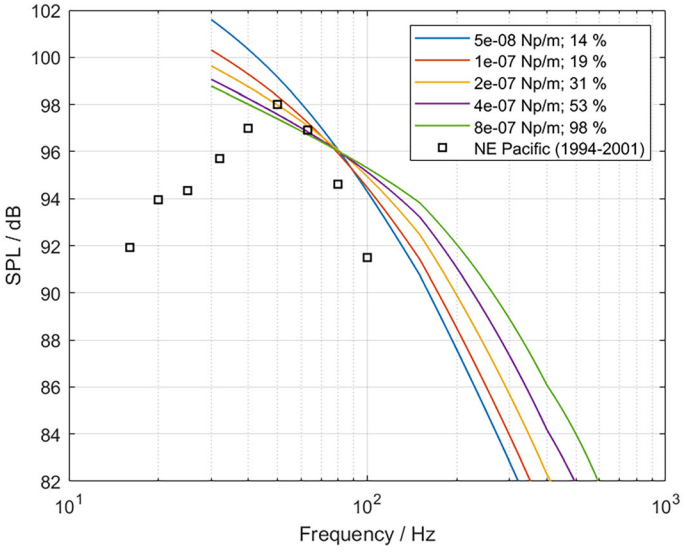

**Fig. 7** Globally averaged decidecade band SPL (re 1 μPa$^2$) versus decidecade band center frequency, scaled to match the 80 Hz measurement for 1994–2001 (0.05 Np/Mm $< \alpha_{\min} <$ 0.8 Np/Mm)

**Table 3** Combinations of $\alpha_{\min}$ and $x$ consistent with late 1990s measurements at 80 Hz in the NE Pacific Ocean

| $\alpha_{\min}$/(Np Mm$^{-1}$) | $x$ | (x/$\alpha_{\min}$)/(Mm Np$^{-1}$) | $\tau_{\max}$/(s Np$^{-1}$) | Minimum decay rate/(Np ks$^{-1}$) |
|---|---|---|---|---|
| 0.05 | 0.14 | 2.8 | 6710 | 0.15 |
| 0.10 | 0.19 | 1.9 | 3360 | 0.30 |
| 0.20 | 0.31 | 1.6 | 1680 | 0.60 |
| 0.40 | 0.53 | 1.3 | 840 | 1.19 |
| 0.80 | 0.98 | 1.2 | 420 | 2.38 |

$$H_{\text{tot}} = \frac{V_{\text{tot}}}{\rho c^2} \langle P_f \rangle. \tag{13}$$

Figure 8 is seen as the first step in constructing a global sound energy budget for both man-made (primarily ships and airgun arrays) and natural sources (primarily wind and whales) in the 10–1000 Hz frequency range (Sertlek et al. 2019).

These measurements are compared with model predictions of the globally averaged spectra, calculated using the method of section "Modeling." The number of ships $M_0$ and their source depth $d$ are obtained from Table 1. In Fig. 7 for 1998, minimum absorption coefficient $\alpha_{\min}$ is varied between 0.05 and 0.80 Np/Mm, and the value of $x$ is adjusted accordingly to match 96 dB in the 80 Hz decidecade band (1 dB higher than the measured value to account for the expected difference between mean and median (Dekeling et al. 2014)). Also needed are total ocean volume $V_{\text{tot}}$ (1.33 Mm$^3$) and sea surface critical angle $\psi$ (0.2), from Ainslie et al. (2021).

The transfer function $\tau$ is equal to the time it takes the amplitude of low-frequency sound to decay by 1 Np (it is the reciprocal of the decay rate). The value of $\tau$ corresponding to 0.2 Np/Mm is approximately 1700 s/Np (Table 3).

## Potential Mitigation Measures

Ships in cold deep water contribute more to ambient sound than those in warm shallow water. This suggests a possible mitigation action involving avoiding cold deep routes where a warmer or shallower route is available, for example, by avoiding the coldest months of the year and giving preference to shallow water routes. Such options should be considered before adopting mitigation measures.

## Conclusions

During a 34-year period in the twentieth century (about 1964–1998), for four sites in the NE Pacific Ocean, the four-site average:

- Increased by 2–5 dB (about 0.1 dB/a) in the 63–125 Hz decidecade bands (mainly shipping sound)

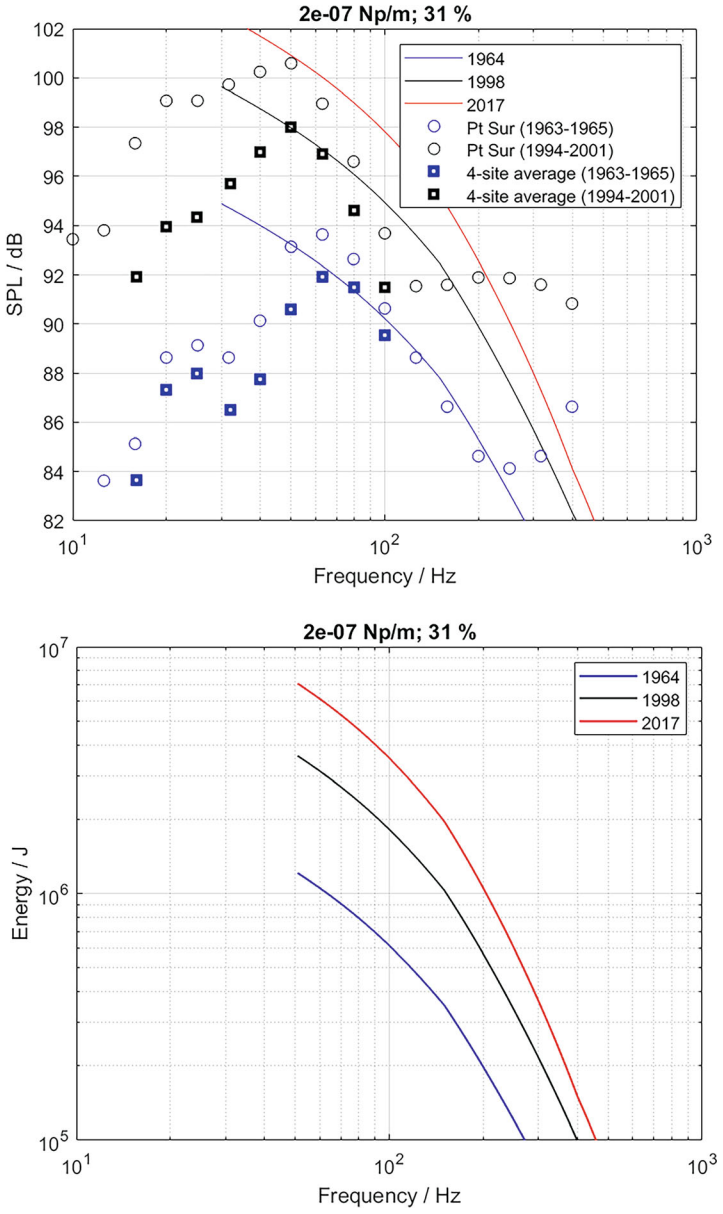

**Fig. 8** Decidecade band hindcasts for 1964, 1998, and 2017 (0.2 Np/Mm). Upper: SPL (re 1 $\mu Pa^2$) versus decidecade band center frequency. Lower: Decidecade band total sound energy versus decidecade band center frequency

- Increased by 6–8 dB (about 0.2 dB/a) in the 16–25 Hz decidecade bands (containing baleen whale calls)
- Increased by 7–9 dB (about 0.25 dB/a) in the 32–50 Hz decidecade bands

At site f (San Nicolas Island), the level increased by 11 dB at 16 Hz (containing baleen whale calls) and by 12 dB in 34 years in the 32 Hz decidecade band. At the same site, increases of up to 12 dB in the 30–50 Hz frequency range were observed in 38 years.

At 50 Hz there is evidence of a 7–8 dB increase between 1950 and 1964, implying a 15 dB increase at this frequency from 1950 to 1998.

No evidence was found at a fixed location of any increase exceeding 12 dB (1964–1998). Without ruling out the possibility of larger increases, no evidence was found of a spatially averaged increase exceeding 15 dB in any time period.

The contribution to ambient sound from ships and its potential to disrupt marine life have long been recognized. Effective management of ship noise would be facilitated by a deeper understanding of the relative contributions from ships and baleen whale calls to the 10–100 Hz ambient sound spectrum. While the ~5 dB increase observed in the NE Pacific Ocean in the 63–125 Hz decidecade bands is fully explained by changes in the number and size of ships between 1964 and 1998 (the power spectral density level varies with global tonnage $G$ and tonnage per ship $g$ as $10\log_{10} G\ g^{-1/3}$), the cause of the ~10 dB increase in the 32 and 40 Hz decidecade bands remains a mystery.

## Research Questions

Research questions for future consideration include the following:

- How much sound energy do ships contribute to the global energy spectrum up to 50 Hz?
- How much sound energy do man-made sources other than ships (e.g., airgun arrays) contribute to the global energy spectrum in the 10–100 Hz frequency range?
- How much sound energy do natural sources (e.g., wind, whales, fishes) contribute to the global energy spectrum in the 10–100 Hz frequency range?
- What causes the larger-than-predicted-level increase in the 32 and 40 Hz bands?
- What infrastructure (e.g., CTBTO, Argo) is best suited to construct an effective, global, hydrophone network to monitor the global soundscape?

**Acknowledgments** The authors thank Dr. Leila Hatch for her insightful comments on a draft version of this chapter.

**Abstract**

Ambient underwater noise levels have been increasing, leading to concern about the impacts to marine species. Extensive research has been conducted on the changes to ambient noise levels of large commercial vessels and potential mitigation measures. However, little is known about smaller commercial vessels (e.g., tugboats) moving throughout coastal waters and what can be done to decrease their influence on marine species. To understand changes to the ambient noise levels (20–24,000 Hz) when tugboats are present, stationary hydrophones were deployed between August and October at two locations: Cowichan Bay, British Columbia (BC) (2019/2020) and Argonaut Wharf, Campbell River, BC (2021). Log transportation tugboats were assessed in Cowichan Bay and the results show

significantly elevated median sound pressure levels (10 dB) when log transport tugs were detected near the estuary where log storage occurs. Even though Argonaut Wharf was used as a site without log transportation tugboats, tugboats were present throughout the study period. Median sound pressure levels were also significantly elevated (6 dB) when tugboats were present in Argonaut Wharf. The results demonstrate the impact that tugboat activities have on underwater soundscapes and are the first step in understanding the impact these activities have on marine organisms and important ecosystems.

## Introduction

Anthropogenic noise has been modifying the global soundscape causing ambient levels to increase (reviewed in Hildebrand 2009). One example is seen in the Northeast Pacific Ocean, where noise levels have increased by around 3 dB/decade for decades leading up to 2000 (McDonald et al. 2006). One main contributor to this increase is the shipping industry, which has been growing for many decades (Tournadre 2014). Shipping noise dominates low-frequency noise (40–1000 Hz), which has increased by at least 10–12 dB since the 1950s in some areas (Ross 1976; Ainslie et al. 2021). Noise produced by large commercial vessels has been extensively documented in the literature (e.g., McKenna et al. 2012, 2013; Gassmann et al. 2017), and mitigation methods are being developed to reduce their impact on the underwater soundscape (MacGillivray et al. 2019; Williams et al. 2019; Burnham et al. 2021).

One shipping noise source that has only been minimally accounted for in the literature is noise produced by tugboats. Tugboats are used in coastal regions to push or tow equipment and to guide larger ships. Previous research demonstrated tugboats produce noise below 3 kHz (frequency range: 170–2629 Hz) with a source level of 119 dB re 1 μPa (predicted) when transiting (not pulling or pushing) using a stationary hydrophone (Amron et al. 2021). When pushing a barge, Sprague et al. (2016) found that a tugboat produced noise at sound pressure level (peak) of 124 dB re 1 μPa (frequency range: 10–22,050 Hz) and a sound exposure level of 143 dB re 1 μPa (time = 0.125 s) at roughly 600 m away from a stationary hydrophone. They also documented that the frequencies most impacted by tugboat sound are frequencies below 1000 Hz. Vessel size has also been shown to have an impact on the noise produced, with tugboats over 50 m having a mean broadband radiated noise level (RNL; 10–64,000 Hz) of 186.2 dB re 1 μPa @ 1 m compared to tugs less than 50 m that have a mean RNL of 180.5 dB re 1 μPa @ 1 m (Houweling et al. 2022).

Around Vancouver Island, British Columbia, tugboats are operating in every month of the year (Houweling et al. 2022) and have the highest vessel hours detected compared to all other automatic identification system (AIS)-equipped vessels in the

area due to high volume of activity (MacGillivray et al. 2016). In addition to traditional roles, tugboats around Vancouver Island are also used to move logs into bays and estuaries where logs are stored prior to processing at pulp and sawmills. Logging booms have been documented to negatively impact estuarine habitats (Power 1987; Levy et al. 1990; Nahirnick et al. 2020), but the additional noise generated by these activities has not been quantified. The goal of this chapter was to examine the underwater noise produced by tugboat activities in two different locations on Vancouver Island, British Columbia, to document differences in sound pressure levels and frequency composition under the different activities that tugboats are used for.

## Methods

### Study Locations

Cowichan Bay, British Columbia, is an approximately 800 ha industrialized bay located at the mouth of the Cowichan River near Duncan, British Columbia on Vancouver Island (48° 44.975' N, 123° 35.922' W) (Fig. 1). Cowichan Bay has a high level of anthropogenic noise that originates from recreational boats entering and leaving two marinas and from commercial activity (e.g., tugboats and bulk carriers).

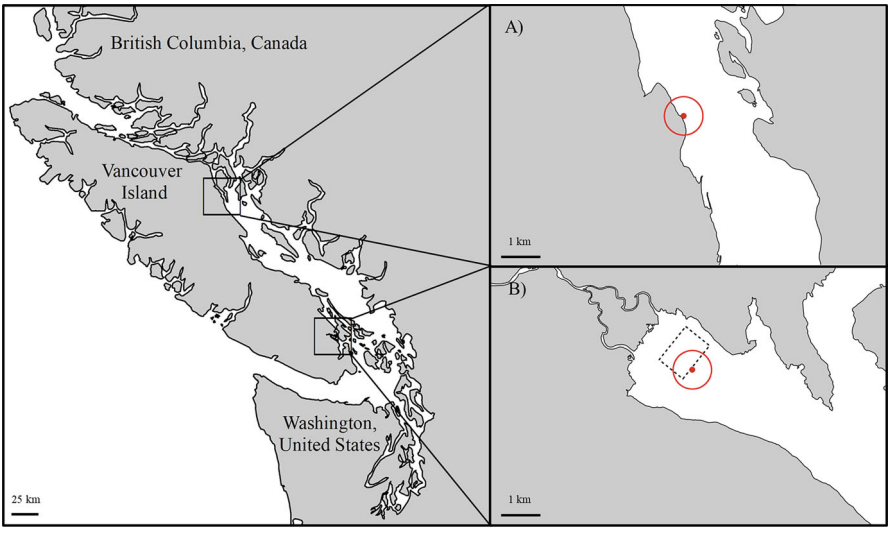

**Fig. 1** Map of Vancouver Island, British Columbia. (**a**) Argonaut Wharf in Campbell River, BC. Red dot shows SoundTrap hydrophone mooring location. (**b**) Cowichan Bay, BC. Red dot shows SoundTrap hydrophone mooring location, and black dashed box denotes the log boom sorting area in the Cowichan River estuary. Map shapefiles were obtained from the Natural Earth and BC Provincial data catalog

Cowichan Bay also has a sawmill that stores log booms in the Cowichan estuary before being brought up to the mill to be processed.

Argonaut Wharf is located at the mouth of the Campbell River, in Campbell River, British Columbia, and extends ~60 m into Discovery Passage, on the east coast of Vancouver Island (50° 2.543' N, 125° 14.834' W). Argonaut Wharf also is in an area of high anthropogenic activity including a ferry that runs every 30 min to and from nearby Quadra Island, commercial vessels (e.g., tugboats, cruise ships) transiting through, and recreational and fishing vessels entering and exiting a marina located 1 km away. Unlike Cowichan Bay, there is no sawmill near Argonaut Wharf.

## Recordings

A SoundTrap (300 STD, Ocean Instruments, New Zealand) internally recording hydrophone system was deployed from August 15, 2019, to October 31, 2019, in Cowichan Bay and then redeployed from August 11, 2020, to October 22, 2020, in the same location (Fig. 1b). The SoundTrap hydrophone was set to a sampling rate of 48 kHz at 16 bits and recorded for 15 min every hour. The SoundTrap was deployed in Cowichan Bay following the methods used in Murchy et al. (2022), on a polysteel line 1 m off the bottom (45 m water depth). Retrieval of the hydrophone was done using an acoustic release.

In 2021, the location was changed to Argonaut Wharf and deployed from August 13, 2021, to September 27, 2021 (Fig. 1a). The SoundTrap was set to the same sampling rate (48 kHz) but recorded continuously throughout the deployment. The deployment method was also modified, and the SoundTrap was secured to an underwater piling using cable ties, at a depth of 5 m off bottom (10 m water depth). Calibration of the SoundTraps was conducted by the manufacturer at 250 Hz with a source level of 120 dB re 1 μPa (B & K 2236 pistonphone).

## Analysis

Data were stored as compressed sud files (.SUD) on the internal memory of individual SoundTraps until retrieval at the end of each deployment. All following data analysis was done using code written in Python (version 3.7). Sound pressure levels were examined in a time series for the full broadband frequency range of the recorder (20–24,000 Hz). The soundscape at both locations was described using 5-min averaged data.

Automatic identification system (AIS) data from equipped vessels in a 5 km radius around Cowichan Bay was obtained for August through October of 2019 and 2020 in 5-min bins and 1-min bins for a 10 km radius around Argonaut Wharf for August and September 2021. AIS data obtained were accurate to ±1 m for the vessel's GPS location. All tugboat data found within the AIS data set were extracted and tracks were generated in ArcMap 10.8 (ESRI, California, USA). Distance between each tugboat's GPS location and the SoundTrap location was generated

using the NEAR function to obtain the closest point of approach for each tugboat, and only tugs that were within 500 m of the SoundTraps were used in the analysis. Additionally, for the Argonaut Wharf data set, tugboats needed to be within 500 m for at least 2 min (half of the 5-min bins used for SPL calculations) to be included.

SPL measurements were binned into two equal time periods (with and without a tugboat present). Depending on the length of the tugboats' presence on a given day, the "no tugboat" time period was selected to match. Power spectral density (PSD) plots were also generated for both time periods for the entire frequency range and compared. Sound pressure measurements between time points with and without tugboats were normally distributed, so *t*-tests were used for analysis, and were performed in RStudio version 4.1.2.

## Results

### Tugboat Logging Activities (Cowichan Bay)

Log transport activities did not occur during 2019 due to a strike at the Western Forest Mill located in Cowichan Bay, but restarted once the strike ended in early 2020. During August and September of 2020, six tugboats pulling log booms were detected within Cowichan Bay using AIS; however, only four times did the tugboat get within 500 m of the hydrophone while it was recording.

Tugboats pulling logs near the estuary in Cowichan Bay significantly changed the soundscape for the full broadband range collected (20–24,000 Hz; Fig. 2a). Median

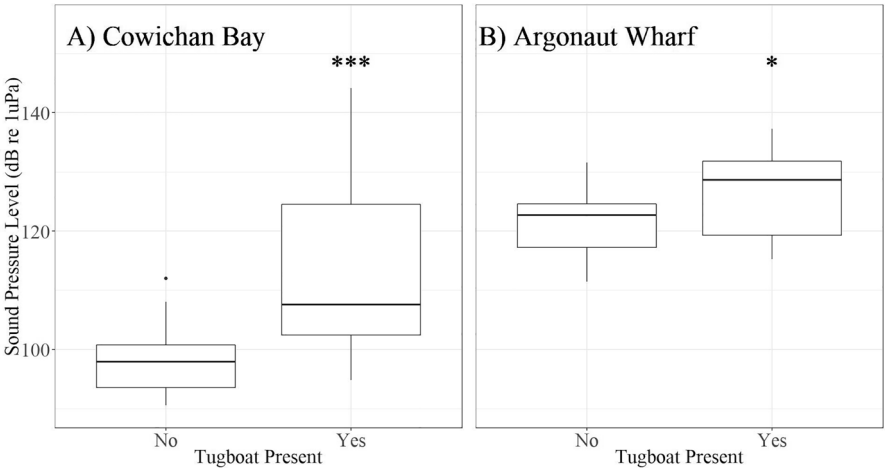

**Fig. 2** Boxplots of sound pressure levels (broadband: 20–24,000 Hz) in (**a**) Cowichan Bay and (**b**) Argonaut Wharf without and with a tugboat within 500 m of hydrophone. Asterisks (***) indicate significantly different mean sound pressure levels at $p < 0.0001$, and a single asterisk (*) indicates significance at $p = 0.02$. Significance was tested using paired *t*-tests

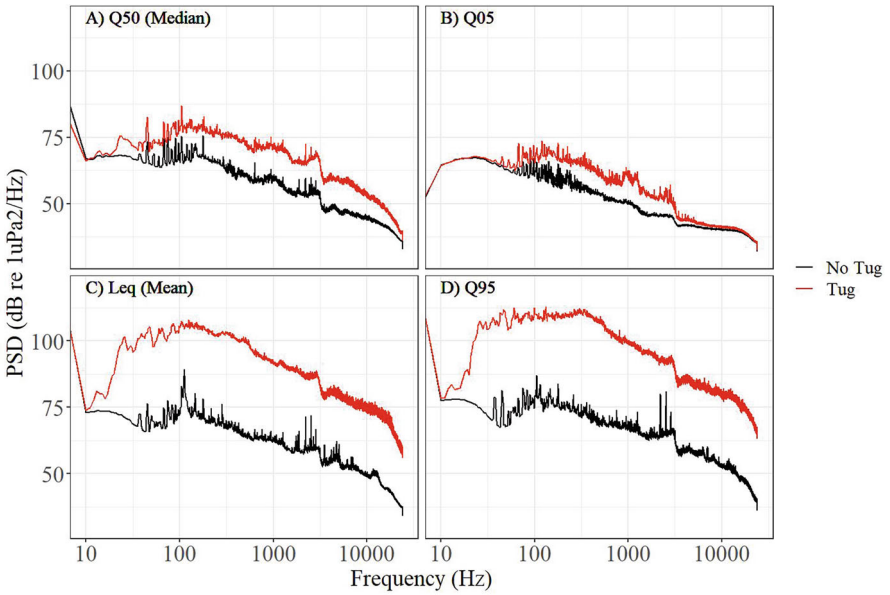

**Fig. 3** Power spectral density (PSD) plots of logging tugboats in Cowichan Bay (**a**) median values (50th percentile), (**b**) fifth percentile, (**c**) mean values (Leq), and (**d**) 95th percentile with no tugboats (black) and while tugboats were moving logs into the estuary (red)

(5%, 95% CI) sound pressure levels near the estuary were 97.8 dB re 1 μPa (91.3; 106.4 dB re 1 μPa) when no tugboats were present. Once a tugboat with logs was within 500 m of the hydrophone, median sound pressure levels were significantly elevated to 107.6 dB re 1 μPa (98.0; 138.3 dB re 1 μPa) (*t*-test, $p < 0.0001$, df = 60, $t = -7.3$).

Tugboats pulling log booms into Cowichan Bay substantially changed the frequency composition near the estuary across the entire frequency range collected (10–24,000 Hz), at all percentiles (Fig. 3a–d). Median increase in sound pressure level at different frequencies varied between 0.5 dB re 1 $\mu Pa^2$/Hz (11 Hz) and 17.2 dB re 1 $\mu Pa^2$/Hz (2216 Hz) when a log transport tugboat was present. However, the largest change was observed at 47 Hz with a 43.6 dB re 1 $\mu Pa^2$/Hz increase in the 95th percentile.

## Other Tugboat Activities (Argonaut Wharf)

Argonaut Wharf had more tugboat activities compared to Cowichan Bay, with 15 tugboats detected within 500 m of the SoundTrap hydrophone in 2021. However, only five tugs were detected within 500 m for longer than 2 min, and only a single tugboat was considered towing, as obtained from the AIS data (September 16). The other four tugboats could not be confirmed to be towing, but it also could not be determined that they were not.

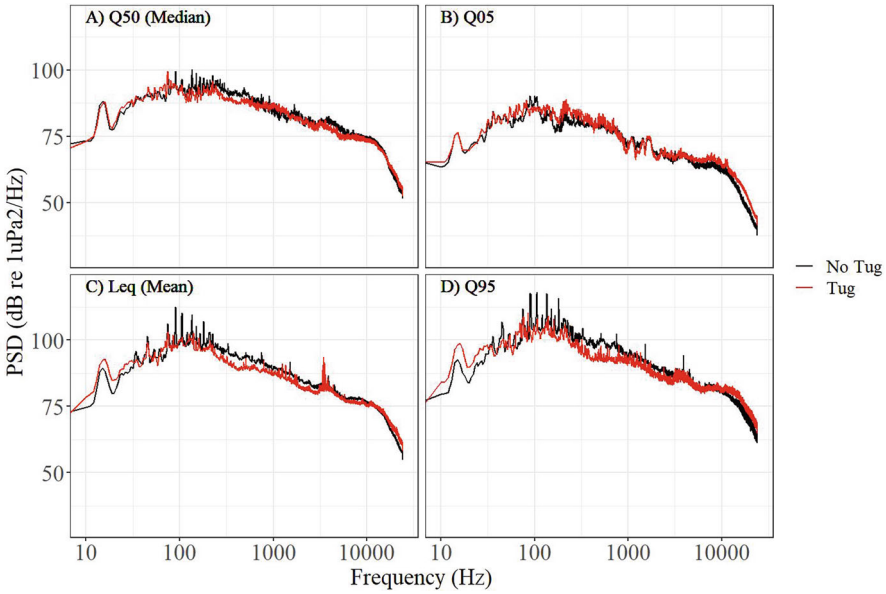

**Fig. 4** Power spectral density (PSD) plots of tugboats in Argonaut Wharf (**a**) median values (50th percentile), (**b**) fifth percentile, (**c**) mean values (Leq), and (**d**) 95th percentile with no tugboats (black) and with tugboats within 500 m of hydrophone (red)

Sound pressure levels (20–24,000 Hz) were higher in Argonaut Wharf compared to Cowichan Bay, but tugboats still had a significant impact on the underwater soundscape (Fig. 2b). Median (5%, 95% CI) sound pressure levels were 122.7 dB re 1 μPa (91.3; 106.4 dB re 1 μPa) when no tugboats were present. Once a tugboat was within 500 m of the hydrophone, median sound pressure levels were significantly elevated to 128.6 dB re 1 μPa (98.0; 138.3 dB re 1 μPa) ($t$-test, $p = 0.02$, df = 33, $t = -2.3$).

Tugboats present in Argonaut Wharf only slightly altered the frequency composition at any of the percentiles examined, with only approximately 40% of frequencies elevated (Fig. 4a–d). Median increase in sound pressure level at different frequencies varied between 0.0002 dB re 1 $\mu Pa^2$/Hz (12,004 Hz) and 6.1 dB re 1 $\mu Pa^2$/Hz (1155 Hz) with a tugboat present. However, the largest change was observed at 7 Hz with a 12.6 dB re 1 $\mu Pa^2$/Hz increase in the 95th percentile.

## Discussion

The presence of tugboats had a significant impact on the underwater soundscape in both locations considered. In Cowichan Bay, tugboats used for log transport activities caused short-term changes to the soundscape by elevating the sound pressure level near the estuary, across all frequencies collected. Similarly in Argonaut Wharf,

sound pressure levels were increased, but frequency composition was similar between time points. The differences observed between the two locations indicate that the impact of tugboats on the underwater soundscape is context specific and varies between locations.

Log transport tugboats present in Cowichan Bay increased the soundscape noise levels near the estuary adding an additional impact to critical habitat already degraded by log storage activities. Currently in British Columbia, timber is stored as rafts in estuaries prior to processing at mills, which can lead to changes to benthic communities through bark being deposited on the ocean floor, and compaction of the sediment (Toews and Brownlee 1981). Bark deposition has also been linked to reduced zooplankton abundance and dissolved oxygen (Power 1987). Additionally, the lower oxygen levels near log storage areas diminished the number of juvenile salmon in those areas, potentially displacing them (Levy et al. 1990). Results from this chapter demonstrate an additional stressor, underwater noise, that requires additional research into its impact to the marine animals that live in the estuary.

Argonaut Wharf had higher sound pressure levels compared to Cowichan Bay when no tugboats were present. This difference is likely due to the high presence of anthropogenic activities in the Strait of Georgia (Erbe et al. 2012). One noise source not found in Cowichan Bay that was present in Argonaut Wharf was passenger ferries. A car and passenger ferry runs from Campbell River to Quadra Island twice an hour transiting between 1.7 and 2.0 km away from the hydrophone location. When examining the contribution (i.e., number of vessels, time present, and source level) of ferries to the underwater soundscape in the Strait of Georgia, passenger ferries account for a high relative noise contribution (approximately 70–88%), but the exact noise contribution varies depending on the time of year (MacGillivray et al. 2016). In comparison, tugboats in the Strait of Georgia account for roughly 7–22% of the relative noise contribution to the area (MacGillivray et al. 2016).

Significant impacts to the underwater soundscape were observed in the study presented in this chapter, but the study was not without its limitations. The study was only conducted over short time periods between August and October. During these time windows, Chinook salmon (*Oncorhynchus tshawytscha*) are returning to spawn in both locations. Cowichan Bay has a First Nation subsistence fishery, while Argonaut Wharf has an open recreational fishery directly in front of the deployed hydrophone, resulting in higher amounts of recreational vessel activities in this area that could be minimizing the observed impacts. Additionally, due to the local geography of the two sites, the data collected for this chapter could only be used to examine the impact of tugboats on underwater soundscape on limited spatial scales (500 m). Larger-scale spatial impacts could not be evaluated. However, estimates of long-distance impacts can be generated using the sonar equation to calculate where the noise produced by tugboats would equal background noise levels. Source levels of tugboats collected in Cowichan Bay and at Argonaut Wharf were back-calculated from the median sound pressure levels when tugboats were within 500 m and were 137 dB re 1 μPa @ 1 m and 155 dB re 1 μPa @ 1 m, respectively. In Cowichan Bay, impacts of tugboat noise were estimated to be above

median ambient sound levels (97.8 dB re 1 μPa) until approximately 10 km away from the hydrophone. Argonaut Wharf had higher median ambient sound levels (122.7 dB re 1 μPa), which resulted in a shorter distance (2 km) at which the tugboat noise was above ambient noise levels. Overall, tugboat noise could be altering the underwater soundscape between 2 and 10 km away from the vessel. Future work should evaluate the impact of tugboats on the underwater soundscape on seasonal scales and a range of spatial scales to account for seasonal variation in vessel activities and oceanographic conditions.

Both locations used in this chapter represent critical habitat for many marine species, but the influence of the noise produced by tugboats on these species has not been evaluated. Resident killer whales (*Orcinus orca*) display avoidance (horizontal and vertical: Williams et al. 2002, 2009) and change foraging behaviors (Lusseau et al. 2009) around vessels. Similarly, Pacific herring (*Clupea pallasii*) and juvenile salmon (*Oncorhynchus* spp.) have behavioral responses to elevated sound pressure levels produced from vessels (van der Knaap et al. 2022). Recent meta-analyses have also documented widespread impact of shipping noise on fish and invertebrates (Cox et al. 2018; Murchy et al. 2020), indicating broad implications for elevated noise levels due to shipping activities. Future research should continue to evaluate the impacts of underwater noise on marine species, and tugboats need to be represented in these studies.

## Conclusions

Large commercial vessels have been documented to increase underwater noise levels, with mitigation methods already being implemented (MacGillivray et al. 2019; Williams et al. 2019). In British Columbia, tugboats represent a significant contributor to local underwater noise, with the highest total vessel hours for all AIS vessel categories (MacGillivray et al. 2016). The work presented in this chapter demonstrates that tugboats significantly elevate ambient underwater sound levels when present, representing an understudied contributor to the underwater soundscape. Future work should continue to examine the impact of smaller commercial vessels, like tugboats, to the underwater soundscape and marine species to help develop mitigation measures to reduce their impacts.

**Acknowledgments** We would like to thank the Juanes lab, specifically Bridget Maher, Jessica Qualley, Katie Innes, Will Duguid and Nick Bohlender, and Jamieson Atkinson from the British Columbia Conservation Foundation, for their assistance in the deployment and retrieval of SoundTraps. We would also like to acknowledge and thank the Coast Salish Peoples (Cowichan First Nation) and the Ligwiłda'xw people (the We Wai Kai, Wei Wai Kum, and Kwiakah First Nations), whose traditional and unceded territory this research was conducted on. Additionally, we would like to thank Guillaume Godbout from the Canadian Coastguard for making AIS data available for within Cowichan Bay and Dalhousie University's MERIDIAN program for making AIS data available for near Argonaut Wharf. Funding was provided by Fisheries and Oceans Canada's Ocean and Freshwater Science Contribution Program, NSERC, and the Liber Ero Foundation.

**Abstract**

Coral reefs are complex habitats that emanate an array of sounds. These acoustic cues are integral to animal behaviors and are increasingly leveraged to discern ecological information. Reef soundscapes are often measured with an overarching view to characterize broad differences between reef sites. Further, there is a

limited understanding of soundscape variation within particular reefs. Here, three acoustic recording methods (benthic recorders, vertical arrays, drifters) were used to address if and how soundscapes vary across coral reefs. Research took place at eight sites in the highly protected region of Jardines de la Reina, Cuba. Sound levels and frequency composition varied across small horizontal and vertical spatial scales. Horizontal differences were notable within reefs over meters, particularly when comparing recordings from adjacent dead and live massive coral. Vertically, sound levels and variation changed with distance from the benthos, with greater variation at lower frequencies. The drifter revealed sound levels that varied substantially relative to bottom type and nearby biota. Overall, the coral reef soundscape, like its biodiversity, was not uniform in distribution. Acoustic patterns varied substantially in ways that likely offer fine-scale acoustic cues to fishes and invertebrates. Moreover, this chapter highlights that small-scale spatial variation must be considered when implementing broad scale eco-acoustic monitoring of coral reef habitats.

## Introduction

Marine animals move through a sea of chemical, visual, and acoustic cues as they select habitats, avoid predators, forage, and enact other vital behaviors. While some of these cues have long been studied, there is a growing understanding of the ecological importance of underwater acoustic cues and signals. Sounds can provide habitat and situational information to a diverse and increasingly realized number of animal taxa including many invertebrates, fish with and without auditory specializations, seabirds, and marine mammals (Buxton et al. 2017; Ellison et al. 2012; Fay 2009; Myrberg 1986). Soundscape data are increasingly being measured for the potential to discern broad-scale differences between habitats such as coral reefs of different quality or health, reefs of different coral cover, or reefs versus adjacent sandy and seagrass habitats (Kaplan et al. 2015; Radford et al. 2014). Yet most reef and coastal animals enact behaviors that likely require sensory information on smaller scales. For example, acoustic communication in fishes is generally considered to be limited to several body lengths or several meters (Coombs et al. 1992; Myrberg 1997; Zeddies et al. 2012). Coral and fish larvae must use vertical water column cues to address depth, vertical distance from a reef, and whether the reef is a proper location to settle (Leis and Carson-Ewart 1999; Leis 2004). Cues in the horizontal plane may offer information such as predator presence, distance of a predator, conspecific territoriality distance, and location of attractive mates (Hanlon and Budelmann 1987; Sweatman 1983). Temporally varying choruses may offer information regarding spawning, help induce physiological or behavioral responses,

coordinate activities, and provide cues to potential settlement locations (Kaplan and Mooney 2016; Mann and Grothues 2009; Parsons et al. 2016).

Despite these ecological benefits, there is limited information regarding the spatial or temporal variation of acoustic cues on smaller scales that likely more relevant to a particular animal. However, initial work suggests such variation exists. An acoustic hydrophone array deployed in the Northwest Hawaiian Islands found sound pressure directionality and hotspots of snapping shrimp sound levels (Freeman et al. 2015). Multiple recorders deployed on reefs in the US Virgin Islands showed small, but significant differences between sites within reefs (Kaplan et al. 2015). The biological relevance or importance of these differences was not considered. Surface drifting hydrophones have detected significant changes in soundscape characteristics across meters within a reefscape, related to benthic habitat structure differences (Lillis et al. 2018). Further, modeled water columns around reefs reflect what are likely distinct vertical gradients of sound, based on frequency and propagation conditions from the reef (Salas et al. 2022). Given this growing suggestive evidence, there is a need to collect empirical data addressing the prevalence of these acoustic hotspots (or cue spaces), and evaluations of their biological relevance.

The reefs of Jardines de la Reina ("Gardens of the Queen") Cuba are an ideal environment to examine soundscapes. The reefs host some of the highest coral cover and fish abundance in the Caribbean (González-Díaz et al. 2018; Navarro-Martínez et al. 2022). This high habitat quality is a result of many factors including their inclusion within one of the largest Caribbean marine protected areas, their large distance from shore, and their strong enforcement of no-take fishing areas. The Jardines de la Reina (JR) reefs are therefore a unique place to study Caribbean reef sounds due to the abundant and diverse reef life as well as limited exposures to boat noise, which can alter animal behaviors (Simpson et al. 2016).

A 2017 cruise of opportunity to the shallow forereefs in the Jardines de la Reina system was used to address fundamental questions in reef soundscapes. Are there within-reef acoustic hotspots? Are there habitat-scale differences within a reef? How do soundscape cues vary in space and time on a reef? The effort sought to more generally address whether there are potential acoustically mediated differences within a reef that may be relevant for fundamental behaviors such as communication, predator detection, settlement, and within-reef habitat selection.

## Methods

Work was conducted from small boat operations based off the *M/V Alucia* scientific vessel. The research cruise took place from November 4–20, 2017. Measurements were made exclusively within Jardines de la Reina National Park, Cuba (permitting noted below). Observations were made opportunistically during the expedition with the overall goal of surveying the reef system using multiple acoustic platforms and examining multiple reefs across multiple days. Long-term deployments in a single location were not possible due to the cruise schedule.

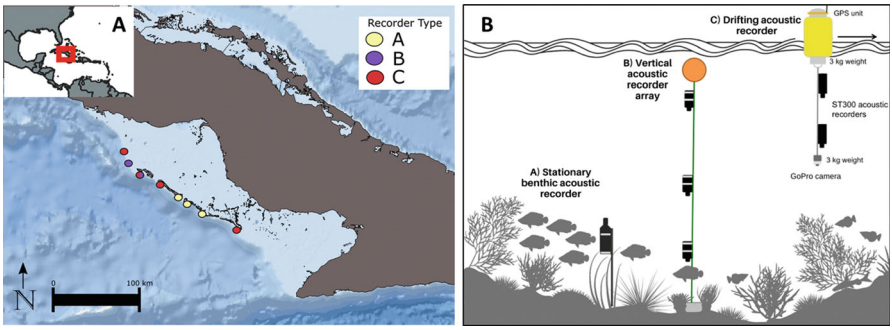

**Fig. 1** (**A**) Map of the study sites off the south shore of Cuba. (**B**) Schematic depicting the three acoustic recorder configurations used to examine scales of soundscape variation on coral reefs

Passive acoustic work was conducted at eight reef sites across the archipelago (Fig. 1a). Data were collected using three complementary recorder configurations with the goal of investigating the small-scale soundscape variation within and above reef mosaics (Fig. 1b). Recorders utilized were either one-channel SoundTrap 300 s or 4-channel SoundTrap 4300 s [ST-300/4300; Ocean Instruments NZ (Ferguson et al. 2022)].

The first configuration consisted of stationary benthic recorders placed at multiple adjacent locations within a reef allowing for comparisons of simultaneous recordings across the horizontal plane of the reef, targeting small-scale differences (tens of meters) in habitat predicted to affect biological sound production (e.g., coral type, bathymetry, fish aggregation distribution). During the study, the set of recorders were able to be placed at three reef sites for 48–72-h periods, capturing 1-min recordings every 5 min.

Second, to examine small-scale depth variation in soundscapes above reef habitat we positioned acoustic recorders on a vertical array. The array was moored in one location and had a subsurface float and from that float, a surface buoy. The latter allowed the array to be sighted from the surface for retrieval while the subsurface float enabled the array to suspend vertically in the water column. On each vertical array, recorders were placed at 1, 5, and 10 m from the seafloor, and sites were selected where water depth was between 12 and 15 m. These systems were deployed at dusk for overnight recordings at 3 reef sites during the study period. Each deployment captured 3–12 h of continuous recording at 96 kHz.

The third recording configuration utilized a drifting hydrophone setup described previously (Lillis et al. 2018). Briefly, a GPS-outfitted surface buoy relayed location to a handheld GPS unit allowing the recording system to be deployed and left to drift on its own, facilitating later retrieval. Below the float was a line with a 3 kg weight at the bottom, and two acoustic recorders were attached vertically along the line. The recorders were located 1 and 2 m from the surface. A GoPro camera facing downwards recorded the benthic composition during the drift track. The drifter allowed for mobile recordings while minimizing the interfering noise of autonomous

vehicles. Surface current and wind direction were visually observed just before deployment to facilitate predicting a general drift direction. The drifter was then typically deployed "up reef" (windward side) and allowed to drift over the reef and observation area, and later retrieved via the GPS location. Drift trajectories, distance, and length depended on currents, wind, and conditions, and were typically 1–2 h in duration, and covered ~0.5–1 km distance. This sampling was conducted at 4 JR reefs, with 2–4 drifts achieved at each site.

### Acoustic Analyses

Acoustic data were analyzed in MATLAB using custom-written code. The files were initially examined for potential transient or anthropogenic (e.g., boat, diver) noise and any such files were removed. Comparisons were then made using acoustic power spectra. Sound pressure levels (in rms – root-mean-squared) were calculated for low (0.1–2 kHz) and high (2–23 to 48 kHz) frequency bands which generally constitute the frequency ranges of fish and snapping shrimp sounds, respectively (Au and Banks 1998; Urick 1983). Where appropriate, the median and interquartile range of spectrum and sound pressure levels were calculated from the analysis of non-overlapping 1-s duration windows spanning the 1-min recordings, which could then be used for plotting and further statistical analysis where appropriate.

## Results

Approximately 16,000 1-min audio files were successfully recorded between the different configurations applied across 8 reef sites in the Jardines de la Reina (Fig. 1) during the research cruise. Below are results describing findings that exemplify the types of small-scale soundscape variation observed using this dataset.

### Horizontal Environment

At site JR10, a relatively high number of large, endangered pillar coral (*Dendrogyra cylindrus*) colonies were observed, of varying size and condition. As these large corals are known to create distinct three-dimensional structure and provide habitat hotspots for reef diversity, the distinct reef features were targeted for acoustic sampling and provide an ideal example for the examination of within-reef soundscape patterns related to coral type and health. Three SoundTrap 300 (ST-300) acoustic recorders were placed at *D. cylindrus* pillar coral towers, and three in nearby soft coral patches for a 72-h period. Recorders were all deployed within a small study area ~100 m × 20 m reef segment. The colonies denoted as DCYL 1 and 2 were live, but the DCYL 3 structure was dead coral skeleton with minimal living tissue (Fig. 2). The spectra of all three sites can roughly be divided into two

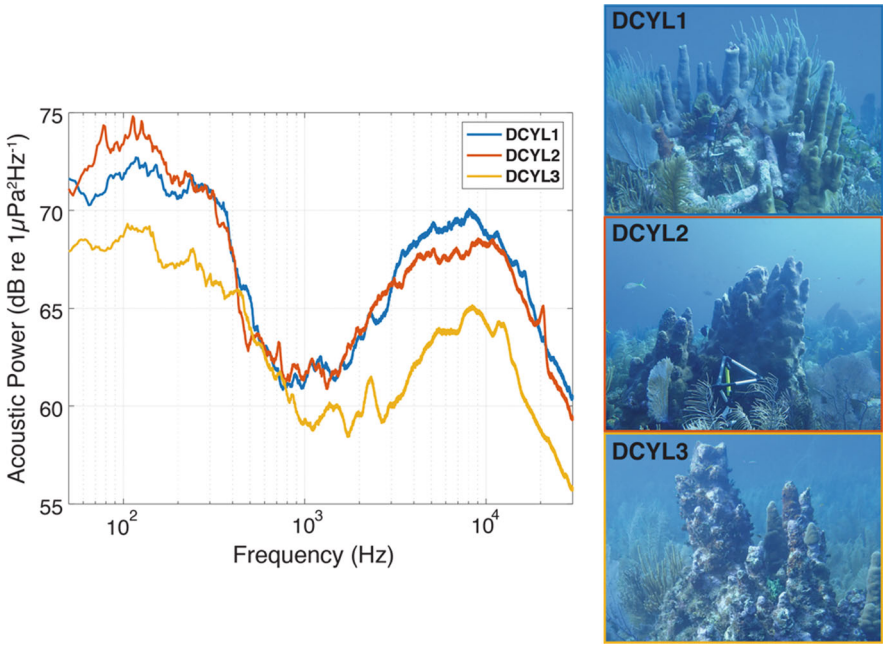

**Fig. 2** Full band acoustic power at two healthy (DCYL1 and 2) and one dead (DCYL3) *Dendrogyra cylindrus* colonies. Note the overall lower sound levels at DCYL3 suggesting a diminished community of soniferous fish and invertebrates

components, below 1500 Hz and above 2000 Hz. Fish sounds are generally found in the former, low-frequency band, while snapping shrimp sounds are typically higher in frequency (>2000 Hz) (Kaplan et al. 2015). All three DCYL spectra showed peaks in the low and high frequency bands, near 100–200 Hz in the low frequency and 7–9 kHz in the high frequency. The sites differed in the amplitude of these peaks; DCYL 1 and 2 were similar in spectral characteristics, and while the spectral shape of DCYL 3 followed the same pattern, median power was ~4–7 dB lower in both the low and high-frequency ranges compared to the healthy DCYLs (Figs. 2 and 3). In comparing the median SPLs by site for the two frequency bands, significant differences existed among nearly all recording sites (Fig. 3b; Kruskal-Wallis test: low frequency $\chi^2 = 977$, $p < 0.001$, high frequency $\chi^2 = 2414$, $p < 0.001$) underscoring the high small-scale inter-reef variability in soundscape. Low frequency sound levels were significantly lower at DCYL 3 compared to DCYL 1 and 2; however, it is important to note that one of the octocoral sites exhibited similar SPL levels to the healthy DCYL in the low frequency band (OCTO 2; Fig. 3b(i).

Spectrograms demonstrate the influence of time of day on these within-reef soundscape patterns and highlight differences among the nearby recording sites (Fig. 3a). At lower frequencies (<2 kHz), diel rhythms were notable at all recording sites with a consistent peak in SPL just after sunset each night (Fig. 3a). DCYL 1 and

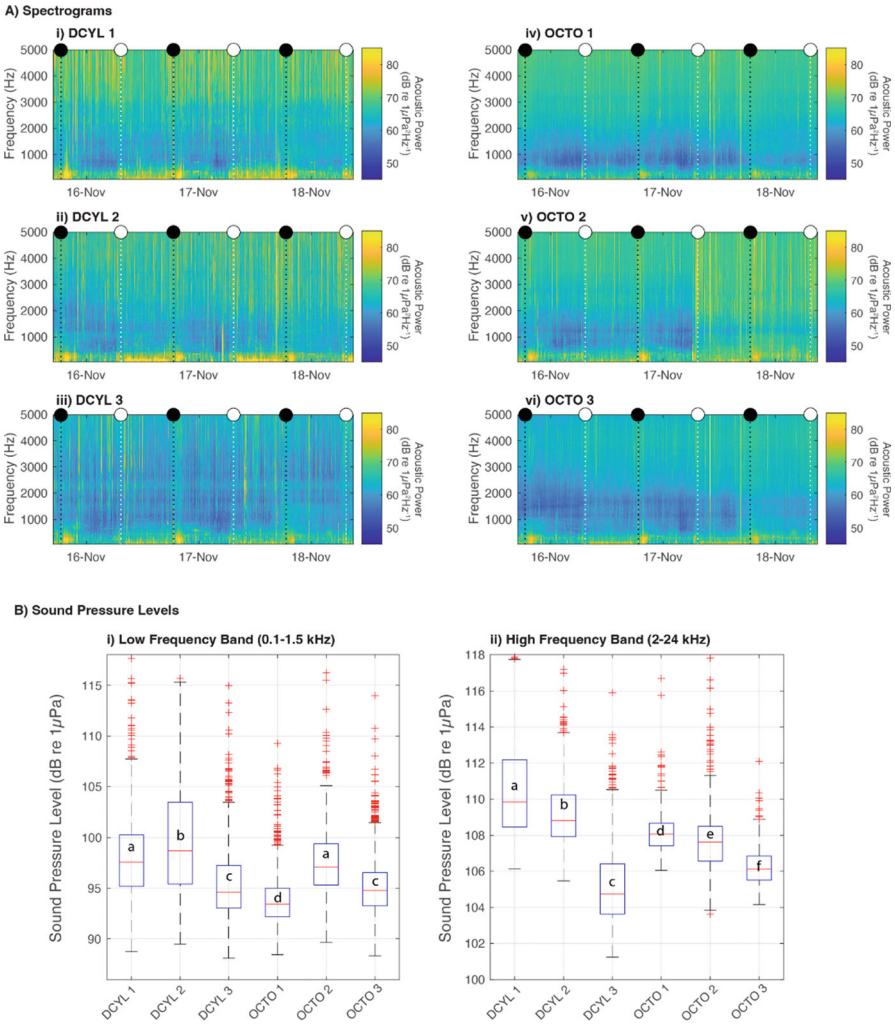

**Fig. 3** (**A**) Spectrograms showing frequency specific patterns for recordings made adjacent to the endangered *Dendrogyra cylindrus* (i–iii) and octocorals (iv–vi). Black and white circles denote sunset and sunrise, respectively. (**B**) Boxplots depicting medians and interquartile ranges for (i) Low frequency (0.1–1.5 kHz) and (ii) High frequency (2–24 kHz) bandwidths. Letters signify statistically significant differences between sites, based on a non-parametric multiple comparison post-hoc test

2 showed stronger dusk increases in low frequency SPL and had more acoustic activity during daytime hours compared to DCYL 3 (Fig. 3a(i–iii)). The day-night low frequency difference is less evident at DCYL 3 and the OCTO sites. Subtle diel patterns were also observed in the snapping shrimp-driven high-frequency band, with modest increases in snapping at night observed across sites (Fig. 3).

## Vertical Profiles

There was a clear vertical gradient of acoustic energy at sampled reefs (Figs. 4 and 5). At JR3, where 2-h continuous recordings were collected, sound pressure levels were greatest near the reef/benthos (10 m) and decreased when measured at 5 and 1 m from the sea surface (Fig. 4a, b). At 1 m depth, median SPL was ca. 6–7 dB lower, or about half the acoustic energy, than the bottom recorder. Variation was similarly lower at 1 m depth, compared to the deeper positions. However, these changes were not equally spread across frequencies. The benthic and mid-water positions showed greater, but variable, acoustic power in the low frequencies (Fig. 4).

For site JR3, at low frequencies (<400 Hz), acoustic power was ca. 5–8 dB higher closer to the reef, but frequency specific variability was relatively large (Fig. 4). At higher frequencies (>1000 Hz) dominated by snapping shrimp, acoustic power was ca. 3 dB lower near the benthos and similar at the mid-water and surface stations. There was also less variability between sites. Between ca. 500 and 1000 Hz, the surface generally showed higher sound levels, and variably was high, perhaps reflecting the effects of noise attenuating from the surface.

Conversely, Fig. 5 shows the results of vertical array recordings made at JR4 for a 12-h period. In this dataset, the mid-water recorder displayed the highest sound levels (Fig. 5b). Upon further inspection, it was determined that the ship thrusters contributed to this low frequency signal elevation, received most strongly at the 5 m depth hydrophone. The higher frequency bandwidth sound levels were relatively consistent with depth for this vertical array (Fig. 4b).

## Spatial Variation in Motion Across a Reef: The Drifter

The drifter spectrogram provides a unique ability to assess how a reef area soundscape varies spatially [(Lillis et al. 2018), Fig. 6]. Over the course of an hour, the

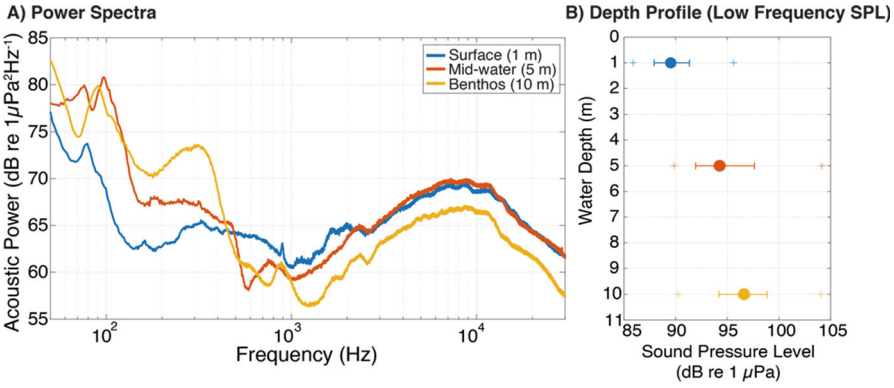

**Fig. 4** (**A**) Power spectra and (**B**) low frequency sound pressure level variation with depth measured at JR3 over 2 h of recording from the stationary vertical array

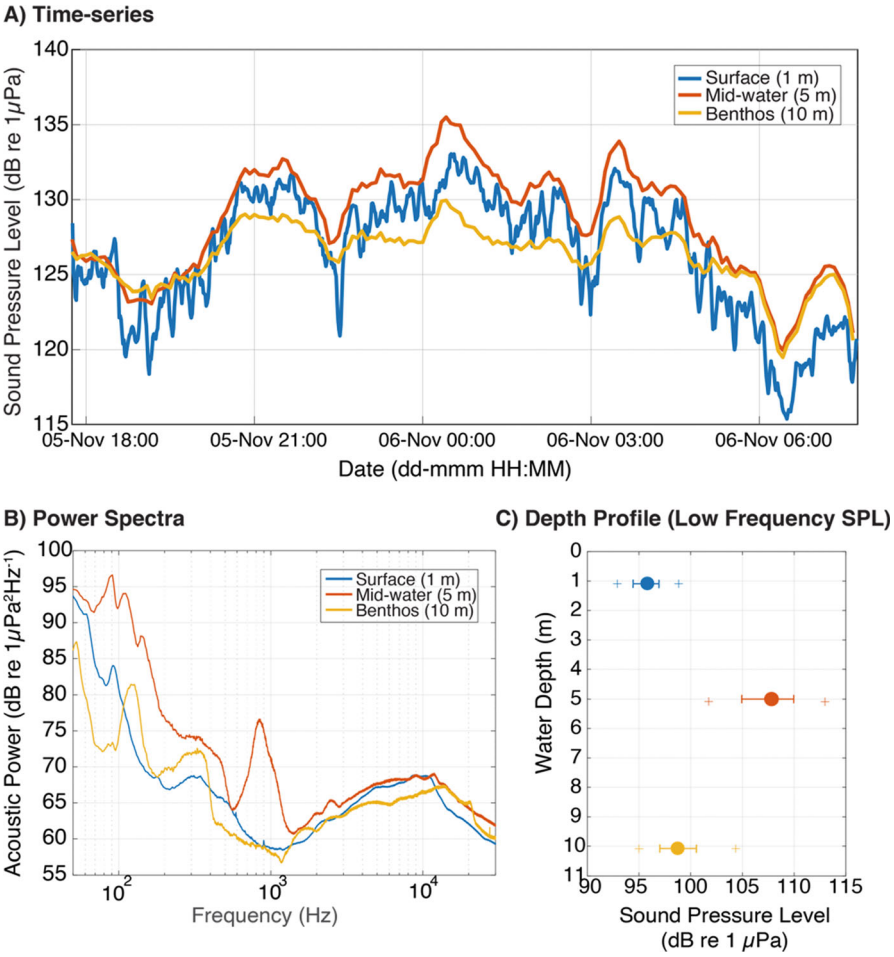

**Fig. 5** (**A**) Time-series, (**B**) power spectra, and (**C**) depth variation in low frequency sound pressure level measured overnight at JR4 from the stationary vertical array

drifter started on the coral reef but drifted off and away to areas of mixed benthic structures. High frequency energy was clearly elevated over the reef and this greatly influenced the full bandwidth analysis. Around 16:50 local time, the drifter approached an area of small patch reefs and subsequently the higher frequency snapping shrimp sound levels increased. Notably, just off the reef, around 16:22 and 16:28 schools of small jacks approached the drifter. At these times, low frequency SPLs peaked (Fig. 6a, b-ii), reflecting sounds produced by these schools. Otherwise, the low frequency fish sounds were generally consistent for the first 20–30 min, and then decreased substantially just off the reef (ca. 16:40), but slowly began to increase as the drifter approached the patch reef.

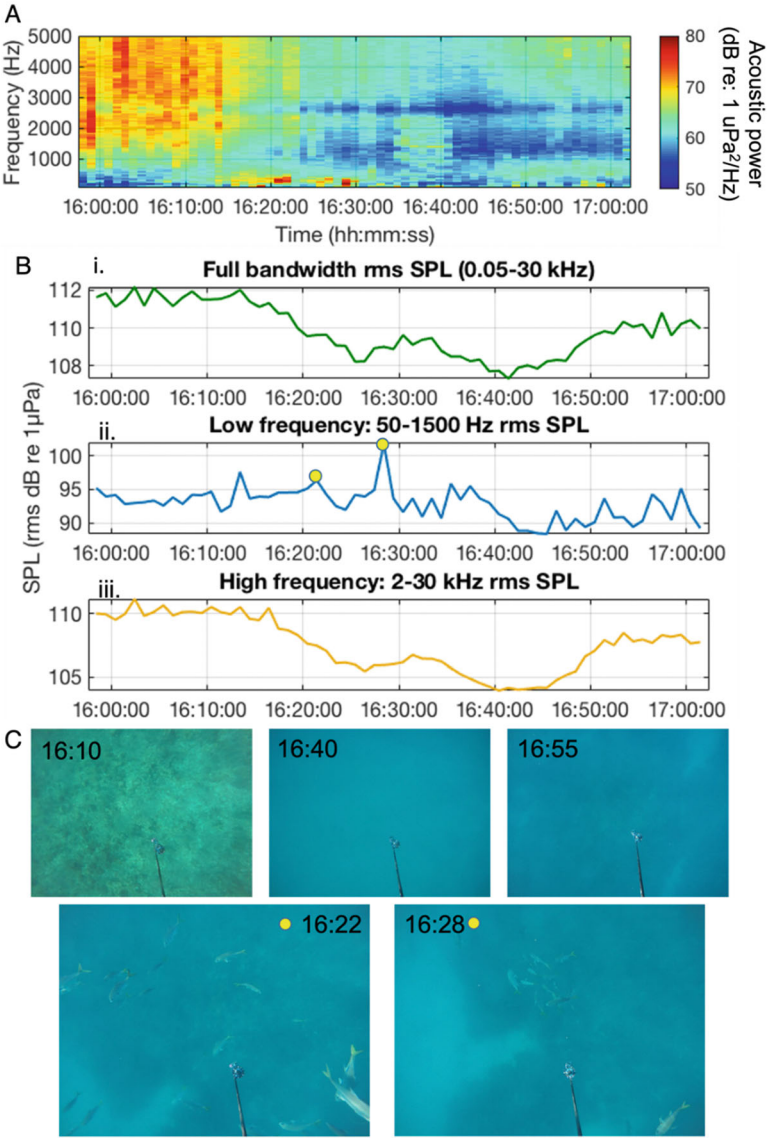

**Fig. 6** (**A**) Spectrogram of the drift; (**B**) i–iii corresponding spectra in the full, low, and high frequency bands, and (**C**) downward facing images at five timepoints during the drift. Note the increased high-frequency and overall sound levels over the initial reef habitat (16:10), reflective of an increase in snapping shrimp. There was increase in sound levels over reef areas, and particularly notable low frequency signals (highlighted by the yellow dots) when fish schools passed by

## Discussion

The goal of this research was to address spatial soundscape variation within a coral reef environment, particularly to establish if substantial variation exists that impacts passive acoustic monitoring, and to provide ecological context for the data collected. The results show evidence of substantial small-scale horizontal acoustic variation using complementary recording configurations: recorders deployed via benthic mooring in close proximity and via a low-noise drifter buoy. Multi-depth vertical arrays revealed that sound levels and frequencies also changed over small depth changes, with substantial particularly at lower frequencies (below ca. 1000 Hz). The suite of configurations was applied to holistically sample the reef environment, rather than focus on fewer locations for a longer period. This allowed us to make inferences regarding the reef soundscape over scales not typically monitored with PAM and emphasizes the importance of careful site selection when initiating an acoustic reef monitoring effort.

The soundscape of the dead pillar coral colony (DCYL 3) differed from the other two living colonies likely because a dead colony does not attract the same soniferous animal community. The structure of large *Dendrogyra* pillar coral is a unique community hub on the reef, providing habitat for fishes, which create nutrient hotspots and in turn increased coral cover additional fish local habitat (Shantz et al. 2015). Together, it is not surprising that these micro-habitats associated with the live *Dendrogyra* would foster a distinct soundscape with high levels of acoustic activity reflecting the community hub this structure provides. Reef soundscapes are expected to change concomitantly with deteriorating reef conditions caused by bleaching, diseases, and loss of corals (Lamont et al. 2022). However, it is important to note that in this chapter our measurements of adjacent soft coral areas also displayed unique and complex soundscape parameters, overlapping with the *Dendrogyra* SPLs and frequency patterns. It is clear that careful application of broad acoustic metrics and cautious interpretation of crude differences associated with reef variation is required. Nonetheless, the insights gained into loss of acoustic activity at a dead *Dendrogyra* colony has implications for broad, community-scale impacts of stony coral tissue loss disease (SCTLD), which has rapidly spread throughout the Caribbean causing nearly complete mortality of *Dendrogyra* corals (Neely et al. 2021). These results support the need for advanced acoustic analyses (e.g., machine learning) and sound libraries (Parsons et al. 2022) to enhance our ability to identify the drivers and understand the ecological relevance underpinning small-scale acoustic variation.

The paired camera-acoustics of the drifter provided a valuable method to visually observe the animals likely making certain sounds. This allowed us to video-capture what appears to be horse-eye jacks (*Caranx latus*), a predator fish, swimming around the recording system and suggests these could be the cause of concurrent higher low-frequency sound levels. These sounds appear to be biological in origin, not animals bumping hydrophones. Carangidae are one of the families with sound

production noted (Fine and Parmentier 2015) but its origin or function has not yet been well-described.

The vertical array provided a new assessment of the shallow coral reef environment demonstrating vertical differences in sound level and frequency at the scale of meters. These differences may be particularly important for understanding the depth distribution of acoustic cues for settling larvae. When near reefs, larvae can be at shallower depths (2–4 m) (Leis and Carson-Ewart 1999) but as they settle and move toward a reef (increasing depth), they may have more low-frequency sound cues available to them. Reef fishes select microhabitats such as species/morphotypes of corals and it is generally assumed that they need to be close to the reef to make such decisions (Sweatman 1983). The variation observed across a 10-m depth water column indicates that such vertical patterns are relevant to studies of the soundscape as an orientation cue and should be considered in measurement of salient larval cuescapes.

The recorded vertical variation of sound pressure level should be addressed further. These measurements were certainly in the acoustic near-field for the low frequencies, yet this is the reality for fish larvae as they swim over a reef. The variability was likely due, at least in part, to the unpredictability of sounds in the near-field (Kalmijn 1988). Indeed, closer to the reef and its sound sources, where soniferous fish and invertebrates are in higher abundance, variability was higher (Fig. 4c). The decrease of variability as shallower depths may be explained because the near-field variability effects would be limited to only the lower frequencies. Although there are few data of in situ swimming behavior of settling fish larvae, they appear to maintain a relatively stable (often relatively shallow) depth although this "stable" depth can vary by ca. $\pm$0.5 m or more (Irisson et al. 2010). This movement would allow them to potentially "sample" this variable acoustic environment to better assess the reef below. Such a mechanism would be quite valuable for fish settling at night.

To our knowledge, this is the first passive acoustic examination of coral reefs in Cuban waters. This environment was particularly compelling to document acoustically as the Jardines de la Reina reef system is relatively healthy, compared to many other Caribbean coral reefs. The region and some reefs within it have higher coral cover than other areas of the Caribbean and are also relatively abundant with large fishes and sharks (Ferguson et al. 2022). The sound dataset collected in Jardines de La Reina offers a starting point for further comparisons with other impacted and declining Caribbean reefs. It also offers an important baseline to this hub of biodiversity as it faces, as other Cuban reefs, ongoing impacts by chronic stressors and stochastic events (Caballero-Aragón et al. 2022).

Importantly, this study demonstrates that the soundscape of a single coral reef is not uniform in distribution. Rather, acoustic cuescapes vary horizontally across the reef and vertically with distance from the seafloor. Given the importance of sounds to reef fishes and invertebrates, these differences likely offer acoustic cues as animals seek to settle, find mates, or establish territories. The shelter that large corals provide to soniferous animals may support acoustic hotspots, given the increased density of fishes and invertebrates at these microhabitats and the potential interactions with the

confined space that the coral-shelter may provide. Understanding the variation in reef soundscape is also important as we seek to leverage these patterns for assessing reef communities. Thus, it is key to determine the diversity and structure of these sound-producer communities associated with reef microhabitats and the ecological function that they provide. Finally, understanding the spatiotemporal distribution of reef microhabitats should be a consideration and caveat to valuations from snapshot acoustic measurements. Indeed, this supports the need for longer-duration measurements as we seek to understand coral reef soundscapes and the communities they represent.

**Acknowledgments** The studies outlined here were carried out under permits NV2370 and NV2568 issued by the Ministerio de Relaciones Exteriores (MINREX), Republic of Cuba. This science described was enabled by a memorandum of understanding between Cuba's National Center of Protected Areas (CNAP) of the Ministry of Science, Technology and Environment (CITMA), and the Woods Hole Oceanographic Institution in the United States. Soundscape analyses and writing were conducted via support from National Science Foundation grants (2133029 and 2024077). Thank you to the crew about the M/V Alucia and for funding from the Dalio Foundation.

**Abstract**

Fisheries and Oceans Canada's Coastal Acoustic Monitoring Project aims to better understand the underwater soundscape at coastal sites off Nova Scotia, Canada. Researchers began deploying passive acoustic monitors for this project in December 2018. In order to compare the contribution of various sources of sound to the soundscape at the different sites, they have taken a sound energy budget approach. Here they present the results from their longest-running site, Chedabucto Bay, near the approaches to one of the largest ports in Nova Scotia. The percent contributions of wind, vessels, and "other" sources to the total sound energy budget for the 1/3 octave bands centered at 100 Hz, 500 Hz, 1 kHz, 2 kHz, 5 kHz, and 10 kHz were calculated. Vessel noise was the dominant contributor to sound energy in the lowest frequency band in almost every month except between August and November 2020, during which irregular vessel movements are suspected to have impacted the accuracy of the sound energy budget estimations. This sound energy budget approach is useful for comparing different sites, as well as the same site over time, but should be complemented by other analyses that can present information on levels of sound energy.

## Introduction

The Marine Planning and Conservation Program, Maritimes Region, Fisheries and Oceans Canada (DFO), initiated the Coastal Acoustic Monitoring (CAM) Project in December 2018 to better understand the types and levels of underwater sound at several coastal sites around Nova Scotia. The project focused on shipping noise to reflect the Government of Canada's priority to better understand the impacts of shipping on marine ecosystems (Transport Canada 2020). The project also aimed to acoustically detect baleen whales; more information on that aspect of the project can be found in Wingfield et al. (2022). The longest-running site of the CAM project is located on the southern shore of Chedabucto Bay (Fig. 1). The bay is located between mainland Nova Scotia and Cape Breton Island and is the pathway to one of the largest ports in Nova Scotia, the Strait Superport. Because of this, the bay is often frequented by commercial vessels. There are also several active fisheries in the bay, including mackerel (*Scomber scombrus*), shrimp (*Pandalus borealis*), lobster (*Homarus americanus*), and other shellfish (Serdynska and Coffen-Smout 2017; Rozalska and Coffen-Smout 2020). Despite this, researchers and local fishers were together able to select a deployment location where fishing does not regularly occur, avoiding the potential for disturbing the acoustic monitoring system deployed on the seafloor while still allowing for the effective recording of noise from nearby vessels. Several species of marine mammals have been sighted in the bay, including fin (*Balaenoptera physalus*) and sei (*Balaenoptera borealis*) whales (Gomez et al. 2020; Jacques Whitford Environmental Ltd. 2004). A large part of the bay is included within the Canso Ledges Ecologically and Biologically Significant Area due to the rich diversity of invertebrate, fish, and marine mammal species that occur there (Hastings et al. 2014).

A soundscape is a recording of all sounds that occur within an area, including from geological, biological, or anthropogenic sources (Havlik et al. 2022; Southworth 1967). A soundscape can therefore be analyzed to determine the type and temporal frequency of anthropogenic activities and weather events taking place in an area and even to assess species richness and general health of an ecosystem (Pijanowski et al. 2011). One way to summarize a marine soundscape is by producing a sound energy budget. In this approach, sound sources are ranked in order of greatest contribution to the overall soundscape (Miller et al. 2008). The researchers chose to characterize the soundscape around the Chedabucto Bay site using a sound energy budget approach similar to that used by Miller et al. (2008) and Nystuen et al. (2010). This allowed for the comparison of the contributions of vessels, wind, and all remaining sources (grouped as "other") to the overall soundscape across different months and between years, and the researchers felt that this method would be an informative way to summarize a previously unstudied soundscape.

Previous acoustic monitoring efforts and ongoing projects carried out by DFO Science branch in Maritimes Region have focused on offshore areas using large and complex recording systems that require large vessels for deployment and recovery. Prior to the initiation of the CAM Project, the closest acoustic monitoring site to Chedabucto Bay was located approximately 93 km east of the mouth of the bay (referred to as "Stn 2," see Delarue et al. 2018, 2022). In their investigation of soundscapes off eastern Canada, Delarue et al. (2018) found that vessels and seismic surveys were the main anthropogenic contributors to ambient sound. At Stn 2 specifically, Delarue et al. (2018) found that vessel noise contributed the most energy to the overall soundscape in the spring, summer, and early fall. They did not detect any seismic survey noise at this site (Delarue et al. 2018). Much of the previous research on underwater noise in coastal Nova Scotia was carried out for national defense purposes, that is, to improve methods of detecting submarines and submarine communications (Chattopadhyay and Pecknold 2016; Osler and Pegg 2018) and to better understand the acoustic impacts of naval activities (e.g., Tollefsen and Pecknold 2012). Piggott (1964)

carried out the earliest acoustic study at a coastal Nova Scotia site, demonstrating a strong correlation between mean sound spectrum levels at multiple frequencies and wind speed. He deliberately excluded periods of time during which there were high levels of shipping noise, as the overall objective was to understand the influence of wind on ambient noise. Chattopadhyay and Pecknold (2016) examined underwater ambient noise in the Bedford Basin, Nova Scotia, for a short period of time in 2014 to better understand the environment for defense-related underwater communications.

While data collection continues, here the researchers discuss their sound energy budget approach and preliminary results for data collected at the Chedabucto Bay study site. To their knowledge, this is the first project to undertake acoustic monitoring within the bay. Major industrial projects have been proposed for this area, including additional marine terminals and a spaceport facility (Black Point 2022; Edwards 2022). These projects are likely to impact the soundscape of the bay in the coming years if they move forward. The data from this project could therefore be considered baseline data, and will serve as a valuable reference point should the aforementioned projects move forward.

## Methods

A SoundTrap (ST300 STD or ST500 STD, Ocean Instruments, New Zealand) mounted in a small, modified lobster trap was deployed for periods of approximately 2 months at a time from December 12, 2018, to April 20, 2021 in Chedabucto Bay, Canada (Fig. 1). A newly programmed SoundTrap was deployed immediately after the previous mooring was retrieved. This allowed for the very near continuous collection of data, even on recovery days, but meant that different instruments were used for consecutive deployments. The SoundTraps were set to record continuously at a sampling rate of 24 kHz with the PreAmp gain set to "high." The 1/3 octave bands centered at 100 Hz and 500 Hz were most sensitive to vessel noise. Researchers found the dispersion between these two bands to be greatest when a vessel was closest to the mooring. The dispersion could therefore be used as an identifying feature of vessel noise. The contribution of vessel noise to the soundscape was determined by calculating the energy added to the overall sound pressure level (SPL) by vessels (Fig. 2). Wind speeds were extracted from Environment Canada's High Resolution Deterministic Prediction System dataset. The minimum wind speed needed to produce white caps, indicators of breaking waves, is ~3.7 m/s (Callaghan et al. 2008). Therefore, when wind speeds were greater than 3.7 m/s, it was assumed that increases in SPL after vessel noise was removed were caused by wind (Fig. 3). The percent energy contributions of vessels, wind, and all remaining sources (grouped as "other") to the total energy budget in 1/3 octave bands centered at 100 Hz, 500 Hz, 1 kHz, 2 kHz, 5 kHz, and 10 kHz were calculated. For a more detailed description of the methodology, see Wingfield et al. (2022).

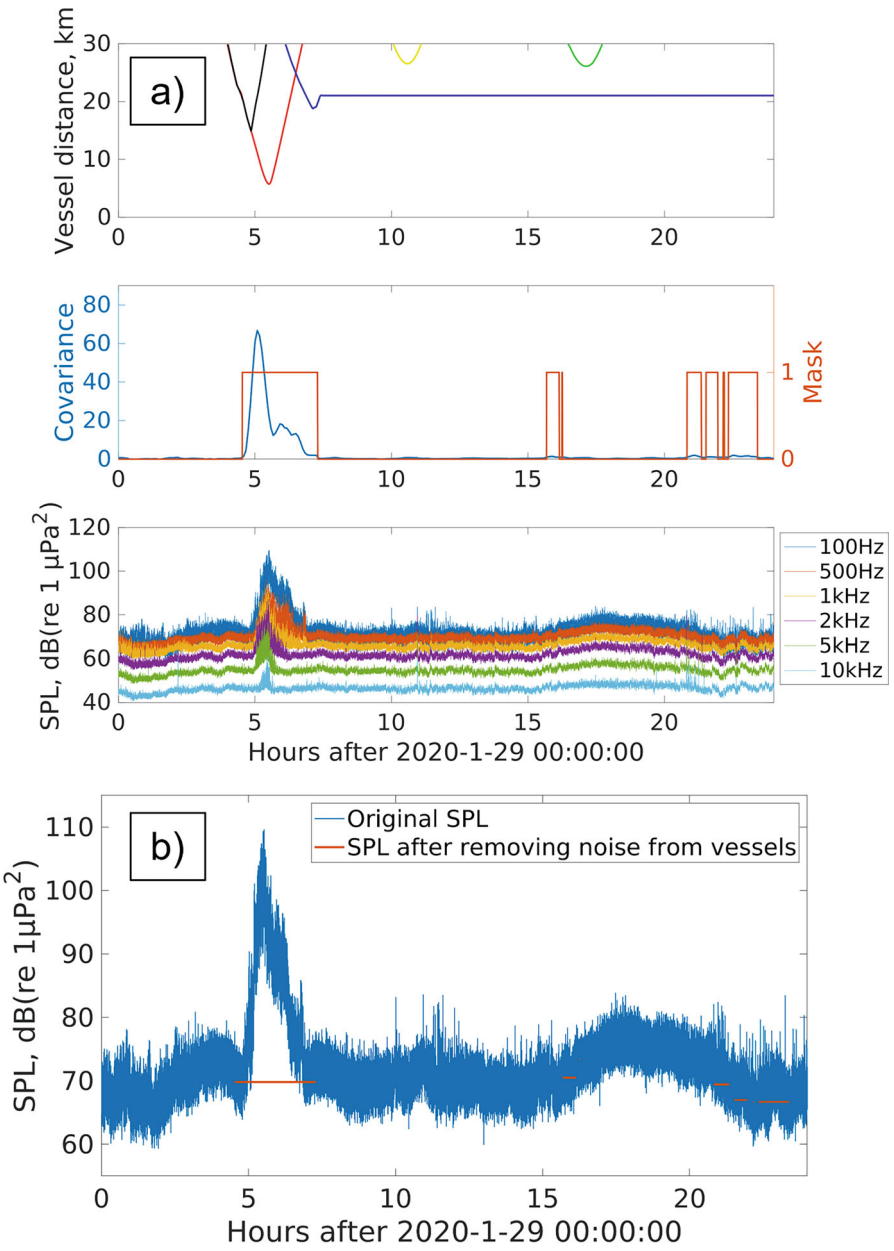

**Fig. 2** (**a**) The distance of vessels from the mooring location (top), the covariance between SPLs in the 100 and 500 Hz bands and resulting mask values (middle), and the SPL (bottom) over time (UTC) on January 29, 2020. (**b**) The original SPL and SPL after removing suspected vessel noise in the 1/3 octave band centered at 100 Hz on January 29, 2020 (UTC)

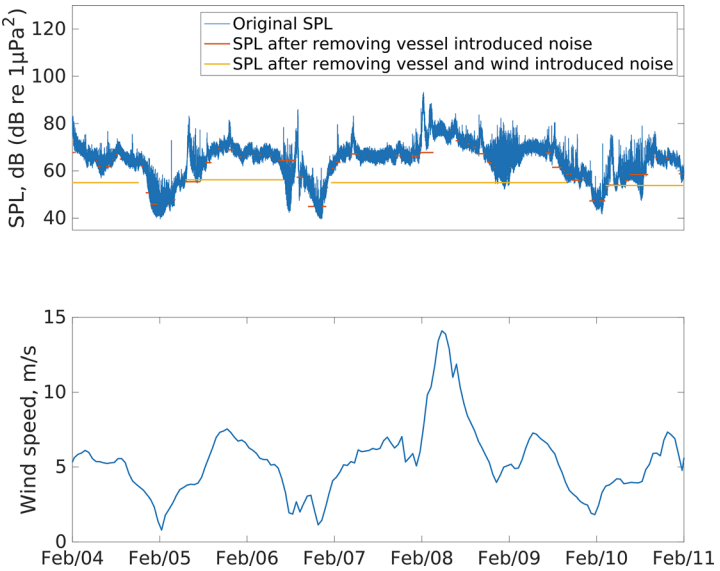

**Fig. 3** The original SPL, the SPL after removing vessel noise, and the SPL after removing vessel and wind noise (top) in the 1/3 octave band centered at 500 Hz and the wind speed (m/s) (bottom) from February 4 to 11, 2020 (UTC)

## Results

The researchers aimed to determine the contributions of vessels, wind, and all other sources (precipitation, biological noise, etc.) to the total sound energy budget for each month of the study period. Some of the preliminary results are discussed here. Overall, wind and vessels dominated much of the soundscape for the six frequencies examined. During the periods examined, vessel noise was the largest contributor to the sound energy budget in the lowest frequency band in almost all months, and in most frequency bands during summer and fall months, except between August and November 2020. During these months, there were several multi-day periods of elevated noise levels in the lower frequency bands caused by the prolonged presence of one vessel, the crane ship *Thialf*, and increased vessel traffic from its support vessels. The sound energy budgets for these months therefore misrepresent the contributions of each source. Vessel noise was likely a dominant contributor to the soundscape during this period, as it was in summer 2019. Wind was often the largest contributor to the sound energy budget in all but the 100 Hz frequency band during winter months (December to March). Fig. 4 shows the sound energy budgets for January 2019 and July 2020. These figures demonstrate the dominance of wind in the winter months and vessel noise in the summer months. For all monthly sound energy budgets and expanded results, see Wingfield et al. (2022).

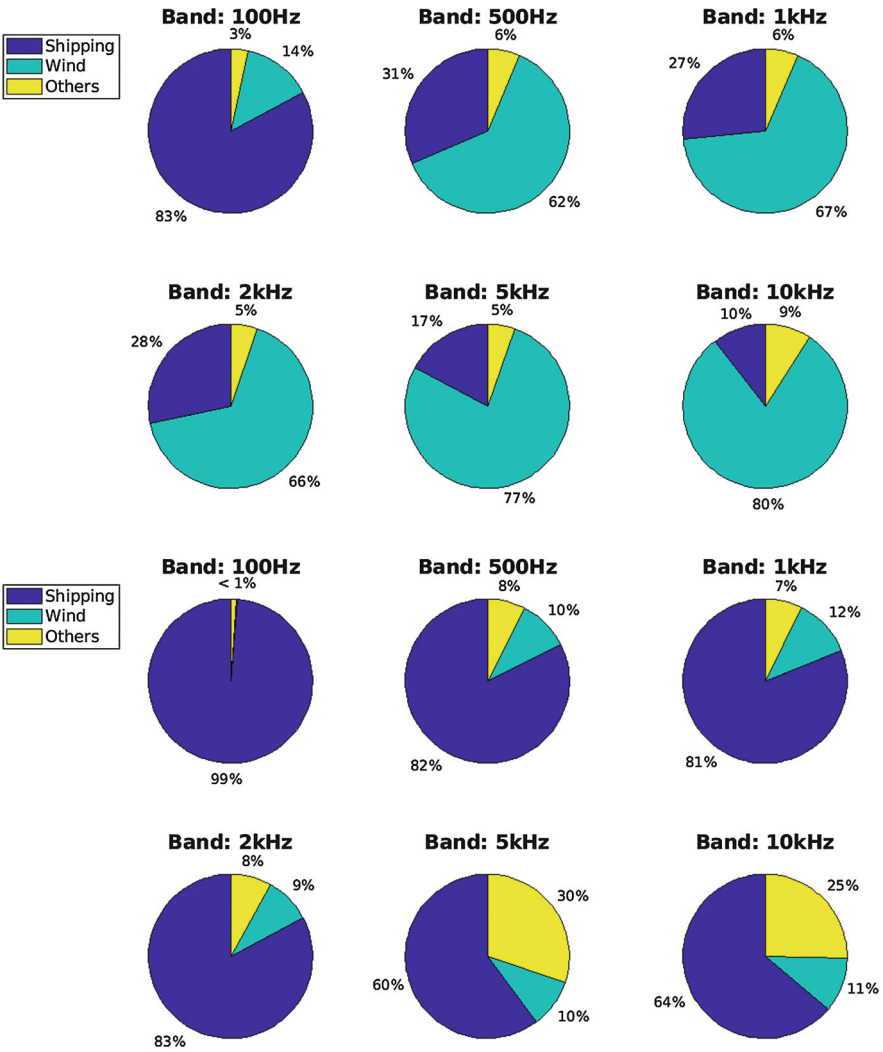

**Fig. 4** The estimated sound energy budgets for January 2019 (*top*) and July 2020 (*bottom*)

## Discussion

The researchers have demonstrated that it is possible to use data from relatively low-cost underwater acoustic recorders to characterize the soundscape of a coastal area regularly frequented by vessels. Vessel noise dominating the lower frequency bands was expected, as the Chedabucto Bay study site is within the approaches to one of Nova Scotia's busiest ports. While understanding absolute sound levels is

important in understanding potential impacts on marine life, characterizing the soundscape using a sound energy budget approach allows for the comparison of the relative contribution of different sound sources at different sites (see, e.g., Breeze et al. 2021) and could inform management measures.

If the new industrial developments proposed for the bay go forward, they are likely to cause an increase in the amount of vessel traffic in the area and therefore an increase in noise levels in the lower frequency bands. This may have implications for use of this area by baleen whales, as these whales communicate mainly in these same lower frequency bands. To investigate the potential impacts of noise on baleen whales, researchers continue to characterize the soundscape and are also analyzing daily and hourly baleen whale call occurrence (Wingfield et al. 2022). Baleen whale call occurrence will be compared to noise levels in future publications.

When this project was initiated, noise levels in the lower frequency bands were of most interest due to the focus on impacts of shipping. However, vessels also contribute to noise levels at higher frequencies, and the coastal construction related to the planned industrial developments (e.g., pile driving) are expected to produce noise at higher frequency levels. Monitoring at this site continues, and efforts have expanded to include an additional site on the north side of the bay. The researchers also plan to increase the sampling rate to record underwater sounds at higher frequencies. From this, a more complete picture of the soundscape of Chedabucto Bay will be developed.

**Acknowledgments** The success of this project is due in large part to the guidance and support received from local fishing associations. Thank you to the Guysborough County Inshore Fishermen's Association for assisting with site selection and for retrieving and deploying the moorings. Thank you also to Jim Theriault for his guidance and advice throughout the project.

**Abstract**

A seven-hydrophone array was deployed in a shallow saltwater creek at the University of South Carolina Baruch Marine Field Laboratory in the North Inlet-Winyah Bay National Estuarine Research Reserve near Georgetown, South Carolina, USA, and sounds were recorded for 24 h from June 01 through June 02, 2017, to identify and localize soniferous animals in the water and to serve as a proof of concept for future studies. The array was calibrated by producing sounds at known locations and using triangulation to determine the hydrophone positions. Similarly, the calibrated hydrophone positions were used to determine the positions of soniferous animals from the signal delays between the different hydrophones using triangulation. The locations of three fish, including one that was moving as it vocalized, are shown.

## Introduction

Soundscape recordings allow listeners to determine the presence and activities of soniferous animals in an area (Pijanowski et al. 2011), and these recordings have been used to learn about both terrestrial (Fischer et al. 1997) and aquatic environments (Parks et al. 2014; Luczkovich and Sprague 2022). If we want to learn about animals that we cannot see, we can listen to them. But most soundscapes recorded with a single hydrophone provide little information about the locations and movements of the sound-producing animals in the recording because hydrophones are omnidirectional at low frequencies. Therefore, a seven-hydrophone array was deployed in a very shallow saltwater creek to learn about the locations of sound producers and their movements.

The study site was Clambank Creek (33°20′2.57”N, 79°11′34.58”W), a saltwater creek at the University of South Carolina Baruch Marine Field Laboratory in the North Inlet-Winyah Bay National Estuarine Research Reserve near Georgetown, South Carolina, USA (see Fig. 1). The goal of the study was to determine which soniferous species were present in the creek and how the activity and locations of these sound producers changed throughout the day and to serve as a proof of concept to be used in future studies.

In order to determine the position of a sound source from an hydrophone array, the positions of the hydrophones, the delay between the arrivals of the same signal at

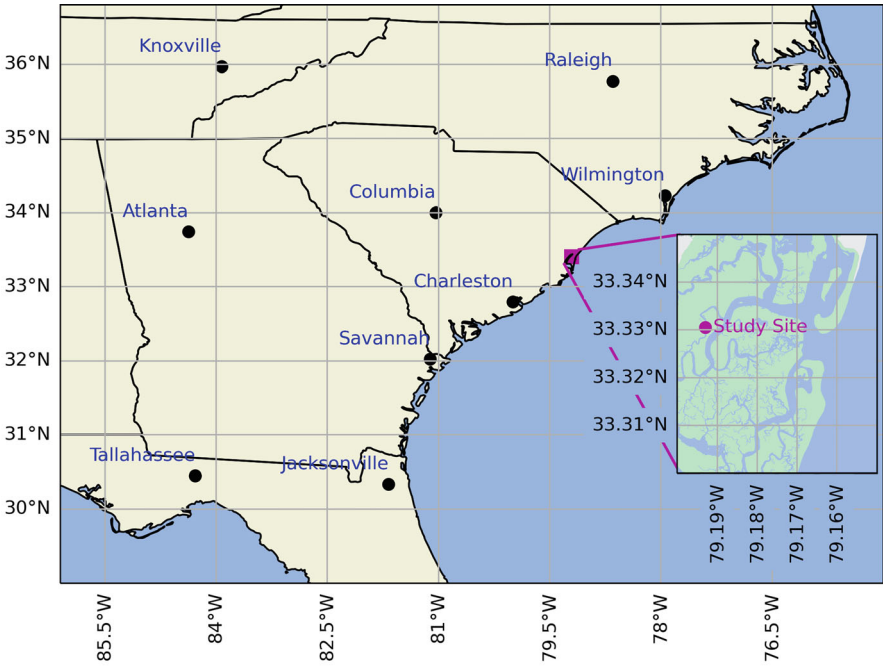

**Fig. 1** The study site shown on a map of the southeastern United States

the different hydrophones, and the sound speed are used to determine the source location using triangulation. This chapter describes how each of these parameters were determined to locate and track sound sources in this shallow water environment.

## Hydrophones and Recorder

The array consisted of seven HTI-96-Min hydrophones (High Tech, Inc., Long Beach, MS, USA). A 100 m, nine-conductor cable (conductors for voltage supply, ground, and hydrophone 1–7 signals) connected an eight-track simultaneous-sampling digital recorder (Zoom F8, Tokyo) and voltage supply on the shore to a junction box. Each hydrophone was connected to the junction box with a 30 m, three-conductor cable (with conductors for voltage, ground, and signal). The recorder made simultaneous 24-bit recordings from each hydrophone sampled at 44100 Hz and stored them on a SD card in the Broadcast Wave file format.

## Reference Positions

Four reference positions (see Fig. 2) were used to accurately locate the position of each hydrophone. At each reference position, a large metal target was positioned so it was visible throughout the site. The location of each reference position was measured using a handheld GPS receiver (Garmin GPSMAP 78sc, Olathe, KS, USA) with Wide Area Augmentation System-enabled Global Positioning System (WAAS-GPS).

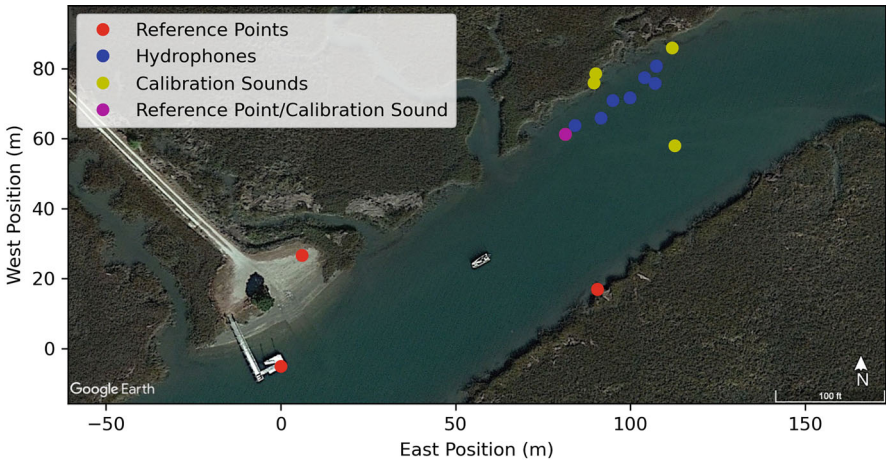

**Fig. 2** Positions of the reference markers, hydrophones, and calibration sounds at Clambank Creek. The Clambank water quality monitoring station is located on the pier on the bottom left of the image. (Satellite image obtained from Google Earth)

## Array Deployment

The array was deployed on June 01, 2017, in water depths of 1.00–1.70 m by wading into the water and mounting the hydrophones on rods connected to cinder block anchors placed on the creek bed. The water depth and time of day were recorded at each hydrophone site. Hydrophone positions were measured with the GPS receiver for validation of the hydrophone locations to be determined by the calibration procedure (section "Array Calibration"). Figure 2 shows the hydrophone positions at the study site. The array configuration was suboptimal with hydrophone locations influenced by bottom conditions and the ability to secure the hydrophone in place while wading.

## Array Calibration

To calibrate the array, impulsive sounds were produced underwater at five positions, determined by triangulation of laser rangefinder (Laser Tech TruePulse 360 °R, Centennial, CO, USA) measurements of the distances to the reference position and also using WAAS-GPS for validation. One of the calibration sounds was produced at the location of reference point 3 (see the reference point/calibration sound point in Fig. 2). The delays of the calibration sounds on the different hydrophone recordings were used to calibrate the array by solving sound propagation equations for the distances from the calibration sounds to each hydrophone and using triangulation to determine the hydrophone positions.

The small pier in Fig. 2 at the second reference point is the location of a National Oceanic and Atmospheric Administration (NOAA) tide and water quality measuring station (station 8662299 Clambank Creek Dock), allowing the determination of the water depth and water quality parameters. The local speed of sound in the water, which was determined with the equation developed by the United Nations Educational, Scientific and Cultural Organization Division of Marine Sciences (the UNESCO equation; Fofonoff and Millard 1983; Wong and Zhu 1995) using water quality measurements taken every 900 s (15 min). Sound speed values for times between the 900-s water quality samples were determined using a third-order cubic spline interpolation.

## Sound Recordings and Source Localization

Sounds were recorded for 24 h and identified using knowledge of the fishes in the estuary (Simpson et al. 2015) and by comparing them to recordings of captive fish. The locations of recorded fish were determined by measuring the signal time delays between each hydrophone recording and solving acoustic propagation equations for the source position using the interpolated local speed of sound in the water.

The soundscape recordings contained rich acoustic activity, including sounds produced by Atlantic croaker *Micropogonias undulatus*, bighead searobin *Prionotus*

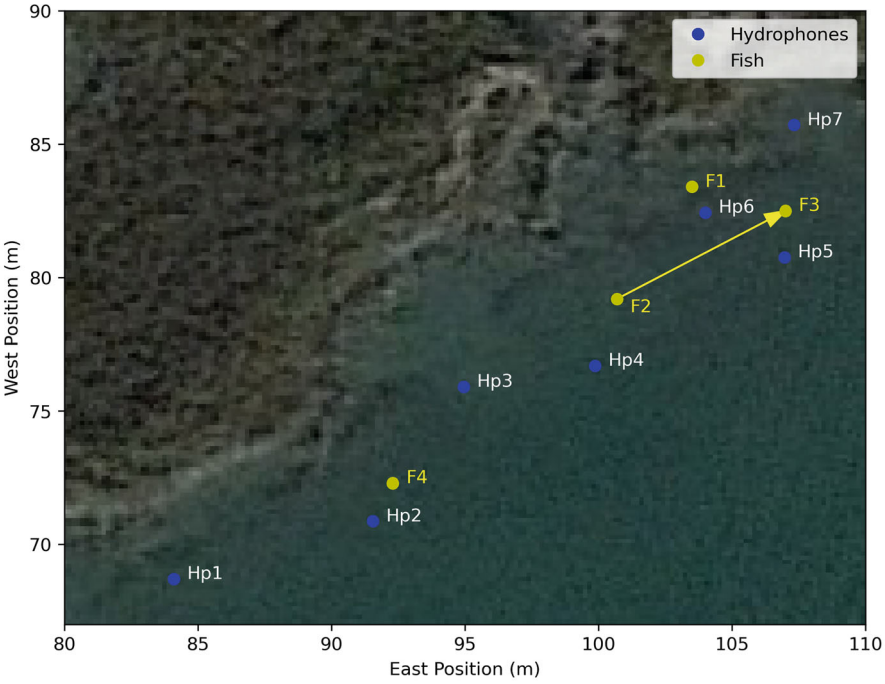

**Fig. 3** Hydrophone positions with fish detections at Clambank Creek. **F1**, a sea robin detected at 2017–06-01 T12:54 (UTC-4); **F2**, a spotted seatrout *Cynoscion nebulosus* detected at 2017–06-01 T18:29:21 (UTC-4); **F3**, the same spotted seatrout as F2 detected at 2017–06-01 T18:30:21; **F4**, a striped blenny *Chasmodes bosquianus* detected at 2017–06-01 T21:06:22. The arrow shows the motion of the spotted seatrout between F2 and F3. (Satellite image obtained from Google Earth)

*tribulus*, oyster toadfish *Opsanus tau*, silver perch *Bairdiella chrysoura*, spotted seatrout *Cynoscion nebulosus*, and striped blenny *Chasmodes bosquianus* as well as snapping shrimp (family Alpheidae). Using the time delays between the same signals in the array channels, the locations of many fish in the recordings were determined. The localized fish sounds shown in Fig. 3 include a bighead searobin at point F1, a spotted seatrout that was "followed" as it vocalized continually for over 60 s as it moved from point F2 to F3, and a striped blenny at point F4.

## Discussion and Conclusion

This chapter demonstrates that sound-producing fish can be located and tracked using a hydrophone array deployed in a suboptimal configuration in very shallow water. The measurements of the calibration sound positions with a laser rangefinder had sufficient accuracy to calibrate hydrophone positions acoustically with results that were consistent with independent WAAS-GPS measurements. The hydrophone positions and measured time delays of sounds in the recording were

used to locate and track vocalizing fish. In the future this technique will be used to locate groups of fishes producing sound and to determine how these fishes move throughout the day.

**Abstract**

The impact of anthropogenic sound on marine fauna is a growing concern, particularly in shallow, coastal, and heavily exploited marine areas such as the Belgian Part of the North Sea (BPNS). Understanding the ecosystem and its limits in these areas is necessary to protect these areas and ensure their sustainable use. To quantify this impact, characterizing and analyzing the soundscape is crucial. However, analyzing soundscapes in shallow and heavily exploited marine areas poses several challenges and particularities. Bio-fouling, flow-noise, unknown sound sources, and masking compromise propagation. This chapter provides an overview of the soundscape in the BPNS and the inherent challenges to measure and analyze it. Some of the challenges are exemplified using data collected in the framework of the LifeWatch Broadband Acoustic Network.

Flow-noise · Bio-fouling · Masking · Shallow waters acoustics · Unknown sound sources

## Introduction

The growing human pressure which is applied to the ocean has raised concern. Consequently, among other pressure agents, it is critical to evaluate the effect of anthropogenic sound on marine fauna. These effects include physical and behavioral effects but also masking of sounds, both for sounds produced for communication and sounds used as cues to obtain information crucial for survival (Duarte et al. 2021). However, to quantify the pressure that anthropogenic sound exerts in the marine fauna and estimate its effects, it is first necessary to understand the sound sources in the soundscape and determine the contributions of human-made sound.

To this effect, soundscape analysis has been a growing field in recent decades. Soundscapes offer rich descriptions of composite acoustic environments, and they provide a more holistic view of the ecosystem than single event analysis. Describing and characterizing a soundscape can comprise one or multiple methods from listening to recordings, via visual inspection of spectrograms, to automated detection of signals of interest, and computation of several acoustic metrics (Schoeman et al. 2022). In this process, understanding natural variability of a soundscape is important for using soundscapes as an ecological and management tool to determine the potential effects of human activity (McKenna et al. 2021).

Often, soundscape ecology is based on the identification of sound sources and their subsequent classification into biophony, geophony, or anthropophony. As a consequence, when the sound sources are not known, or the anthropogenic sound is too loud, some of the traditional ways of analyzing soundscapes do not provide enough information for ecological assessment. For this reason it is necessary to develop new techniques to analyze soundscapes focused on shallow water highly

used marine areas. There has been some focus on developing more integrated approaches to characterizing soundscapes, for example, adding contextual information to understand possible sound sources (McKenna et al. 2021; Parcerisas et al. 2023), but there is still a knowledge gap.

The Belgian Part of the North Sea (BPNS) is located in the southern part of the North Sea. It only reaches 45 nautical miles offshore and it is very shallow. It has an average depth of 20 m and a maximum of 45 m. The BPNS is characterized by a unique subtidal sandbank system, which is very dynamic and has strong tidal currents (Kerckhof and Houziaux 2023). The sandbank system is subdivided into shallow sandbanks, sand mason worm banks, and gravel beds. Shipwrecks, which are artificial hard substrates in these sandbank systems, attract various species (Belgium Health, Food Chain Safety and Environment 2016). The BPNS is also one of the most exploited marine areas in the world. In an area that covers only 0.5% of the entire North Sea, activities such as shipping, blue energy, fisheries, and dredging converge. Every year, there are more than 300,000 shipping movements, ranging from commercial ships to pleasure boats. In addition, Belgium is the country with the highest percentage of offshore renewable space in the world (Belgian Federal Public Service (FPS) Health, Food 2020).

Highly exploited marine areas, such as the BPNS, have important economic value but are threatened by overexploitation of resources. Therefore, it is necessary to understand the ecosystem and its limits to protect it so that use can continue in a sustainable way.

In this chapter, we provide an overview of the particularities of shallow and heavy-explored soundscapes, and we present a list of some of the challenges which can arise when analyzing them. Furthermore, we exemplify them using data collected in the framework of the LifeWatch Broadband Acoustic Network (Parcerisas et al. 2021).

## Sound Sources

### Biophony

Biophony comprises all sounds produced by non-human organisms. Sound is an important source of information for many marine animals. For this reason, all vertebrates and many invertebrates are sensitive to sound (Duarte et al. 2021).

The BPNS can be characterized by a positive east-west gradient of species richness and densities in coastal waters (Cattrijsse and Vincx 1999). Furthermore, a clear coastal-offshore pattern is visible in the plankton communities (Aubert et al. 2022). In the BPNS, there are four main benthic communities linked to different seabed habitats. From these habitats, the sandbanks cover more than 80% of the North Sea, and they consist of gullies, flanks, and a sandbank top. Each part is home to one of the benthic communities. The highest biodiversity is found on the flanks and in the gullies. Further out at sea, there are also gravel beds, which consist of coarse sand and gravel bigger than 2 mm. They have an important function as a

breeding ground and nursery for some species, but the current species composition of the gravel beds has been impoverished by frequent fishing. There used to be banks of the native flat oysters, which create their own micro-habitat just like the sand mason worm. However, these were fished empty in just a few years from the end of the nineteenth century. Additionally, shipwrecks are artificial hard structures that are hotspots for biodiversity. During a study of ten shipwrecks in the BPNS, more than 200 animal species were observed (Zintzen and Massin 2010).

There are 140 different species of fish listed in the BPNS, and the largest group is the demersal species. The many sandbanks provide shelter and breeding ground for many species. All studied fishes have been shown to be sensitive to sound (Popper et al. 2019), although not all species use sound for communication. Nevertheless, sound production is vital for territorial defense, reproduction, and feeding for many species of fish. In a recent review about fish sound production, Looby et al. (2022a) identified 989 actively soniferous fish species, evenly distributed among all the geographical areas of the world. However, this represents a substantial underestimate of global actively soniferous fish diversity as over 96% of fish species lack published examination. The active sounds they produce are usually in the lower frequencies (<1 kHz), and are often described as "grunts," "growls," "thumps," "knocks", among others (Amorim 2006). In addition to active sounds, it is probable that all fishes produce passive sounds, such as feeding sounds, but it still remains unknown which ones do it often and have a recognizable signature. Due to the importance of sound for many species of fish, masking of their signals can have a large impact on their fitness (Popper and Hawkins 2019). Despite the importance of fish sounds, the field of fish bioacoustics has historically been less developed than for other taxa higher in the food chain (Looby et al. 2022a). Moreover, the studies on fish sound production are biased toward fish species from areas where visual ground-truthing is possible.

Marine invertebrates can produce and use sounds for a variety of behaviors. They can generate the sound unintentionally or deliberately for communication. The capacity to produce sounds is known in only three groups of marine invertebrates: bivalves, echinoderms, and crustaceans (Solé et al. 2023). From the crustacean group, only barnacles (Cirripeda) and decapods (Decapoda) have been observed to produce sound. However, many species have been described to be sensitive to sound. They are the group of animals living in the BPNS less studied in terms of sound production and reception, and there exist very few automated detectors focused on sound produced by marine invertebrates.

The most common marine mammal in the BPNS is the harbor porpoise (*Phocoena phocoena*), which is using echolocation to forage, navigate, and communicate. These echolocation clicks are very typical and concentrated around 132 kHz, making them a perfect target to study using passive acoustics (Gillespie et al. 2005; Todd et al. 2009; Verfuß et al. 2005). Harbor porpoises are present throughout the year, but are found in greater abundance between January and April. Other vocalizing cetaceans are the bottlenose dolphin (*Tursiops truncatus*) and the white-beaked dolphin *Lagenorbynchus albirostris*, which are also residents in Belgian waters. Furthermore, less vocal marine mammals are the grey and common seal (*Halichoerus grypus* and *Phoca vitulina*, respectively).

In Table 1 a non-exhaustive list of the species of the BPNS that have been reported to produce sound is provided, together with the available information about the sound they produce.

## Anthropophony

The most important source of anthropogenic sound in the BPNS is shipping. Farcas et al. (2020) reported that the shipping sound exceeded the modeled ambient noise by more than 50% of the time in most of the Belgian Exclusive Economic Zone (EEZ) and by more than 10% in the resting area. They also reported that the annual median ship noise excess in the BPNS is more than 20 dB from 63 Hz to 4 kHz for the shallower waters of the North Sea. For the deeper areas, the sound in these bands attenuated clearly in frequencies above 250 Hz. This means that there are very few places free from shipping noise in the BPNS.

Although knowing the total sound level generated by shipping is crucial for policymakers, shipping sounds can be very different from each other. Shipping noise has most of its energy at low frequencies (50–150 Hz), but sound can be up to 10 kHz (Zhang et al. 2020). Furthermore, several characteristics of the ship (type, size, speed, maintenance state, operational settings, etc.) influence its source levels and frequency distribution (MacGillivray and de Jong 2021). Small recreational vessels have a different sound signature than large cargo vessels, and anchored ships also contribute differently from moving ships. Furthermore, in Belgium there are also dredging and trawling activities, which are also audible in the soundscape and have a clear and recognizable signature. All these differences should be reflected in soundscape analysis for ecological purposes.

Most studies concerning shipping sound use data from the Automatic Identification System (AIS) combined with models of ship sound production (MacGillivray and de Jong 2021). In the North Sea, several propagation models have been developed, in the context of the JOMOPANS project, and AIS-based sound level models have been developed for the Dutch part of the North Sea (Sertlek et al. 2016). AIS data are commonly used to predict ship intensities on large spatial and temporal scales. They have been proven to be a valid source of information on global sound levels produced by shipping noise, which is useful for policy and management decisions (Farcas et al. 2020). Nonetheless, small vessels without AIS transponders and vessels switching their transponders off should not be underestimated in terms of sound pollution. This is particularly important in shallow waters, where the low frequencies are not propagated as well and therefore shipping contribution could be concentrated in higher frequencies generated by smaller recreational boats (Hermannsen et al. 2019).

In addition to the unintentionally generated noise, some shipping activity also produces some intentional sounds using sonar. Sonars use frequencies higher than those of sound unintentionally generated by ships, typically between 2 and 400 kHz, depending on the application.

**Table 1** Summary of all the known soniferous species of the BPNS

| Group | Scientific name | Common name | Sound production | | | |
|---|---|---|---|---|---|---|
| | | | Type | Bandwidth | Frequency peak | Comment |
| **Fish** (Looby et al. 2022b) | Anguilla anguilla | European eel | Click | 10 kHz | ** | ** |

In addition to all the shipping lanes, Belgium is also the country with the highest percentage of renewable offshore space in the world (Belgian Federal Public Service (FPS) Health, Food 2020). Wind turbines do not produce loud sounds during operations, though the sound production of large offshore wind farms should not be underestimated because they elevate the ambient noise due to cumulative effect (Tougaard et al. 2020). During the construction phase, pile driving can reach very loud levels (Madsen et al. 2006). These impulsive sounds appeared to be correlated with a large-scale avoidance of the construction zone by porpoises, which led the Belgian Federal Government to implement a maximum threshold of 185 dB re 1 μPa (sound pressure level, zero to peak) at 750 m from the source for pile driving events. Therefore, since 2017, offshore wind farm constructors have developed sound mitigation measures that are applied during their construction phase to reduce the sound produced (Degraer et al. 2021; Norro 2018).

Other sources of anthropogenic sound present in the BPNS are sparkers (frequency range 200 Hz to 2 kHz), sub-bottom profilers (frequency range 2 to 20 kHz), and underwater explosions, which are characterized by very loud impulsive sound sources which are only active for a short period of time.

## Geophony

Some of the geophony sound sources in the BPNS are related to current: strong currents around hard structures at closer distances or very loud sources further away (several kilometers) such as coastal surf and tidal river currents. In Rogers et al. (2021), they relate these distant sound sources with the tide. Together with particle motion measurements, they propose that these low-frequency sound sources of 10–20 Hz and 20–40 Hz are possibly river mouths from some of the main Belgian, Dutch, and English rivers (Scheldt Estuary, Rhine Delta, North Sea Canal, and Thames River).

Current is also the main agent for sediment transport, where seabed material is brought into suspension by currents (Cotter 2008). The collision of particles generates high-frequency sound, which is largely dependent on the grain size and speed of the particles during impact (Thorne 2014). The theoretical peak frequency of the generated sound can be approximated according to the formula in Eq. 1 (Thorne 2014):

$$f_{peak} = 0.15\left\{\frac{E}{\rho_s(1-\sigma^2)}\right\}^{0.4}\frac{U^{0.2}}{a} \tag{1}$$

Where

for glass spheres: $E = 7.10^{10}$ $\mathrm{Nm}^{-2}$ is the Young's modulus, $\sigma = 0.2$ is the Poisson's ratio $\rho_s = 2500$ $\mathrm{kgm}^{-3}$ is the density.

And $U$ is the collision speed and $a$ is the radius.

Therefore, considering a collision speed between 0.2 and 0.6 $ms^{-1}$ (Vindenes et al. 2018) and a radius between 50 μm and 1 mm (Lee et al. 2012), the frequency of sound produced by sediment transport in the BPNS should be between 12 and 300 kHz.

Besides, current generates flow-noise, which is not actual sound which propagates but just pressure turbulence generated by the shape of the hydrophone and/or the anchoring system. In any case, even if it is not a sound wave, this turbulence is picked up by the hydrophone and has to be removed before analyzing the data. Flow-noise and the other sounds generated by the current dominate the lower frequencies of the BPNS soundscapes, below 100 Hz. An example of this effect can be seen in Fig. 2a.

Another source of nonbiological natural underwater sound is wind, which appears between 100 Hz and 25 kHz, and the sound level generated depends on its speed (Wenz 1962). The higher frequency components come from oscillating and bursting bubbles and splashes created by breaking wave crests (Cotter 2008). Bubbles generated by waves in shallow waters also contribute to the decrease in the propagation of other sound sources (Ainslie 2011).

Last, rain can also contribute significantly to underwater sound between 1 and 50 kHz. The sound is generated from the splashes of raindrops falling in the water. The generated sound depends on the drops size distribution, the wind speed, and the rainfall rate. In the lower frequencies, lightning is a less common event, but it is very loud compared to other sources of natural noise such as wind or rain (Ainslie et al. 2009).

## Common Soundscape Analysis Techniques and Their Applicability in Shallow Anthropogenic Marine Areas

As identified in the report of the International Quiet Ocean Experiment (IQOE) on marine bioacoustics standards (IQOE – Marine Bioacoustical Standardization Working Group 2021), there are currently no standards to measure, characterize, and analyze underwater soundscapes.

Regarding data acquisition, there are no international standards or procedures on how to measure underwater sound for ecological analysis. Different projects have published their best practices (Robinson et al. 2014; Fischer et al. 2021; European Commission. Joint Research Centre. Institute for Environment and Sustainability 2014), but different duty cycles, sampling frequencies, anchoring systems, measuring depth, and so on make it hard to compare results between them. There are also different approaches regarding calibration and data cleaning (Robinson et al. 2021; Ward et al. 2021). For frequency domain calculations, a frequency-dependent calibration can be applied, but this is difficult for calculations in the time domain. Regarding data cleaning, it is common to have artifacts when recording such as flow-noise, electronic noise from the instrument, or sounds produced by the anchoring system. Some approaches propose the removal of these artifacts, and in some studies, these are not reported.

Regarding data processing, there are no standards for analyzing and reporting these soundscapes, which makes them difficult to compare among each other. Some studies focus on temporal patterns, while others report broadband frequency spectrum per site. Nonetheless, some practices have become widely used to analyze

underwater soundscapes, as summarized in Schoeman et al. (2022). Some of these analyses focus on a general overview. They can be used to describe the soundscape of a particular habitat or to compare multiple habitats between them. Data are generally explored using spectrograms for shorter periods (minutes or hours) and the long-term spectral average (LTSA) for longer periods (days, months, or years) (Schoeman et al. 2022). Spectral Probability Density (SPD) plot is a common way to plot a soundscape summary, it gives an idea of how often certain frequencies appear at a certain sound pressure level (Merchant et al. 2013). However very informing, these features are multidimensional and therefore not straightforward to compare between sites and moments. To ease this problem, several acoustic indices have been developed. These indices summarize the acoustic information from a particular soundscape into a single value. They have been used to characterize the acoustic features of the soundscape and to test their relation to the structure of the ecological community, habitat quality, and ecological functioning in ecosystems (Sueur et al. 2014; Buxton et al. 2018). They have been successfully implemented in terrestrial ecosystems, but it is not clear whether they are robust in marine environments (Bohnenstiehl et al. 2018).

Another common way of analyzing soundscapes is to compute the Sound Pressure Level (SPL) broadband or at specific frequency bands of interest. These frequency bands are sometimes selected according to the expected sound sources of interest or known sensitivity of certain species, but third-octave bands or decidecade bands are also commonly used. Recently, Miksis-Olds et al. (2021) proposed the use of hybrid millidecade bands as the best current solution to share trends in ocean noise. Per contra, characterizing marine soundscapes using sound levels of frequency bands is not appropriate to answer other research questions, because it does not contain all the information about the frequency and temporal distribution of the soundscape and its unique acoustic characteristics. For example, when studying biophony in areas dominated by anthropogenic sound, averaging in frequency bins can lead to the fading of some shorter and less common biological sounds.

Apart from general trends in the soundscape, other analyses can be performed to identify known sound sources and to quantify their distribution and percentage. Usually, these are certain species calls and/or ship sounds. The detection of sound sources is often performed manually, but this approach is only feasible for small amounts of data. This is why over the last decades the interest in automatic detectors and classifiers has increased. These automatic source detectors are based on rule-based algorithms, where the user defines certain thresholds for hand-picked acoustic features, to fully unsupervised machine learning algorithms. In the BPNS, this is the case with the harbor porpoise and the dolphins, which can be studied because their vocalizations are known. Moreover, masking occurs mainly at frequencies below the echolocation clicks of harbor porpoises and dolphins. Therefore, these can be monitored using Passive Acoustics Monitoring (PAM), which is already happening within the framework of the LifeWatch Cetacean Network (Debusschere et al. 2015) with the use of C-PODs. These devices can detect the stereotypical clicks produced by harbor porpoises and store the metadata of these detections. The information of the spatio-temporal distribution of these mammals can then be used in impact assessments. However, the source

code used in the C-PODs to detect the echolocation clicks is not available, and therefore it is a "black box" which is hard to evaluate. To overcome this, there are several other open source algorithms that can be used on raw acoustic data or on the output of a SoundTrap Click Detector (OceanInstruments, New Zealand), such as PAMGuard (Gillespie et al. 2009) and D-PorCCA (Cosentino et al. 2019). These algorithms have to be applied after the raw acoustic data are collected because they are not embedded in a sensor. This has the advantage of also having access to the raw data and therefore to more information and easier performance evaluation, but the disadvantage of a higher battery consumption and storage need.

For shallow, highly used areas such as the BPNS, some of these approaches are not descriptive enough. For example, the Joint Research Center of the European Commission set root mean squared (RMS) sound levels in 1/3 octave bands centered at 63 and 125 Hz as indicators of ship noise (Tasker et al. 2010). In a shallow area like the BPNS, these frequencies are below the theoretical cut-off frequency in places where the water depth is shallower than 70 and 35 m, respectively. Therefore, these indicators could lead to misleading information of shipping sound. Additionally, RMS levels are sensitive to outliers, so a few very loud events will affect the mean (Merchant et al. 2016). Furthermore, other shipping activities such as trawling and dredging have distinct sound signatures from underway ships, and should also be considered.

The underwater soundscape of the Belgian Part of the North Sea has been very little studied. In general, most of the soundscapes analysis in literature is focused on describing natural or pristine areas, or to compare managed ecosystems with non-managed ones. Therefore, the tools developed so far to describe and analyze underwater soundscapes may not apply to highly exploited areas.

In the following subsections, we list some of the most common challenges and particularities of recording and analyzing underwater sound in shallow highly anthropogenic areas. To exemplify these challenges, we analyzed data from the LifeWatch Broadband Acoustic Network (Parcerisas et al. 2021). These data were collected using a RESEA 320 recorder (RTSys, France) together with a Colmar GP1190M-LP hydrophone (Colmar, Italy, sensitivity: −180 dB/V re $1\mu Pa$, frequency range −3 dB: 10 Hz to 170 kHz). All acoustic data were processed using the Python package pypam (Parcerisas 2022).

## Propagation

As summarized in Ainslie and Dahl (2014), in shallow water, propagation is influenced by multiple reflections from the seabed and sea surface, so geometrical spreading laws need to be modified. The resulting effect depends on the kind of source and its directivity. Several other studies have focused on trying to understand the propagation patterns in shallow marine areas and simplify their computation (Sertlek 2016; Sertlek et al. 2016; Sertlek et al. 2013). Furthermore, the cut-off frequency is the minimum frequency at which sound will propagate. For shallow water, the cut-off frequency can be approximated to (Jensen et al. 2011) (Eq. 2):

$$f_{cutoff} = Cw/\left(D * \sqrt{1-(Cw/Cb)^2}\right) \quad (2)$$

Where

$f_{cutoff}$ is the cutoff frequency
$Cw$ is the velocity of the sound in water
$Cb$ the sound velocity in homogeneous bottom
$D$ depth in meters

In the BPNS the cut-off frequency is somewhere between 100 Hz and 400 Hz, depending on the water depth. Due to the change of water depth generated by the tides, the cut-off frequency changes with the tide, and so do the propagation patterns. Consequently, the local water depth and bottom material have a clear influence in the propagation of further away sound sources (Ainslie et al. 2009). For this reason, some sources at lower frequencies do not propagate, and others are distorted when propagating simultaneously in the water column and the seabed.

On the other hand, in the BPNS the water mass is considered to be mixed, and therefore there are no big changes in salinity and temperature. This makes the sound speed constant throughout the water column (Ivanov et al. 2020). Furthermore, in shallow waters, the sounds generated at the sea surface by rain, wind, or waves have an influence in the entire water column and can be received by the benthic habitats. This is because there are more reflections and a smaller propagation range to attenuate the sound.

## Flow Noise and Bio-Fouling

Another challenge of measuring underwater sound in the BPNS is flow-noise. The turbulence generated by the current around the hydrophone or the mooring system produces pressure changes that are not actual propagating sound. This pseudo-noise, however, is picked up by the hydrophone anyway and can mask other sound in the lower frequencies below 1000 Hz, limiting the capability to reliably measure ambient noise (Bassett et al. 2014; von Benda-Beckmann et al. 2016). This turbulence depends on the current speed. In the North Sea, the tidal current is estimated to range from a few $cms^{-1}$ to 67.7 $cms^{-1}$ (Vindenes et al. 2018). Furthermore, the flow-noise recorded by the hydrophone depends on the shape and size of the hydrophone and/or the anchoring system.

When deploying bottom long-term observatories in the North Sea, the instruments will be exposed to bio-fouling. The growth of living organisms on top of the sensors can lead to a change in sensitivity (Heupel et al. 2008). The anchoring system is an artificial hard substrate that is sometimes rapidly colonized by many organisms, depending on the location and season. The fauna residing on top of the mooring therefore can affect the soundscape. Furthermore, the presence of bio-fouling on top of the hydrophone can lead to changes in sensitivity, particularly to the sensitivity of the hydrophone to pick up flow-noise.

We exemplify these particularities with data analysis from deployments in the BPNS. For this example, three frequency bands were selected for analysis: broadband (up to 24,000 Hz), low frequency (10–1000 Hz), and higher frequency (1000–10,000 Hz). For each of the band, the signal was filtered using a band-pass Butterworth filter of order 4, and data were down-sampled to twice the higher frequency limit. Next, the RMS value of the calibrated data was computed for each file, of equal duration (10 min and 15 s). For each processed point, the bottom current was retrieved from the COHERENS model for the North Sea (MFC ODNature RBINS 2023) and assigned using the Python package bpnsdata (Parcerisas 2021).

This process was done for all the recording stations (see Fig. 1). In some deployments, it could be observed that the low-frequency band was dominated by a source that is correlated with the current speed, which we assume is flow-noise (e.g. 2a). However, this pattern did not repeat in other deployments (e.g. 2b). This could be due to a different position of the anchoring system with respect to the current and the sand banks, or it could be due to the fact that the sound levels in 2022 were higher than in 2021, and these loud sources could be masking the flow-noise. When checking the AIS-based route density from EMODnet (EMODnet Human Activities 2022a), the average between March and May in the vicinity of the Grafton station is 173.75 routes/km$^2$/month for 2021 and 196.83 routes/km$^2$/month for 2022, so the increase in sound levels could be due to increased shipping.

In the deployments where flow-noise was present, most of them seemed to show a decrease in correlation with the current after a certain time. The hypothesis was that

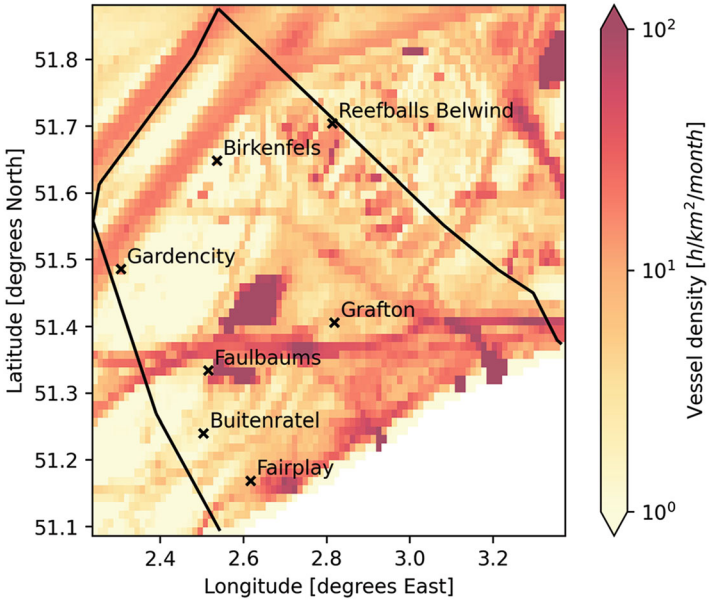

**Fig. 1** Vessel density from EMODnet (EMODnet Human Activities 2022b) in the BPNS, together with the station location of the LifeWatch Broadband Acoustic Network (Parcerisas et al. 2021)

the bio-fouling growing on top of the hydrophone would decrease the flow-noise picked up by the hydrophone or its sensitivity. A linear mixed effects regression as described in Eq. 3 was fitted to check whether the effect of the number of days deployed was significant. To this effect, only deployments with a total correlation higher than 0.4 between the sound pressure in the low-frequency band and the current were included. The deployments with a low correlation with flow-noise were assumed to be in a spot where currents were less strong because of the sandbanks or the protection of a nearby shipwreck. Because the effect of the bio-fouling was not expected to change proportionally to the days but rather at a

decreasing rate, the variable expressing the days since deployment was converted to a logarithmic scale.

$$SPL_low_frequency \sim current + days_since_deployment + current : days_since_deployment + (1|deployment) \quad (3)$$

The results (see Table 2) showed that the days since deployment, the current and the interaction between the two were significant. The interaction and the days since deployment have a negative coefficient, which could be because the flow-noise is diminished due to bio-fouling (in time), and it has a bigger effect when the

current is high than when it is low. However, this effect could also be due to sand burying increasing with time, change of depth because of the movement of the sandbanks, loss of sensitivity from the hydrophone for technical reasons, or other causes.

## Unknown Sound Sources and Low Visibility

A common technique to link sound to its producer is visual correlation, both in the lab, in the wild with cameras deployed together with hydrophones or in the wild with visual surveys. Thanks to these efforts, all the marine mammals species are nowadays known to produce sound, and many of their signatures can now be recognized without the need for a visual confirmation.

However, many other biological sound sources are still unknown, particularly those of fish and invertebrates. The examination of fish and invertebrates for sound production can be complex, difficult, irresolute, and inefficient. Laboratory experiments can be time and resource intensive and do not guarantee results (Looby et al. 2022a), and field work to correlate sounds with their producers in areas with high turbidity, such as the BPNS (Fettweis and Van den Eynde 2003), is often not possible due to low visibility.

Furthermore, in shallow waters the propagation patterns can be complex, so sound signatures can be distorted when received (Ainslie and Dahl 2014). This complicates the recognition of certain sounds. Moreover, due to the propagation patterns, it is also complicated to know which environmental event produces received sounds, and therefore the mathematical models for sound sources comprising the lower frequencies are not correlated with the received levels.

As an illustration for these unidentified sound sources, some examples were manually selected. In Fig. 3 the short spectrograms of these sounds can be found, illustrating sounds that could be from a biological source, but have not been identified at the moment.

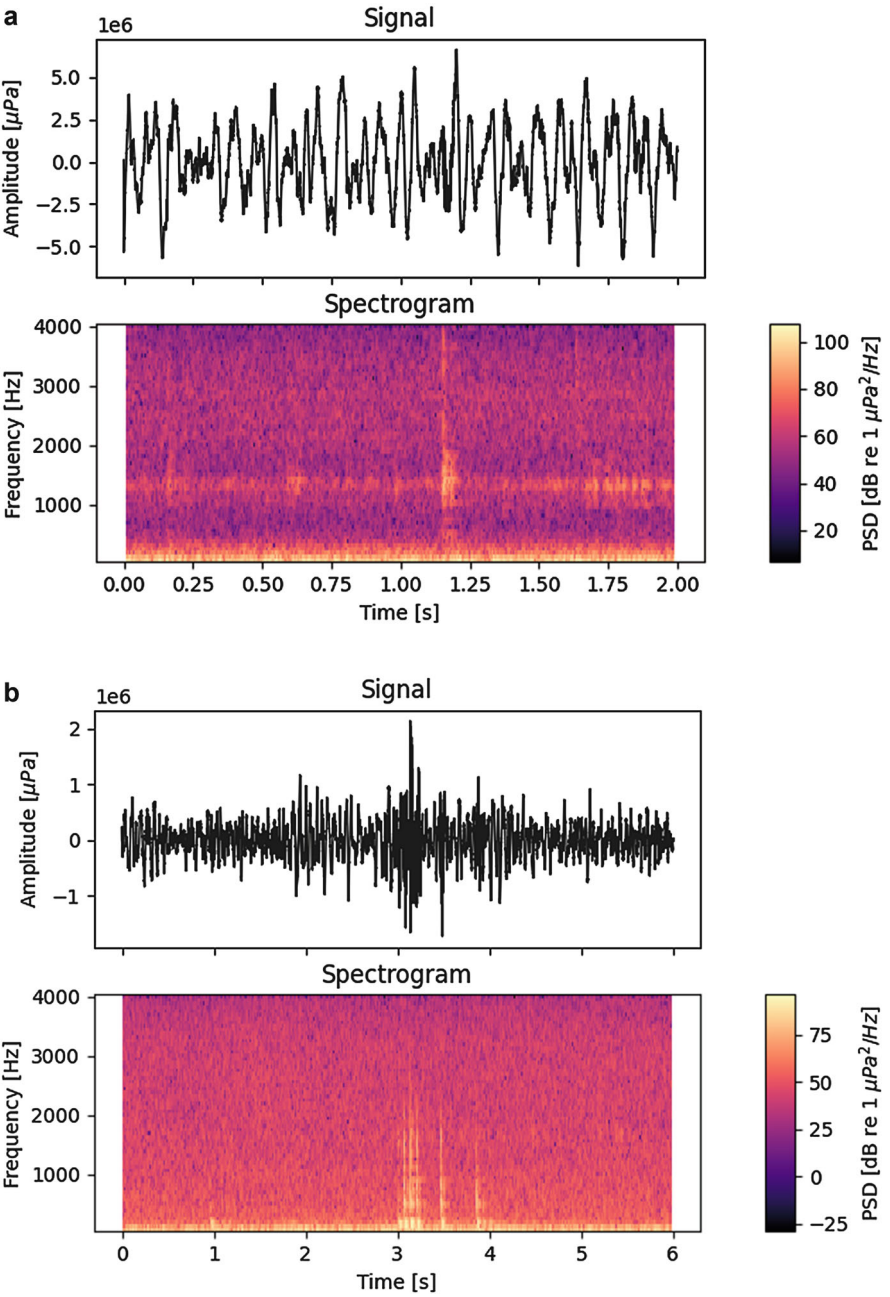

**Fig. 3** Several examples of unknown sound sources in the BPNS. For the short spectrograms computation, data were filtered using a band-pass Butterworth filter of order 4 between 10 and 8000 Hz, and data were down-sampled to 16,000 Hz. For the spectrogram computation, the length of the Fast Fourier Transform (FFT) was chosen to be 128, with a 70% overlap. The descriptions of the detected unknown sounds are (**a**) stridulation, possible source: crustacean, (**b**) single "drum," possible source: fish, (**c**) consecutive "pocs," possible source: unknown, (**d**) continuous "drumroll," possible source: fish

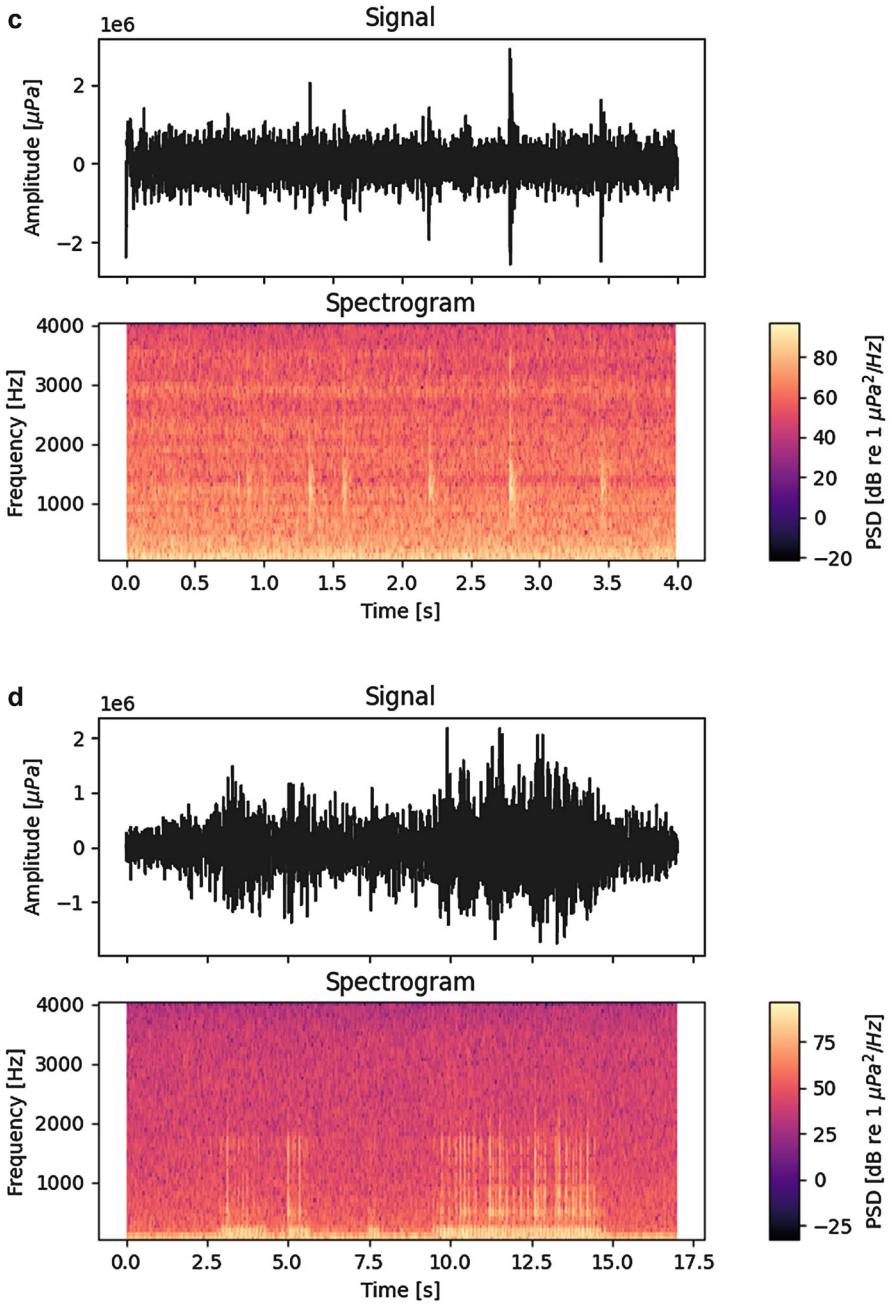

**Fig. 3** (continued)

### Masking

When interested in monitoring biodiversity using PAM, it is necessary to exclude almost constant anthropogenic noise to analyze biophony. This can be done by analyzing only quiet periods or with automatic denoising techniques. Shipping sounds have most of their energy from 50 Hz to 10 kHz (Zhang et al. 2020), which overlaps with most of the biological sounds produced by fishes, invertebrates, seals, and dolphins. This can lead to potential masking effect, where a louder sound source disrupts the reception of a weaker sound.

The sound produced by harbor porpoises is found at higher frequencies and is therefore not prone to be masked by human-made sounds. However, some sonar activities are in that frequency range, which are also detected by some click-detector algorithms such as the KERNO algorithm from the C-PODs (Chelonia Ltd., Penzance, UK) and could be a source of masking for these species.

Besides the impact that masking can have on marine fauna communication, it also complicates the soundscape analysis. Anthropogenic noise can decrease the ability of humans to detect certain sounds in short-term spectrograms. Furthermore, biological sounds can disappear in the general overview plots like LTSA or SPD because of their minor contribution to the soundscape compared to anthropogenic and geophonic sounds.

## Tackling Shallow Water Challenges

The challenges discussed above complicate marine soundscape analysis in shallow heavily used areas. Nevertheless, these can be tackled using pre- and post-processing techniques.

Concerning the technical limitations specific to the BPNS with respect to flow-noise, there are several ways of reducing its impact. One way of denoising flow-noise is to record simultaneously with an array of hydrophones and during the data processing discard the parts of the signal that are not correlated between the multiple channels. However, this approach can be costly due to the increased number of hydrophones needed and the increase in memory use. Furthermore, it also risks removing parts of the signal of interest (Beerens et al. 1999; von Benda-Beckmann et al. 2016). Some studies have been conducted to investigate mitigation techniques during recording (Wei et al. 2021), but there are still no accessible robust technologies that can be deployed in long-term monitoring stations that completely suppress flow noise. Finally, flow-noise is limited if the recording system is drifting (Merchant et al. 2015), because it moves with the water column. Therefore, drifting can be chosen as an acoustic recording strategy, which allows for a higher spatial resolution but a lower temporal one, but it is not applicable for long-term monitoring stations.

Regarding the deployment of equipment, in shallow waters it can be done without leaving anything behind on the sea floor (Goossens et al. 2020). Moreover, using this

type of moorings allows for practical and efficient procedures of deployment and recovery. The rigid design of the frame results in higher stability of the sensors compared to the common anchored buoy lines.

As a ground-truthing method to discover fish sounds and relate them to the species producing them, other methods besides direct visual observations can be used. For example, the European Tracking Network (ETN) aims to track aquatic animals across Europe using Telemetry, which uses acoustic tags to investigate the ecology and movement behavior of aquatic species in relation to their environment. This technology can thus be used to know when a certain fish species was present in the vicinity of the acoustic station. Therefore, the LifeWatch permanent acoustic receiver network in the BPNS (Reubens et al. 2017) combined with the LifeWatch Broadband Acoustic Network (Parcerisas et al. 2021) makes it possible to reduce the amount of acoustic recordings to be manually annotated to find fish vocalizations and could be used as a semi-ground-truthing mechanism.

Additionally, the recent development of the FishSounds database (Looby et al. 2022b) provides a framework to share knowledge about fish sounds, and the GLUBS initiative (Parsons et al. 2022) aims to create a collective and global open-access platform that provides a reference library of known and unknown biological sound sources. However, more research is still needed to verify and identify fish and invertebrate species that produce sound, document the behavioral contexts of their sound production, record and describe the acoustic characteristics of the sounds, and create a repository of sound production information and recordings (Looby et al. 2022b; Solé et al. 2023; Parsons et al. 2022).

Sounds which remain unidentified might be – or might not be – of importance for the marine fauna. Finding, reporting, and understanding the patterns of these unidentified sounds are of significant benefit to PAM and the assessment of underwater soundscapes. Furthermore, it can lead to an increase of the knowledge about the local acoustic community, as a proxy for biodiversity and ecosystem health. Documenting them before they are identified provides a baseline for their presence and extra information for later source identification.

Once more data is gathered on the sound production of fish and invertebrates, access to these open sound source libraries can lead to the further development of detectors and classifiers of fish (e.g. Urazghildiiev and Van Parijs 2016; Ibrahim et al. 2018; Vieira et al. 2015) and invertebrate sounds. Furthermore, with the advancement of machine learning tools, other approaches for marine sound identification can be developed which do not need annotated data or need little labeling effort. These approaches include unsupervised models, which have already been developed and applied to marine ecosystems, such as the one described in Ozanich et al. (2021). Other state-of-the-art machine learning algorithms with great potential to be applied to marine ecosystems use a semi-supervised approach including humans in the loop. These approaches are classified into active learning, in which the system remains in control; interactive machine learning, in which there is a closer interaction between users and learning systems; and machine teaching; where human domain experts have control over the learning process (Mosqueira-Rey et al. 2023).

When the sound sources of interest are partially masked, one possible way to extract the signal of interest is to apply source separation algorithms. Even though source separation has received comparatively less attention than automatic detection and classification of sounds, in this context, it is useful to develop source separation algorithms. This has already been applied to soundscape descriptions (Lin and Tsao 2020; Lin et al. 2021) and has also been applied to solve the cocktail party problem (Bermant 2021). Applying these tools to soundscape description in a standardized way could be an added value to the field.

Finally, soundscape analysis can be done through a more holistic approach, which does not depend on the recognition of sound signatures. The most common ways of general soundscape analysis are not always applicable to shallow highly anthropogenic areas. In recent years, new approaches have appeared, such as the categorization of soundscapes in an unsupervised way (Parcerisas et al. 2023), where the different soundscapes are grouped into groups of acoustically similar types, which are then correlated to environmental parameters using explainable artificial intelligence.

Sometimes noise can mask the biophony, but that does not mean that the biophony is not there. Therefore, there is a need to develop more PAM analysis techniques robust to anthropogenic noise, which are sensitive to acoustic signals of not so vocal communities like sandy benthic habitats.

**Acknowledgments** The project was realized as part of the Flemish contribution to LifeWatch. The authors thank the Simon Stevin RV crew for their help with the deployment and retrieval of the acoustic instruments.

**Abstract**

The St. Lawrence River is a large river system in North America, connecting the Great Lakes to the Atlantic Ocean (~1500 km) and is a major commercial waterway in the world. The fluvial portion has a highly diverse mosaic of habitats that support ~100 species of freshwater fish. Fed by numerous tributaries of varying quality, the St. Lawrence includes three large, shallow, slow-flowing fluvial lakes that alternate with narrow, fast-flowing stretches and numerous islands sometimes grouped in archipelagos, all of which are exposed to various anthropogenic pressures. Lake Saint-Pierre (LSP), located downstream, has been recognized as a World Biosphere Reserve (UNESCO, 2000) for its rich biodiversity and extensive wetlands. This UN status does not, however, protect it from the intense pressures associated with agricultural practices, water discharge regulation and, of special interest to us here, acoustic pressures, some of which are of particular concern. First, between 1952 and 1999, the Canadian Department of National Defense fired more than 500,000 projectiles at nearly the entire southern shore of the SLP. It is estimated that 7880 pieces of unexploded ordnance –UXOs – (3%) could remain with an explosive charge of 0.5–7.0 kg. For public safety reasons, a clearance, expected to last 9 years, has begun. Some UXOs will be removed and detonated at a land-based site, while those deemed too hazardous to be moved will be detonated directly in the lake, with the expectation that effective mitigation measures will be taken. These operations involve a vast 16,000 hectare area of shallow, highly productive habitat used for spawning and rearing by approximately 40 species of fish, some of which are threatened. Second, the navigation channel, which is ~300 m wide and ~ 12 m deep, is used year-round by commercial vessels, whose noise contribution to the soundscape has never been characterized in these fresh waters. In addition, during the ice-free season, the LSP and its archipelago are frequented by numerous recreational vessels, whose acoustic effects have not yet been measured. Also, the exposure to winds and waves of this large shallow lake is likely to generate significant ambient noise fluctuations, which would deserve to be quantified. Finally, there is great interest in characterizing biophony in this unique environment and testing some of the effects of underwater sound (including particle motion) and ground vibration on fish and invertebrates, especially during bombshell explosions. It is in this context that a joint academic-department acoustic research program has been initiated, with the aim of preparing a first portrait of the soundscape in this World Biosphere Reserve and possibly proposing recommendations for mitigation measures regarding the most important anthropogenic noise sources.

## Introduction

Since the 1950s, anthropogenic underwater noise has doubled every decade in the oceans and near shipping lanes (Frisk 2012; McDonald et al. 2006). Underwater soundscapes – defined here as the ensemble of acoustic signals characterizing a particular underwater environment – are therefore changing rapidly. The soundscape of many aquatic ecosystems is currently dominated by anthrophony events (sounds of anthropic origin, e.g., vessel noise, pile driving, or sonar), compared to the preindustrial era when soundscapes were dominated by biophony (sounds of biotic origin, e.g., sciaenid fish or snapping shrimps) and geophony (sounds of abiotic origin, e.g., rain, thunder, ice, etc.) (Duarte et al. 2021). Understanding the extent to which this change is affecting the behavior and life cycle events of aquatic fauna is crucial to maintain or restore the integrity of marine and freshwater ecosystems. It is therefore essential to quantify and mitigate the impacts of rapid transformations of underwater acoustic landscapes caused by human activities on fauna.

The acoustic dimension is an important feature of aquatic habitats. Sound travels faster and farther in aquatic environments than in the air and the aquatic fauna's capacity to hear and communicate through acoustic cues can be advantageous, especially in environments with limited visibility (e.g., under ice and turbid water). Fish have evolved a great variety of inner ear and accessory hearing structures that allow them to perceive sound, as well as a diversity of sound-generating mechanisms (e.g., drumming muscles or stridulatory bony structures). It is estimated that approximately two-thirds of fish species produce sound (Rice et al. 2022) and active sound production has been reported in a wide variety of behavioral contexts including reproduction (courtship and spawning), food source, or territory defense and predator avoidance (Ladich 2015).

Pervasive noise pollution has the potential to affect both sonic fish and species that hear sound and use it to navigate, feed, or detect potential threats. Impacts of shipping noise on fish include behavioral changes such as avoidance (Weilgart 2018), altered antipredation behaviors (Simpson et al. 2016), decreased parental care of newborns (Nedelec et al. 2022), as well as physiological impacts such as increased stress levels (Mills et al. 2020). Effects from underwater explosions are even more severe and can be expected to range from temporary or permanent anatomical damages to death (e.g., Dahl et al. 2020; Smith et al. 2022).

Although noise pollution is globally raising important concerns, its effects are little documented in freshwater environments and the underlying mechanisms are poorly understood. In Quebec (Canada) in particular, little scientific knowledge and data exists on the effects of shipping noise or underwater explosions on freshwater fish species and their habitat. This includes the St. Lawrence River fish communities. The St. Lawrence River is a large river system in North America, connecting the Great Lakes to the Atlantic Ocean (~1500 km) and is a major commercial waterway in the world. The fluvial portion has a highly diverse mosaic of habitats that support ~100 species of freshwater fish. Fed by numerous tributaries of varying quality, the St. Lawrence includes three large, shallow, slow-flowing fluvial lakes that alternate

with narrow, fast-flowing stretches and numerous islands sometimes grouped in archipelagos, all of which are exposed to various anthropogenic pressures.

Lake Saint-Pierre (LSP), located downstream, has been recognized as a World Biosphere Reserve (UNESCO 2000) for its rich biodiversity and extensive wetlands (Quebec; Fig. 1). The fish community of LSP, composed of approximately 90 species identified by the Ministère de l'Environnement, de la lutte contre les changements climatiques, de la Faune et des Parcs (MELCCFP, Québec, Canada), including about 20 species of precarious status, is potentially exposed to underwater noise from shipping. There are also native mussel beds at both ends of the LSP that have a precarious status. Although there is scarce information available on invertebrates hearing, recent studies point out that they are sensitive to particle motion and therefore can detect and react to sound in the water column and related physical vibrations near or within the substrate (see Solé et al. 2023 for a review). Indeed, there is evidence for a range of behavioral responses, and even higher mortality rates, in mussels exposed to air gun sound and substrate vibration (e.g., Roberts et al. 2015;

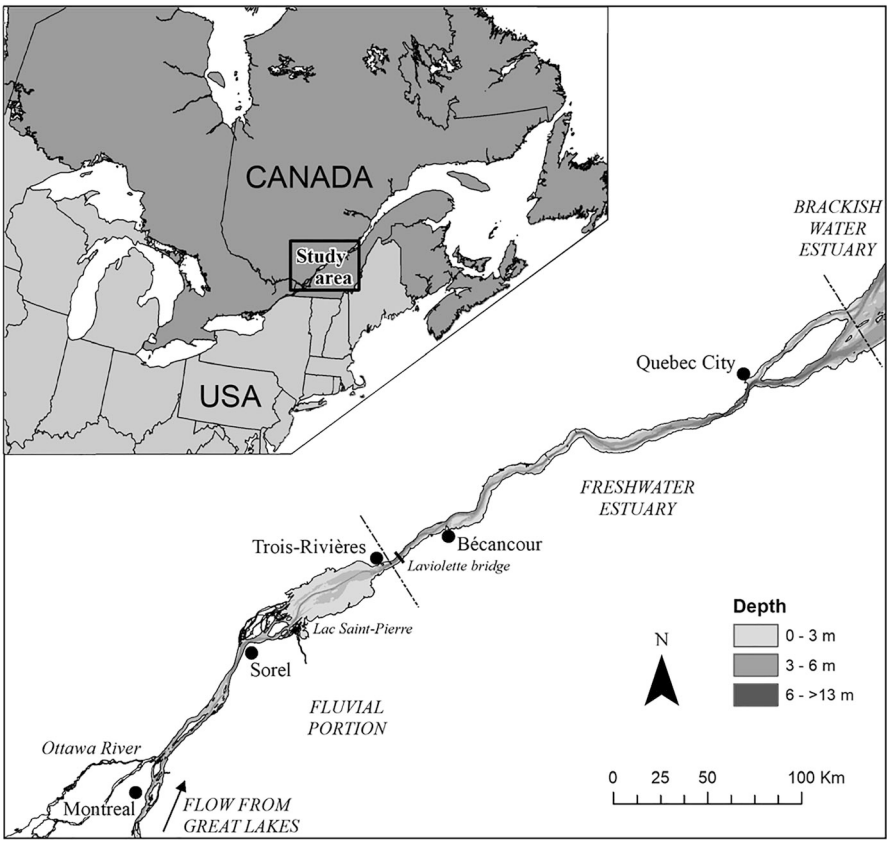

**Fig. 1** Great Lakes–St. Lawrence River basin and detail on the course of the St. Lawrence River

Day et al. 2017) and thus could potentially be threatened by the high power of underwater explosions.

The physical properties of LSP are unique, with a particular configuration that differs from an open ocean environment and makes it a true open-air laboratory for acoustic research. It is a freshwater fluvial lake, consisting of a vast and shallow floodplain (average depth is 3 m), crossed by a wide (~300 m) and deep (at least 11.3 m) navigation channel, dug in the clay and rock over 250 km between Montreal and Quebec City. In addition, there are horizontal gradients of conductivity, temperature, and turbidity reflecting the different water masses flowing in LSP from various tributaries.

The contrasting LSP bathymetric and physicochemical configuration hosts a rich aquatic fauna, which is exposed to noise sources, whose propagation and effects need to be studied. First, the seaway that crosses this fluvial lake supports approximately 4800 transits of merchant ships/year (Bernier, 2022). Secondly, this area is also very popular with hundreds of recreational fishermen and boaters attracted by the scenic beauty of the landscapes, whose frequent trips alter the underwater soundscape. Finally, the Canadian Department of National Defense tested numerous munitions in the highly productive aquatic habitats on the south shore of the LSP between 1952 and 1999, many of which remained unexploded. For public safety reasons, a cleanup needs to be undertaken, involving the removal of shells but also the in situ explosion of unexploded ordnances (UXOs), posing a threat to the physical integrity of animal and plant species, and their habitats.

These multiple acoustic pressures are the subject of recent research efforts led by academia (e.g., Univ. du Québec en Outaouais, Univ. du Québec à Trois-Rivières and Univ. Laval) and the MELCCFP (e.g., Barbeau 2023). The initial work highlights a pressing need to (i) establish acoustic baselines of the natural soundscape characteristics and of fish species bioacoustics (hearing capacity and sound production) and (ii) to assess the impact of vessel traffic and underwater explosions on resident and migratory species for which the St Lawrence River is a critical habitat.

The poster presented at the Aquatic Noise Congress (Berlin, July 2022) was intended to introduce the scientific community to a research program that had just started in 2022 in the fresh waters of the St. Lawrence River. This paper provides more details on the physics of this unique environment, which is described as an open-air laboratory where the following research objectives are pursued:

(a) Prepare an initial acoustic portrait of LSP to assess the exposure and vulnerability of fish communities to noise from commercial and recreational boating in this UNESCO Biosphere Reserve.
(b) Characterize the acoustic capacity of LSP's fish species.
(c) Make accurate measurements when detonating UXOs implying the deployment of high-sampling rate (>1 MHz) and high-pressure-resistant (~250 dB) hydrophones in close collaboration with the Canadian National Defense.
(d) Develop an acoustic propagation model to simulate the acoustic landscape in wildlife habitats of interest and different noise sources. To do so, several layers of information were collected, including topography, substrate, density of

submerged aquatic vegetation, and gradients created by water masses (conductivity, temperature, and turbidity).

(e) Evaluate the impacts of anthropogenic sounds on target species based on their level of exposure, auditory sensitivity, and behavioral changes.

(f) Recommend potential mitigation measures to reduce the acoustic footprint of the most important sources of anthropogenic noise that are identified as critical to sensitive aquatic wildlife.

## Geographical Context and Heterogeneity of the St. Lawrence River

The Great Lakes-St. Lawrence River watershed is one of the largest freshwater ecosystems in the world (Fig. 1, top panel). Located in the eastern region of North America, it contains about 84% of all North American freshwater (18% of the world's freshwater) and is home to about 30 million people. It is a natural migration route of approximately 1500 km that connects the Great Lakes to the Atlantic Ocean. It is also one of the most important commercial waterways in the world, contributing significantly to the economy of the entire St. Lawrence-Great Lakes region.

With a naturally contrasting topography and a complex hydrological network, the St. Lawrence River presents a mosaic of highly diverse habitats that are home to some 100 species of freshwater fish (Fig. 1). It is generally divided into three main sections: (i) a fluvial section extending from the outlet of the Great Lakes to Trois-Rivières (~350 km), in which Lake Saint-Pierre is located; (ii) followed by an estuarine section composed of a long freshwater estuary (~160 km) progressively influenced by the tide, which reaches a tidal range of 6 m near Quebec City, and then a brackish water section (~150 km), where salinity increases progressively from 0.2–25 ppt; and (iii) further out, a long marine section that joins the Gulf of St. Lawrence and the Atlantic Ocean (salinity >25 ppt; see Fig. 1).

The fluvial section presents a variety of aquatic habitats with three slow-flowing fluvial lakes (lakes Saint-François, Saint-Louis, and Saint-Pierre; Fig. 1), separated by narrow fast-flowing corridors and dotted with numerous islands and a few archipelagos. The heterogeneity of the habitats is accentuated by the contribution of numerous tributaries. These produce highly contrasting water masses that can be identified along the river, depending on their origin and their changing physico-chemical properties (temperature, conductivity, and turbidity). Water masses flow side by side with little lateral mixing for hundreds of kilometers (e.g., the clear green water of Lake Ontario, the brown from Ottawa River, and more turbid water of agricultural watersheds; Fig. 2), creating strong horizontal gradients that largely influence aquatic habitats (e.g., abundance of submerged vegetation and fish diversity) and presumably also sound propagation (suspended particles, temperature, and conductivity).

The entire course of the St. Lawrence River is of great interest for acoustic studies, but the focus here is on LSP, the largest and most productive of the fluvial lakes of the St. Lawrence River. LSP has been recognized as a World Biosphere

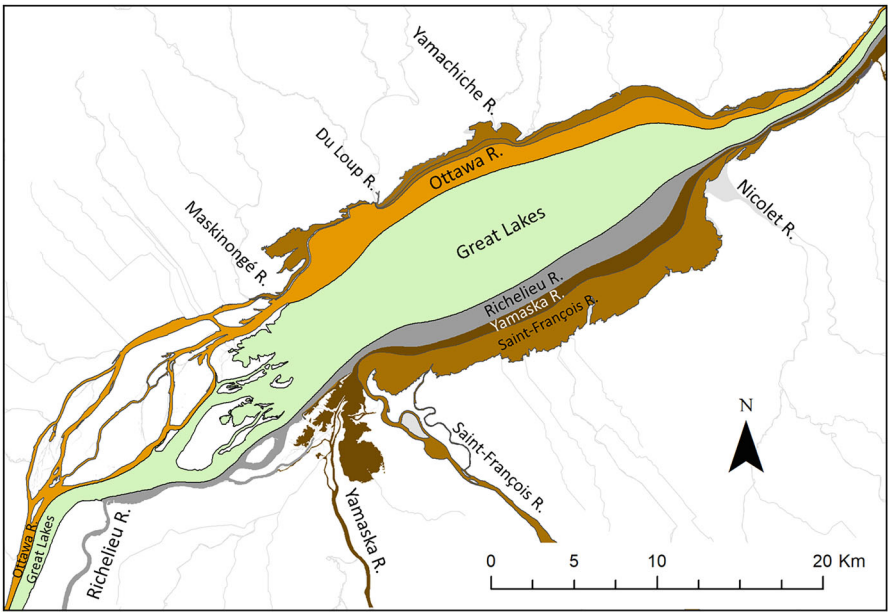

**Fig. 2** The study area is in Lake Saint-Pierre, the largest fluvial lake in the St. Lawrence River, where water quality is strongly influenced by the flow of several tributaries. These tributaries generate contrasting water masses, flowing side by side for tens of kilometers and creating strong horizontal gradients that largely influence aquatic habitats (e.g., abundance of submerged vegetation and fish diversity) and presumably also sound propagation (i.e., suspended particles, temperature, and conductivity). The current water mass simulation corresponds to an average hydrological event during the summer. (Adapted from Martin et al. 2016)

Reserve (UNESCO 2000) for its rich biodiversity and extensive wetlands. It is home to about 100 species of fish, nearly 300 species of resident and migratory birds and about 30 rare plants.

## Main Anthropogenic Pressures

Although the St. Lawrence River is vast and emits an impression of great strength, this does not make it sheltered to pressures of various kinds from human activities in its watershed. On a smaller scale, the UN status of LSP does not protect it from local anthropic pressures.

### Agriculture

Nearly 5000 ha of intensive annual crops are planted directly in the floodplain, destroying a significant area of critical habitats for many species, and diminishing

the production and diversity potential of the lake (Foubert et al. 2020). On a larger scale, land use in the LSP watershed shows intensive agriculture, resulting in high nutrient and contaminant loads and high turbidity.

## Hydrological Alterations

Dams and flow regulation, which have been progressively implemented in the Ottawa River and St. Lawrence River, for more than a century, have reduced the height and duration of floods, altering the natural hydrological regime to which aquatic life had been adapted for centuries (Foubert et al. 2020).

## Fishery Decline

LSP was home to a thriving yellow perch fishery that had to be closed in 2012 and extended until 2027, due to low recruitment and advanced degradation of aquatic habitats (Magnan et al. 2022).

## Anthropogenic Noise

There are acoustic pressures that have never been documented:

- **Commercial ships.** Commercial shipping is concentrated in the shipping channel. Approximately 4800 merchant vessels use the seaway through the LSP throughout the year. In the Montreal-Sorel section of the St. Lawrence River, a voluntary measure to reduce the speed of commercial ships was implemented in the fall of 2000 by the shipping industry to reduce erosion problems. Over a length of nearly 25 km in the Sorel-Varennes sector, this measure encouraged ship pilots not to exceed a speed of 10 knots upstream and 14 knots downstream. This measure is also a good study avenue to reduce ship underwater noise.
- **Harbors.** In the freshwaters of the St. Lawrence River, there are five main harbors (from upstream to downstream): Montreal, Sorel, Trois-Rivières, Bécancour, and Quebec City (Fig. 1). These harbors are central to Canada's internal and external trade. They have different functions and jurisdictions that will not be discussed here. The harbors of Sorel and Trois-Rivières are located at both ends of LSP and represent sources of anthropogenic noise to be assessed.
- **Bridge.** The Laviolette Bridge, located downstream from LSP, is the only bridge connecting the two shores between Montreal and Quebec City and linking the city of Trois-Rivières to Bécancour. It is an arch bridge with the longest steel structure in Quebec (1383 m and maximum deck height of 54 m), supported by large concrete foundations, many of which are in contact with the waters of the St. Lawrence River. With a traffic flow of approximately 42,000 vehicles per day, it represents a source of noise that deserves to be estimated.

- **Recreational boats.** During the summer months, LSP is also heavily visited by hundreds of fishermen and boaters attracted by the landscape beauty. Boaters are heavily concentrated along the slope of the navigation channel throughout LSP, as well as in the many smaller channels throughout the Sorel archipelago. The most intensively frequented locations will be targeted in this study.
- **UXOs removal.** Explosions of UXOs are expected in the next 9 years for public safety reasons. Indeed, between 1952 and 1999, the Canadian Department of National Defense fired over 500,000 rounds into the CYR 606 area, covering almost the entire southern shore of the LSP (16,000 ha; BAPE 2020). It is estimated that nearly 300,000 unexploded projectiles could end up on the bottom of the lake, of which 7880 (~3%) would contain explosive material (0.5–7.0 kg; maximum caliber 155 mm) and must be removed to reduce the risk to public safety. Some will be removed and detonated at a land-based site, those deemed too dangerous to be safely moved out of water will be detonated directly into the lake, hopefully with effective mitigation measures. This large CYR 606 area consists of shallow, highly productive habitats used by ~40 species of fish for spawning and juvenile growth, some of which are threatened. Native mussel beds have also been observed at both ends of LSP.

## Habitat Characteristics in Relation to Acoustics

The St. Lawrence River and more specifically LSP are real open-air laboratories because they present a strong heterogeneity in their aquatic habitats, which make them unique environments for acoustic studies. In addition to spatial heterogeneity, the physical characteristics of LSP also show temporal dynamics with (1) significant seasonal changes in river flow, space occupied by water masses from tributaries, water temperature, and submerged vegetation cover showing cycles of growth and senescence, and (2) also longer-term changes related to climate. All these changes influence the propagation of sound underwater and the exposure of aquatic fauna and their habitats.

### Bathymetry

The LSP is a widening of the St. Lawrence River, 30 km long by 12 km wide, with an average depth of about 3 m (Fig. 1). It consists of a large floodplain that extends toward the center of the lake with a gentle side slope. The center of the lake is occupied by a deep navigation channel 300 m wide and guaranteeing a minimum depth of 11.3 m for commercial ships, which was gradually dug out from the middle of the nineteenth century. The upstream portion of the lake is an ancient delta that formed an archipelago containing 103 islands and numerous small channels rich in biodiversity and used by boaters. The ends narrow rapidly, are deeper, and show fast currents $>1$ $ms^{-1}$.

## Hydrology

The flow of the St. Lawrence River comes mainly from the Great Lakes watershed, but it is largely influenced in the spring by the inflow from tributaries, including the Ottawa River, which amplifies the variability of the hydrological regime. In LSP, the average annual variation in water level is 2 m (Morin and Bouchard 2000), with a spring flood and a low water level during the summer period. In addition to seasonal fluctuations, climatic cycles with a period of 20–35 years also influence the hydrological regime of the St. Lawrence system (precipitation and evaporation), modifying the availability of water for natural and anthropogenic uses and modifying the acoustic configuration of LSP (depth and surface). The digging of the navigation channel was accompanied by the construction of important works along the St. Lawrence River which aimed at raising the water level to facilitate navigation during low water periods and at regulating the flow of the river to avoid the flooding of large urban centers in spring.

## Water Masses and Horizontal Stratification

The many tributaries are producing highly contrasting water masses that can be identified along the river, depending on their origin and their changing physicochemical properties (temperature, conductivity, and turbidity; Fig. 2). Water masses flow side by side with little lateral mixing for hundreds of kilometers (e.g., the clear green water of Lake Ontario, the brown from Ottawa River, and more turbid water from agricultural watersheds), creating strong horizontal gradients that largely influence aquatic habitats (e.g., abundance of submerged vegetation and fish diversity) and presumably also sound propagation (suspended particles, temperature, and conductivity).

## Substrate

Fine substrates such as clay, silt, and sand are dominant at LSP. They are of agricultural origin and transported primarily by tributaries because the LSP central water mass, which originates from the Great Lakes, is very clear. Coarser sediments such as gravels and pebbles are found near the fast-flowing channel, but also compact clay, which dates back to the Champlain Sea 10,000 years ago, and which was dredged during the digging of the channel. Other portions of the navigation channel between Montreal and Quebec City were dug directly in the rock (Fig. 3).

## Submerged Aquatic Vegetation

Until the mid-2000s, LSP bottom was covered by very dense and extensive beds of submerged aquatic vegetation occupying much of the water column. With increasing nutrient, contaminant, and turbidity loads, this submerged aquatic vegetation has greatly declined, either disappearing or being replaced by benthic algae (Giacomazzo

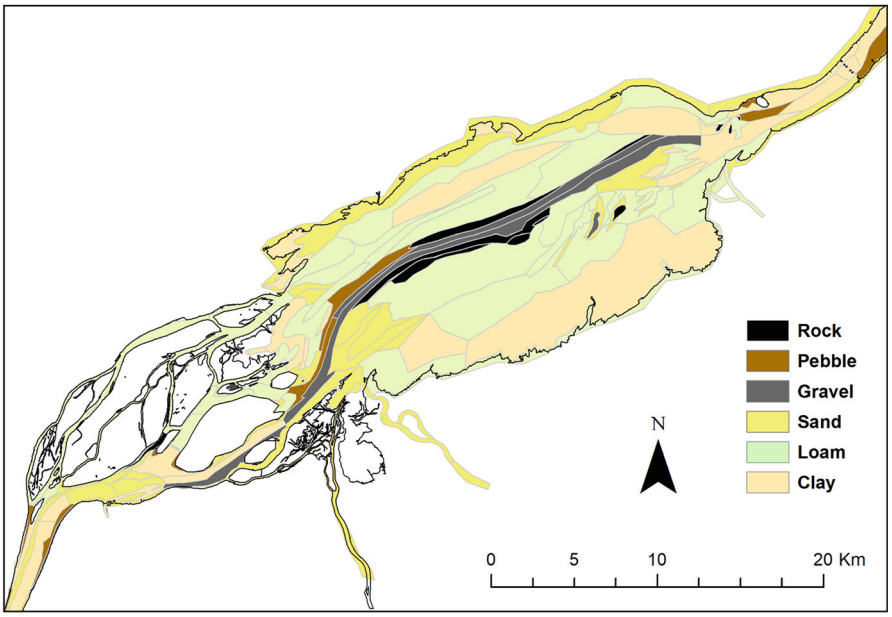

**Fig. 3** Substrate classification based on data from the literature and field campaigns, revealing that Lac Saint-Pierre is dominated by fine substrates such as clay, silt, and sand. The navigation channel is occupied by coarse substrates or has been excavated in clay. (Unpublished data from J. Morin, Environment and Climate Change Canada)

et al. 2023). It is important to consider the remaining vegetation cover as a factor influencing acoustic propagation (Fig. 4) and a potential acoustic refuge for some fish species (Wilson et al. 2013).

## Water Properties and Sound Propagation

Propagation loss in the LSP is defined by (i) the geometric dilution as the sound travels away from a source and (ii) the absorption of the sound waveguide by the surrounding medium. The geometric dilution is range dependent as it depends on the varying geophysical properties of the medium as the sound travels between two points (Collins 1995; Porter 2011). The geometric dilution is linked to the bathymetric profile, the height of the water column, the properties of the substrate, and gradients in speed of sound in the water. While the bathymetry remains the same under natural conditions (i.e., without human intervention), the height of the water column is determined by the hydrological regime (Morin and Bouchard 2000). The nature of the substrate can be expressed in terms of its geoacoustic properties: density and speed of sound in the substrate, shear, and compressional absorption coefficients (Jensen et al. 2011). The computation of the speed of sound in the water is a function of the water's conductivity ($\mho$), temperature ($t$), and depth ($z$) (Leroy et al. 2008). Table 1 presents preliminary results of field expeditions to the SLP

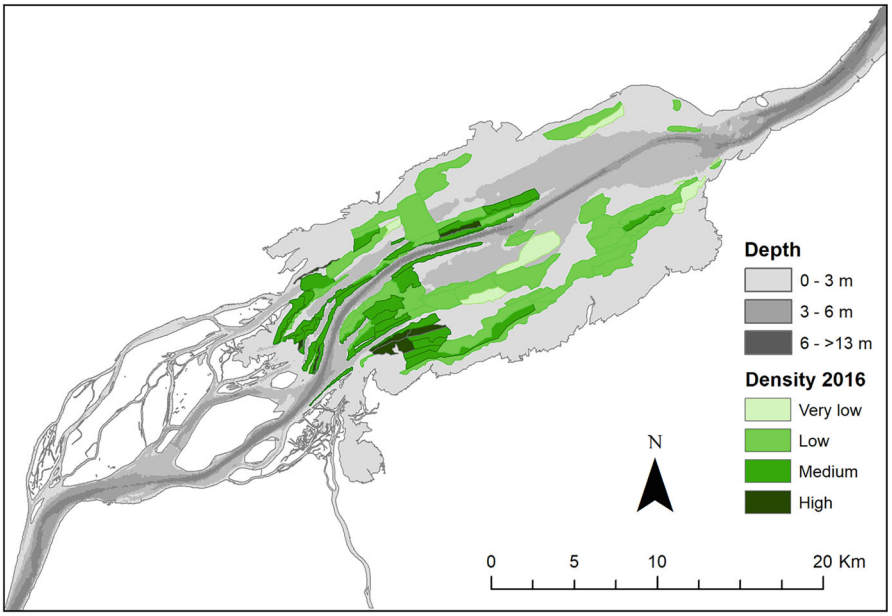

**Fig. 4** Density of submerged aquatic vegetation in 2016. (Adapted from J. Morin, Environment and Climate Change Canada, unpublished data)

**Table 1** Average chemical-physical properties of water ($\pm 1\sigma$)

| Season | $\mho$ | $t$ | $z$ | $S(\mho)$ | $c_w(t,S(\mho),z)$ |
|---|---|---|---|---|---|
| | (mS cm$^{-1}$) | (°C) | (m) | (ppt) | (m s$^{-1}$) |
| Spring | 0.203 ± 0.058 | 16.8 ± 0.9 | 1.705 ± 1.681 | 0.083 ± 0.025 | 1472.2 ± 2.9 |
| Summer | 0.247 ± 0.046 | 23.2 ± 1.2 | 1.226 ± 1.270 | 0.102 ± 0.020 | 1491.8 ± 3.4 |
| Fall | 0.241 ± 0.049 | 3.4 ± 1.1 | 1 | 0.099 ± 0.022 | 1418.9 ± 5.2 |

conducted to characterize the chemicophysical properties of the water from season to season. Spatial coverage extends from the north shore to the south shore.

Absorption by the water medium is caused (i) by boric acids and magnesium sulfate diluted in the water and whose concentrations are monotonically dependent on the water salinity S(℧) (François and Garrison 1982a, b) and (ii) by nondiluted suspended material in the water column due to thermo-viscous and diffusive interactions with the waveguide (Richards 1998). Suspended particles are characterized in concentration ($C_V$) using nephelometric turbidity measurements ($\zeta$) as shown in Table 2.

Absorption by the diluted content is highly dependent on the signal frequency and becomes significant only above 10 kHz. Absorption caused by nondiluted particles depends on their nature (more specifically, their volumetric density). In situ sedimentology and granulometry measurements are expected to take place in 2023 to identify and characterize the nondiluted suspended content in LSP.

**Table 2** Average turbidities of suspended sediments (±1σ)

| Season | $\zeta$ | $C_V(\zeta)$ |
|---|---|---|
| | (NTU) | (kg m$^{-3}$) |
| Spring | 4.835 ± 2.588 | 0.0016 ± 0.0009 |
| Summer | 8.440 ± 3.203 | 0.0028 ± 0.0011 |
| Fall | 5.126 ± 1.332 | 0.0017 ± 0.0004 |

## Fish Species, Habitat Type, and Noise Exposure

Of the 118 freshwater fish species living in Quebec, 79 have been reported in the LSP area by the MELCCFP monitoring campaigns using seines, gillnets, and trawls (1995–2019), of which 22 are sport species, 22 are commercial, and 7 have a precarious status (threatened or vulnerable). Trawl sampling has demonstrated that the navigation channel is not a desert and revealed several significantly different fish assemblages, whose composition is influenced by exposure to ship activities and habitat type (Mingelbier et al. 2019). Lake sturgeon is a dominant species in deep habitats, including the navigation channel, where shorthead redhorse, silver redhorse, channel catfish, and other species with known enhanced hearing sensitivity also occur. Among the deep environments, the pools are the richest in diversity and biomass, compared to the channel and its slope. Habitats exposed to ship activities had the lowest indices of diversity and abundance compared to unexposed environments. Shallow-nearshore habitats supported the most diverse fish communities, but not the greatest biomass, found in natural deep pools. Fish communities differed between the shipping channel and the shallow nearshore, suggesting that fish species are differentially exposed to various sources of noise in LSP, which is an avenue for further research. Depending on the species, it will be important to test whether fish with precarious status are exposed to noise and to explore causal relationships between low-diversity fish communities and noise intensity. Accurate description of noise exposure should help identify areas of higher intensity and acoustic refuges for fish, characterize noise in deeper pools, and potentially link noise to aquatic habitat connectivity, for example, for migrants such as lake sturgeon that primarily use the shipping channel to migrate through the river corridor. In addition, there is a unique opportunity to study the relevance and effects of noise propagated through the substrate, and its interface with the water column, on fish but also on invertebrates (e.g., indigenous mussels). Indeed, it is suggested in the literature that the possibility for noise propagating through the substrate to resurface further away in the water column at unexpected locations (e.g., Dahl et al. 2020). The explosion of UXOs will provide an excellent opportunity to explore such complex behavior and its ecological implications.

## Agenda for Future Research and Conservation

LSP is a UNESCO World Biosphere Reserve that is exposed to multiple anthropogenic pressures, some of which are acoustic pressures of ecological concern that raise several questions. The freshwaters of LSP present a diverse mosaic of habitats,

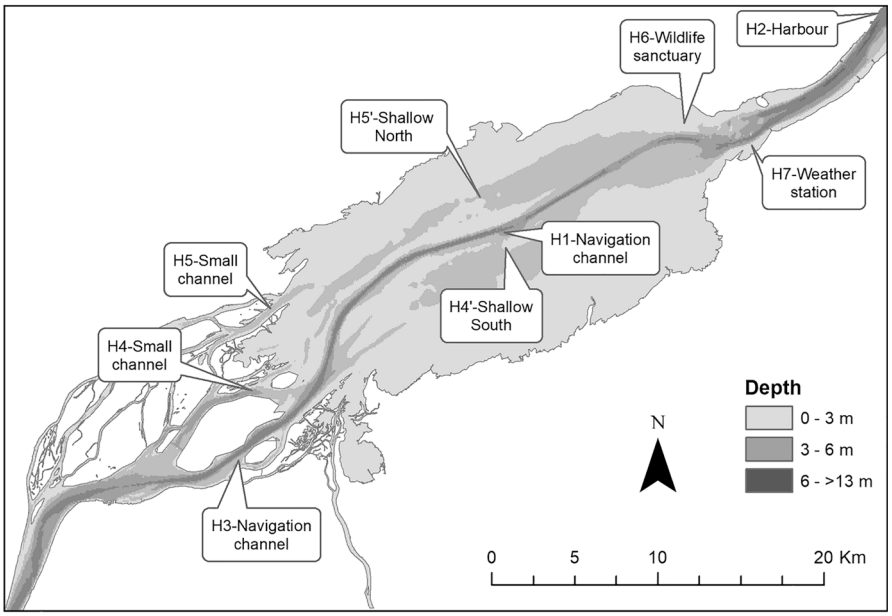

**Fig. 5** Acoustic recording stations during the 2022 season at Lake St. Pierre, showing the variety of environments and noise sources sampled: a harbor (H2), the deep navigation channel (H1 and H3), secondary channels frequented by recreational boats (H4 and H5), a wildlife refuge (H6), shallow environments (H4' and H5'), and near a weather station (H7)

where the soundscape has never been characterized and which, with its unique physical properties, represents a real open-air laboratory. The ongoing academic-departmental collaboration is an excellent opportunity to improve knowledge in the following research avenues (Fig. 5).

## Acoustic Portrait

Preparing an acoustic portrait in the freshwater of the LSP involves quantifying the main sources of anthropogenic noise, which have never been characterized in this area, from different navigation activities (merchant ships, recreational boats, and harbors) and paying particular attention to UXOs explosions. In this large shallow lake exposed to wind, waves, and ice, it would also be relevant to quantify geophony. Regarding biophony, an ongoing literature review on fish acoustic capacity (hearing sensitivity and sound-producing mechanisms) and an evaluation of available information on their generated sound patterns will allow us to assess species-specific vulnerability to anthrophony for the 118 freshwater fishes in Quebec. The plan is to (i) characterize the acoustic activities of a few key species (lake sturgeon and Atlantic sturgeon), by sampling their acoustic signatures in different natural situations (e.g., spawning grounds) and in captivity (e.g., fishermen's nets, aquariums, or

rearing) and (ii) develop a method using artificial intelligence applied to hydrophone recordings to automate the detection of acoustic activities of sturgeon in the St. Lawrence River. Finally, changes in the behavior of several focal fish species will be characterized in relation to changes in the soundscape by using fish positioning data from acoustic telemetry.

## Modeling

In a physical context with so much spatial heterogeneity and temporal changes, it is essential to develop an acoustic propagation model adapted to the situation of LSP to simulate the propagation of the main noise sources across different environmental conditions. This model will consider the physicochemistry, the submerged vegetation, and the substrate, and will be validated with field measurements. It will be useful to compare the exposure of deep and shallow habitats to very different sources of anthropogenic noise. On the one hand, the deep habitats of LSP are exposed to noise from commercial shipping and it would be relevant to verify if this noise propagates into the shallow habitats. Conversely, shallow habitats are exposed to UXO explosions, and it is questionable whether this intense noise propagates into the deeper environments further away from the explosions and whether the more distant mussel beds are exposed to such noise with sound propagation through the substrate.

## Conservation Measures

Based on these results, it will be possible to explore several avenues for conservation measures, including the following.

- **Navigation versus slowdown.** We intend to verify if the voluntary slowing down measure, initially motivated among commercial ships to limit bank erosion, could be applied to reduce the noise of these ships in the most ecologically sensitive sectors. Additional measures could be studied for recreational boats, particularly in the LSP archipelago, which is very busy in summer.
- **Explosions**. UXO explosions are an opportunity to improve knowledge in shallow freshwater and to present a critical analysis of the methods used by the Department of National Defense to estimate the lethal radius for fish species. This will also allow the coproduce mitigation plans and measures to abate the effects on aquatic fauna (e.g., bubble curtains). It will at the same time provide an opportunity to experiment with some of the effects of particle movement on fish and invertebrates, establish (long-needed) conservation thresholds regarding this parameter, and provide potential mitigation recommendations and guidance in this context.
- **Risk analysis.** Acoustic risk mapping for aquatic wildlife in Lake Saint-Pierre will be produced by combining the acoustic sensitivity of aquatic wildlife with

their exposure in various habitats. This will provide an opportunity to georeference sound levels, acoustically polluted environments, and to identify potential acoustic refuges. Recommendations for mitigation measures may be proposed regarding the most important anthropogenic noise sources.

The successful completion of this research and conservation agenda will rely not only on strong interdisciplinary scientific collaborations but also on the active participation of all stakeholders from both the public and private sectors.

activity. Here a soundscape study was conducted to understand the changing sound levels on the Southern California Antisubmarine Warfare Range during a deepwater ocean mapping survey using a 12 kHz Kongsberg EM 122 multibeam echo sounder. The exercise confirmed the expected temporal and spatial dependence of the mapping survey activity contribution to the soundscape. The change in sound levels was closely tied to a narrow angular sector around the mobile survey vessel, which meant the temporal impact at any given location was also confined to a brief time period that the vessel was in the corresponding area. The EM 122 signal was detectable above baseline sound levels in the acoustic records only when the survey vessel was within 17 km of the hydrophone receiver and was clearly and consistently associated with changes in the 12.5 kHz decidecade spectral density levels. The results provide important context for simultaneous works assessing beaked whale foraging behavior during the mapping survey, where no adverse change in foraging behavior was found.

## Introduction

In the context of anthropogenic noise and marine life, soundscape studies can provide insight into how, and the extent to which, an acoustic environment has changed due to anthropogenic noise-generating activity. When possible, baseline assessments are made prior to the activity of interest to provide a foundation upon which to assess the extent of change beyond expected natural variation. Soundscape studies are imperative for providing context to our understanding of the interplay between anthropogenic noise-generating activity, natural variability within the ecosystem, and marine life behavior.

The goal of the work in this chapter was to understand how the acoustic activity of a 12 kHz deepwater mapping survey impacted the overall marine soundscape of the Southern California Antisubmarine Warfare Range (SOAR). The motivation for this was two-fold. While modeling efforts (Lurton and DeRuiter 2011; Lurton 2016) show that the Kongsberg EM 122 multibeam echo sounder – the primary system used in the mapping survey discussed herein – should be below the currently accepted injury thresholds for marine mammals, a thorough assessment of its impact on the marine acoustic environment during typical operations had not been undertaken prior to the work in this chapter. Thus, the first motivation was to provide empirical observations of the spatial and temporal frequency-dependent impact on the marine soundscape of the acoustic sources (vessel sound and active acoustic sources) associated with a typical deepwater multibeam mapping survey. The second motivation for understanding the impact of the mapping survey on the acoustic environment was to provide context for parallel marine mammal behavior impact studies conducted during the same mapping survey (Kates Varghese et al. 2020, 2021).

Multibeam echo sounders (MBES) were developed to provide detailed maps of the seafloor. The original MBES utilized the natural radiation pattern of a long thin transmitting array to generate a narrow, angularly constrained swath of sound that propagates to the seafloor – wide across-ship, but narrow along-ship. Present-day systems have undergone significant technological advancement in electronic and beamforming capabilities, resulting in multi-swath and multi-sector capabilities which significantly increase the insonification capacities but also greatly complicate the transmission pattern. The active component of a MBES ping cycle is comprised of a train of short independent pulses with non-overlapping, narrow bandwidths. Each pulse in the ping corresponds to a specific sector in a given swath. State-of-the-art multibeam systems can be dynamically operated under various permutations of several operating modes: (1) single/dual swath, (2) auto-ping mode/manually selected mode, (3) depth-specified modes, (4) with/without motion compensation, (5) various angular swath widths, (6) gated continuous-wave (CW)/frequency-modulated (FM) pulses, among other options which may further complicate the radiation pattern (note: features 2 and 5 (The setting of the swath width on EM122 (when changing modes) may correspond to various angular coverage (narrowing in very-extra-deep modes) hence a change in the radiation characteristics.) will not impact the sound radiation characteristics) (Kates Varghese et al. 2019). Most of these parameters are dictated by the survey requirements and the operating environment. Dual swath coverage enables the user to obtain a higher density of pings in a fixed area, which can be important for the quality of data required for a survey and/or for the survey speed. Similarly, the use of various swath widths and motion compensation capabilities allow the user to adapt to rough seas and various survey speeds while ensuring quality data collection. Essentially the options available with state-of-the-art multibeam allow the user to adapt to dynamic conditions in a variety of ways. Therefore, the exact signal transmitted may vary from one survey to the next (Kates Varghese et al. 2019) and the ensonified area will be a function of the water depth, achievable swath width, firing mode, and applied motion compensation parameters.

The Kongsberg EM 122 deepwater MBES operates using either single or dual swath mode with 4–8 sectors per swath. The EM 122 can be manually or automatically set to different depth-dependent operational modes implying, as depth increases, higher source levels, longer pulse lengths, more sectors in a narrower angular coverage, and frequency-modulated pulses at deeper depths. Pulse lengths may vary from 3 ms (CW) in the shallowest depths (i.e., <450 m water) to 100 ms (FM) in very deepwater (i.e., up to 11,000 m). A typical deepwater survey (i.e., deep mode is defined as 1000–2600 m depth) operates in dual swath mode with eight sectors, each with pulse durations of 8–15 ms and inter-ping intervals of about 5–10 s.

## Methods

A deepwater ocean mapping survey was conducted over an approximately three-day time period at the SOAR. In order to characterize the marine soundscape modifications caused by the survey, several sound level metrics were computed and compared across time and space. The SOAR consists of a hydrophone array which spans

an approximately 1800 $km^2$ area and contains a subset of 89 bottom-mounted hydrophones. Acoustic data from all 89 hydrophones were collected from January 4, 2017, 20:13 until January 7, 2017, 06:55 UTC, which spanned a time period before, during, and after a deepwater MBES mapping survey of the SOAR. A subset of the acoustic data was used for characterizing the marine soundscape before and during the survey.

The bottom-mounted (~5 m above the seafloor) omnidirectional hydrophones are at depths from 850 to 1750 meters, have a roughly flat sensitivity response between 50 Hz and 48 kHz, and are sampled at a rate of 96 kHz (Smith 2019). Acoustic data from nine hydrophones were used in the work in this chapter. The raw acoustic data were extracted at a duty cycle of 5 min on/10 min off to reduce time and memory during processing. The acoustic data were then converted to various broadband and band-specific sound level metrics, including:

- Peak sound pressure levels (*SPLpk*), identifying the maximum pressure amplitude in a given time window and measured in units of dB re 1 μPa
- Sound exposure levels (*SEL*), measuring all of the energy within a specific (100 ms) time window, reported in units of dB re 1 $\mu Pa^2$ s
- Decidecade band levels (*BL*) with center frequencies between 50 Hz and 40 kHz, representing the mean square sound pressure spectral density level in each decidecade, or one-tenth of a decade band (ISO 18405), reported in units of dB re 1 $\mu Pa^2$/Hz

The *BL*s were chosen to directly align with the Atlantic Deepwater Ecosystem Observatory Network (ADEON) project (Ainslie et al. 2017). But, as no formal standard exists yet for computing and reporting broadband quantities, a decision was made to maximize the spectral observations available with this data set. Consequently, broadband was defined here as the 30 bands inclusive of the 50 Hz through 40 kHz center frequency decidecade bands (i.e., $n = -13$ to 16, Ainslie et al. 2017). A 100-ms time window was used to produce the sound level metric time series, selected because of its relevance to the duration of the MBES signals (typical magnitude of 10 ms). Sound levels weighted with the NMFS mid-frequency cetacean weighting function (2018) were also produced, but are not discussed further here. The interested reader is referred to Kates Varghese 2021 for details on that portion of the work.

Sound level metric time series were generated and partitioned into four analysis periods based on the anthropogenic activities that occurred during the overall time period examined. These analysis periods were defined as:

- No Activity (NA) – a time immediately preceding the mapping survey when no activity related to the mapping survey was occurring on the SOAR array;
- Vessel Only (VO) – a period when only the survey vessel was known to be on the array and all active acoustic systems related to mapping were off;
- Vessel and MBES (VM) – a period which included the presence of the survey vessel and the active EM 122 MBES on the SOAR array;

- Mixed Acoustics (MA) – a period that included the survey vessel on the array with transmitting Kongsberg EM 122, Kongsberg EM 712 MBES (40 kHz), Simrad EK 80 wide-band echo sounder (18 kHz), and a Knudsen sub-bottom profiler (3.5 kHz) at various times during this period.

Note: Due to the sporadic and intermittent use of the various active acoustic systems during the MA period, the ability to characterize the impact of the other active acoustic systems (excluding the EM 122) on the marine acoustic environment was limited and therefore is not further discussed here. The interested reader is referred to Kates Varghese (2021) for the results from this analysis period.

Aside from the known active acoustic sources used during the mapping survey, there were most certainly other acoustic sounds incidentally recorded on the array hydrophones. These may have included sounds inherent with the safe operation of the research vessel, radiated noise from other vessels and anthropogenic activity near the array, and/or biological, mechanical, or geophysical activity. There was no way of excluding other potential sound sources from the soundscape assessment of the survey activity. The presence of other sounds – anthropogenic or natural – is a reasonable expectation for the SOAR soundscape. It is worth noting that the survey took place during the first week of January when activity at the SOAR was very limited, if at all.

A purposeful selection of the *BL*s was chosen for more detailed analysis, representing specific acoustic sources expected to contribute to the SOAR soundscape. These were the *BL*s with center frequencies of 50 Hz, 500 Hz, 3.2 kHz, 12.5 kHz, and 40 kHz. The 12.5 kHz band (11.2–14.1 kHz) was selected because it encompasses the majority of the frequency content of the EM 122 MBES signal (11–13.25 kHz). This band may also be occupied by biological sounds, such as those from vocalizing marine mammals. The 40 kHz band (35.5–44.7 kHz) was chosen as it contains the peak frequency of beaked whale foraging clicks (Baumann-Pickering et al. 2013). (Note: It also contains the signal of the EM 712 echo sounder used during the MA period of the mapping survey (40 kHz).) The 50 Hz (44.7–56.2 Hz), 500 Hz (447–562 Hz), and 3.2 kHz (2.8–3.5 kHz) bands were chosen as they each represent a distinct regime of the low-frequency signals that often dominate a marine soundscape. The 50 Hz band represents vessel engine sound, the sound from propellers, as well as the low-frequency harmonics of these sources (Hildebrand 2009). The 500 Hz band includes other ship-radiated sound, as well as other natural and ambient sources such as marine mammals that communicate at low frequencies (Wenz 1962). The 3.2 kHz band was selected because it can contain higher frequency radiated vessel noise. (Note: it was also selected because it would contain significant energy from the sub-bottom profiler, nominal frequency of 3.5 kHz, used during the MA period. Reader is again referred to Kates Varghese 2021 for details pertinent to the MA period.)

A subset of nine hydrophones – numbers 14, 16, 19, 22, 45, 57, 63, 70, and 85 – were selected to provide a representative spatial coverage of the array, while avoiding peripheral (or edge) hydrophones (Fig. 1). There was roughly a 5–15 km horizontal distance between any two adjacent hydrophones examined.

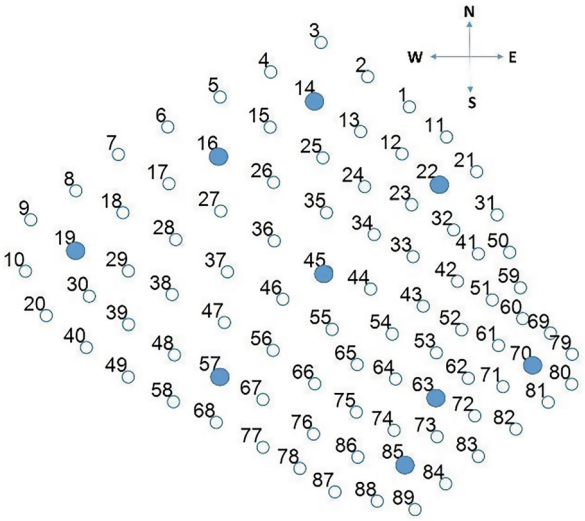

**Fig. 1** SOAR hydrophone array layout and the nine hydrophones examined in the work in this chapter (blue filled circles)

In order to understand how the MBES mapping survey impacted the local soundscape, the sound level metric time series, along with several spatio-temporal-spectral plots and animations, and sound files were reviewed to identify, describe, and characterize acoustic events in the SOAR during each of the analysis periods. In addition, the oblique range of the survey vessel to each hydrophone, and the expected transmission loss in the select frequency bands examined at those same ranges (based coarsely on spherical spreading loss and frequency-specific attenuation) were plotted along with the sound level metric time series, all at the same time resolution to aid in the interpretation of the source of the acoustic events with respect to the mapping activity. This was done for each of the nine selected hydrophones.

In addition to generating the sound level time series, sound level percentiles, i.e., 1, 5, 10, 25, 50, 75, 90, 95, and 99th, were computed for the following sound level metrics: *SPLpk*, *SEL*, 50 Hz, 12.5 kHz, 40 kHz *BL* for each analysis period and used to inform and focus the review of the acoustic activities in the data set. To facilitate the review, an acoustic event was defined *a priori* as a period in the *SPLpk* time series when the 95th percentile, for a given analysis period, was exceeded. The *SPLpk* time series had to return to or below baseline conditions – defined here as the 50th percentile of the *SPLpk* metric for a given analysis period – before a separate acoustic event was defined in the time series. Acoustic events were described by the maximum *SPLpk* value during an acoustic event. Changes in the other sound level metrics are discussed with respect to the 50th percentile level for the same metric and analysis period. The 50th percentile level for a given metric in a given analysis period is considered as, and referred to throughout this report, as the baseline sound level. For those *BL* metrics where the percentiles were not calculated, maximum changes in the sound levels during an acoustic event are discussed relative to a local baseline sound level, defined here as the approximate static sound level value for a given metric before and/or after an acoustic event.

Because of its location in the center of the SOAR and its proximity to repetitive passes of the survey vessel during the mapping survey, the review of the hydrophone 45 (see Fig. 1 for location) acoustic events is presented here as a representative example to aid in the discussion of the changing sound levels on the SOAR array. The intensive approach used for hydrophone 45 was modified based on the findings of this initial analysis for the other eight hydrophones. Details of that process and the results from the other eight hydrophones are freely available to the interested reader in Chap. 5 and associated appendices of Kates Varghese (2021).

## Results and Discussion

The No Activity (NA) period was based on the period of time prior to the survey vessel's presence on the SOAR array for which acoustic data could be obtained. This was an approximately 3 h and 40 min period from 1/4/17 20:13 to 23:51 UTC (note: all times are presented in UTC).

The Vessel Only (VO) period, which began 1/4/17 23:51 and ran until 1/5/17 08:16 for a total of 8 h 25 min, consisted of two vessel survey tracks across the hydrophone array from the south center edge to the north center edge of the array and back to the south. The ship's speed was approximately 10 knots throughout this period. All active acoustic sources were off. The track lines of the VO period are shown in blue in Fig. 2.

The VM period consisted of the primary mapping survey utilizing the hull-mounted Kongsberg EM 122, a MBES with a 12-kHz center frequency and source level of 239–242 dB re 1 μPa m. The VM period began at the end of the VO period on 1/5/17 at 08:16, and ran until 1/6/17 13:48, for a total of 29 h 32 min. The survey was conducted as a typical mapping survey for the water depths in the SOAR area, using a "mow-the-lawn" pattern (Fig. 2, red lines) with the EM 122 in deep, dual swath mode and CW pulses only. The survey was conducted in a calm sea state with

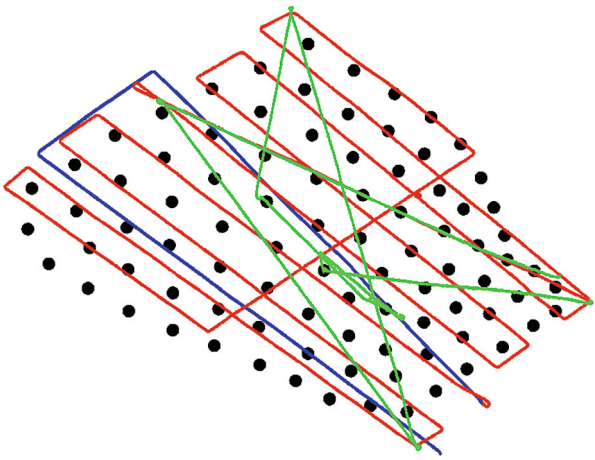

**Fig. 2** Track lines of the vessel during the analysis periods containing anthropogenic activity: blue lines correspond to the VO period, red to the VM period, and green to the MA period. (Discussed further in Kates Varghese 2021)

0.3–0.6 m (1–2 feet) swells. The vessel's survey speed was 10 knots except during turns when the speed was dropped to 5 knots.

Examples of the spectral probability density (SPD) animations (spectral-temporal-spatial animation_hydro45.pptx), and array-wide spatial animations iterating through the one-minute broadband and select decidecade band levels (array_wide_sound_levels.pptx, Smith et al. 2021), were used to inform the acoustic data set review are provided in the supplementary materials. The spectrograms for each of the events can be found in Chap. 5 of Kates Varghese (2021) and associated appendices.

Acoustic events in the hydrophone 45 dataset were triggered if the 95th percentile *SPLpk* threshold of each analysis period, listed in Table 1, were exceeded. Where possible, the maximum changes in the sound level metrics associated with an acoustic event were discussed with respect to the baseline sound level, i.e., the 50th percentile level, if calculated for a given metric (Table 1), or relative to the local baseline – the approximate static sound level for a given metric before and/or after an acoustic event (Table 2).

The detailed review of the acoustic time series data from the nine hydrophones on the SOAR provided useful insight about how the various anthropogenic activities related to the mapping survey contributed to the sound levels of the local soundscape. It also provided awareness about other sound sources present in the acoustic data that could not be linked to activity on the SOAR. The review of hydrophone 45, in particular, provided a representative example of the expected and unexpected changes in sound levels observed across the array. For example, during the NA and VO periods, there were epochs of low-frequency sound present in the hydrophone 45 data set, which was also identified in the larger review across all 9 hydrophones (see spl_peak_1min_viridis.mp4 animation in Supplementary). There were also instances where vessels, other than the survey vessel, passed nearby the array boundaries. These events were routinely detected on the northern and western edge hydrophones which was consistent with standard vessel traffic routes around the SOAR. There was also salient biological activity interspersed throughout the acoustic data on all of the hydrophones, which was particularly prominent in the changing 12.5 kHz and 40 kHz band levels. And finally, there were several unknown

**Table 1** Percentile values (dB re 1 μPa) for each analysis period used for annotating the sound level time series on hydrophone 45. *SPLpk* values given are in units of dB re 1 μPa, *BL* values given are in dB re 1 $\mu Pa^2$/Hz

| | Percentile value | | |
|---|---|---|---|
| Percentile | NA | VO | VM |
| *SPLpk* 50th (baseline) | 101 | 99 | 103 |
| *SPLpk* 95th (threshold for triggering an acoustic event) | 111 | 113 | 112 |
| 50 Hz *BL* 50th (baseline) | 68 | 60 | 55 |
| 12.5 kHz *BL* 50th (baseline) | 19 | 21 | 31 |
| 40 kHz *BL* 50th (baseline) | 13 | 14 | 16 |

**Table 2** Summary table of the acoustic events identified on hydrophone 45 during the study period, by analysis period. Table includes associated acoustic event number which corresponds with acoustic events annotated in Fig. 3, a description of the acoustic event and most prominent spectral changes, the distance of the survey vessel to hydrophone 45, and the most likely sound source, if identifiable. The asterisk in value 138* demarcates acoustic events during which a portion of the received signal was clipped due to limitations in the dynamic range of the hydrophone receiver (i.e., only sounds of 138 dB re 1 μPa or less were able to be fully captured)

| Analysis period | Acoustic event # | Acoustic event *SPLpk* maxima (dB re 1 μPa) | Context/spectral description | Oblique distance (km) of survey vessel to hydro 45 at maxima in acoustic event | Likely source |
|---|---|---|---|---|---|
| NA | 1 | 116 | Array-wide phenomenon; spectral energy greatest at very low frequencies (10's of Hz) | >30 | Another passing vessel |
| | 2 | 113 | Isolated to the western edge of the array; spectral energy greatest at very low frequencies (10's of Hz) | >30 | Another passing vessel |
| VO | 3 | 116 | array-wide phenomenon; spectral energy greatest at 5 kHz and below, tonal bands at 400 Hz, 1.2 kHz and 5 kHz | >20 | Uncertain |
| | 4 | 125 | Clear increase in all *BLs* starting when vessel was ~15 km away, clear decrease in *BLs* until vessel was again 15 km away; 50 Hz band increased by 26 dB; 40 kHz band increased by 8 dB | <2 | Survey vessel radiated sound |
| VM | 5 | 129 | Correlated with peak in 40 kHz band | 15 | Beaked whale foraging clicks |
| | 6 | 138* | corresponds with survey vessel transiting from the south to the north by hydrophone 45; sound levels were 25–35 dB | 5.3 | Survey vessel and MBES |

(continued)

**Table 2** (continued)

| Analysis period | Acoustic event # | Acoustic event *SPLpk* maxima (dB re 1 μPa) | Context/spectral description | Oblique distance (km) of survey vessel to hydro 45 at maxima in acoustic event | Likely source |
|---|---|---|---|---|---|
| | | | over baseline for the 12.5 kHz, 40 kHz, *SEL*, and *SPLpk* metrics; peak in 12.5 kHz band 33 dB over baseline | | |
| VM | 7 | 114 | Correlated with peak in 40 kHz band | >20 | Biological clicks |
| | 8 | 120 | Correlated with peak in 12.5 kHz band; 12.5 kHz band 15 dB over baseline | 10 | Survey vessel and MBES |
| | 9 | 114 | Very loud low frequency (50 Hz) noise, occurring every 20 s for about 1 s | >30 | Uncertain |
| | 10 | 115 | Elevated levels between 50–100 Hz; peak in 12.5 kHz band 7 dB above baseline | 14 | Vessel and MBES |
| | 11 | 133 | Low-frequency signal; short regularly spaced pulses in 40 kHz band | >25 | Another vessel? biological activity? |
| | 12 | 135 | Survey vessel passing from west to east by the hydrophone; peak in 12.5 kHz band 33 dB above baseline | 3.5 | Vessel and MBES |
| | 13 | 121 | Peak in 12.5 kHz band 12 dB above baseline | 12.5 | Vessel and MBES |
| | 14 | 123 | Peak in 12.5 kHz band 17 dB above baseline | 9.3 | Vessel and MBES |
| | 15 | 138* | Peak in 12.5 kHz band 33 dB above baseline; also peaks in the 50 Hz and 40 kHz band (i.e., local increases of 12–45 dB), with a visible increase in the other bands (i.e., local increases of 3–12 dB) | 4.7 | Vessel and MBES |

(continued)

**Table 2** (continued)

| Analysis period | Acoustic event # | Acoustic event *SPLpk* maxima (dB re 1 μPa) | Context/spectral description | Oblique distance (km) of survey vessel to hydro 45 at maxima in acoustic event | Likely source |
|---|---|---|---|---|---|
| VM | 16 | 138* | Peak in 12.5 kHz band 42 dB above baseline; also peaks in the 50 Hz and 40 kHz band (i.e., local increases of 12–45 dB), with a visible increase in the other bands (i.e., local increases of 3–12 dB) | 1.6 | Vessel and MBES |
| | 17 | 138* | Peak in 12.5 kHz band 35 dB above baseline; also peaks in the 50 Hz and 40 kHz band (i.e., local increases of 12–45 dB), with a visible increase in the other bands (i.e., local increases of 3–12 dB) | 5.7 | Vessel and MBES biological clicks? |
| | 18 | 132 | Marine mammal clicks centered around 40 kHz, as well as a longer, louder, and more irregular signal around 50 Hz; correlated with peaks in the 50 Hz and 40 kHz bands | 9 | Biological clicks |
| | 19 | 131 | Marine mammal clicks centered around 40 kHz, as well as a longer, louder, and more irregular signal around 50 Hz; correlated with peaks in the 50 Hz and 40 kHz bands | 24 | Biological clicks |

sources and signals identified, some of which were as loud as some of the closest passes of the survey vessel to the hydrophones.

The NA period, during which the survey vessel was not on the array, was meant to provide information about the background SOAR soundscape and variability without anthropogenic acoustic activity. There were several events on many of the hydrophones that indicated closely passing vessels, i.e., anthropogenic activity not

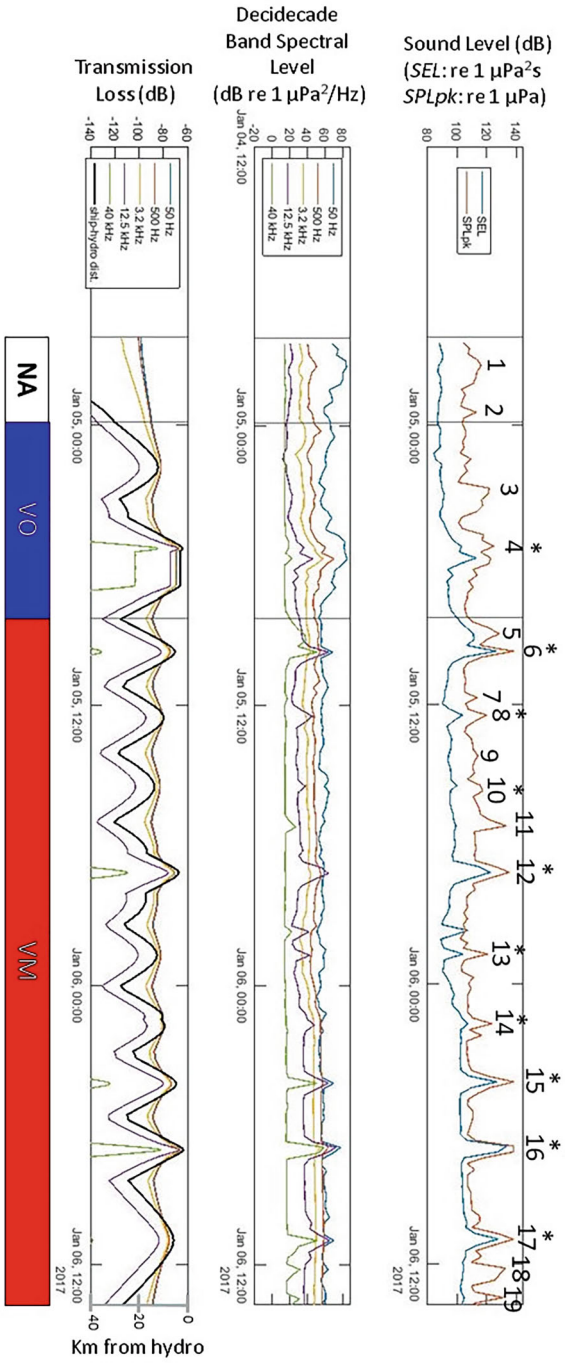

**Fig. 3** Sound level time series for hydrophone 45, data smoothed over 5-min window for ease in viewing. Time along the x-axis begins with the start of the NA period and runs to the end of the VM period. Top plot: Broadband sound level time series: *SEL* (blue), *SPLpk* (orange). Numbers correspond with the acoustic events identified. Asterisks indicate that the acoustic event was most likely attributed to the survey activity. Vertical lines on all graphs delineate the time periods of the three analysis periods, NA, VO, VM, also shown at the bottom of the figure, respectively. Middle plot: Select *BL* time series: 50 Hz (blue), 500 Hz (orange), 3.2 kHz (yellow), 12.5 kHz (purple), and 40 kHz (green). Bottom plot: The vessel's oblique distance from hydrophone 45 in kilometers (black line, right axis), and time series of modeled frequency-specific transmission loss from a hypothetical source if it were the same distance from hydrophone 45 as the vessel at that respective time (left axis). Color of frequency-specific transmission loss corresponds to the colors of frequencies described for the middle plot

related to the ocean mapping survey, during this period. It was also expected that this period would be stable and quiet in comparison to the other periods. However, there was a high amplitude, low frequency (visible in 50 Hz band) signal detected across the entire array over much of the NA period. Because the assumptions about this period were not met, a comparison of the NA period with the other analysis periods with these attributes in mind may be misleading. The assumption that the NA period was not influenced by substantial anthropogenic activity appeared to hold better for some hydrophones (i.e., 22, 45, 63, 57, and 70; closer to San Clemente Island and farther from the typical vessel traffic corridors) in comparison to the others. Ultimately, the characterization of the NA periods on each hydrophone and comparison to the periods with survey activity provided understanding of what the added input of a mapping survey would be on top of the typical ambient SOAR soundscape variability.

The close passes of the survey vessel alone had a very characteristic sound level signature indicative of ship-radiated sound, i.e., elevated levels across a broad range of frequencies. A spectral analysis of the specific signature of *R/V Sally Ride* in comparison to other vessels present in the acoustic data was not made. When the survey vessel alone was within 3 km of a hydrophone, the peaks in the 50 Hz, 500 Hz, 3.2 kHz, and 12.5 kHz bands were all about 15-26 dB over their respective local baselines, and this was similar for *SPLpk*. (Note: Event 4 on hydrophone 45 occurred when the survey vessel was within 2 km and was characterized by maximum increases in *SPLpk* and the 50 Hz band of 26 dB. There were local maximum increases of 8–23 dB in the other select decidecade bands.) Beyond 10 km, it was difficult to distinguish just the survey vessel in the sound level time series, and there were few instances to reliably characterize the sound levels at more intermediate distances.

A comparison between the VO and VM periods provides insight as to how the sound levels were influenced by vessel only related sound versus vessel sound plus multibeam signals. The two activities had different and distinguishable sound level signatures. For example, events 4 and 16 on hydrophone 45 represented the closest approach of the survey vessel during the VO and VM periods, respectively. In the VO period, the elevated sound levels in the five select decidecade *BL*s scaled similarly (i.e., the increase in levels parallel each other), whereas in the VM period, the close approach of the vessel and the actively transmitting EM 122 manifested as strong peaks in the high frequency bands (i.e., 12.5 kHz and 40 kHz) which surpassed the peaks in the lower frequency bands (i.e., 3.2 kHz and 500 Hz) (see Fig. 3, events 4 and 16). The 12.5 kHz and the 50 Hz bands were similarly loud. The peak in the 12.5 kHz band matches expectation since the EM 122 signal is a known sound source in this band. The energy in the 50 Hz band was most certainly driven by vessel-radiated noise.

The peak in the 40 kHz band was likely a measurement artifact related to the times when the EM 122 signal was clipped at the receiver and occurs only when the survey vessel comes within close range of the hydrophone. Because this is a likely measurement artifact, it is difficult to distinguish real signal content from aliased signal content due to clipping. Harmonics related to the EM 122 transmissions are possible due to harmonic distortion caused by the transducer, but are typically observed about 30 dB less than the fundamental frequency (as shown by dedicated

source transmission recordings (Smith 2019)). So although some energy from harmonics may be present, in this case, they cannot be separated from the clipping-related artifact, and are most certainly only a small contribution to the elevated 40 kHz band observed here. Moreover, source-generated harmonics at 40 kHz should attenuate much faster with range than the fundamental 12.5 kHz signal, and thus would only be detected at very short distances from the source. On the other hand, receiver-generated harmonic tones caused by clipping have intensity levels with magnitudes comparable to the signal's fundamental frequency, making them very likely to dominate over the source-generated harmonics.

With regard to the changes in the sound levels during the VM period, clipped peaks in *SPLpk* (i.e., at 138 dB re 1 μPa) were observed when the EM 122 was in use 6 km away or less from the hydrophones. These events had corresponding peaks in the 12.5 kHz band of 50–75 dB re 1 $\mu Pa^2$/Hz that were 19–42 dB over baseline, while the 40 kHz band was elevated by a similar magnitude (Note: hydrophone 45 was characterized by maximum increases of 25–35 dB in the 12.5 kHz and *SPLpk* metrics). The lower select decidecade *BL*s (50 Hz, 500 Hz, 3.2 kHz) were generally 10–15 dB over local baselines when the vessel was at close distances to the hydrophone (i.e., <6 km). When at distances of 6–10 km, peaks in *SPLpk* ranged between 107 and 127 dB re 1 μPa and the 12.5 kHz peaks were 30–54 dB re 1 $\mu Pa^2$/Hz, or 6–23 dB over baseline (Note: hydrophone 45 was characterized by increases of 15–20 dB over baseline in the 12.5 kHz band and *SPLpk* metrics). At this range, the other decidecade *BL*s were only elevated by about 3–6 dB, and there was no longer a similar magnitude peak in the 40 kHz band which is consistent with the observed absence of clipping (though some events may have elevated levels in the 40 kHz band because there were biological clicks present at the same time). Distinguishable peaks in the 12.5 kHz band time series that were clearly associated with the vessel and EM 122 activity were identified up to distances of 13.5–17 km (although EM 122 pulses were faintly visible in a few spectrograms out to 20 km). Within this range, *SPLpk* varied from 107 to 134 dB re 1 μPa with peaks in the 12.5 kHz band of 35–44 dB re 1 $\mu Pa^2$/Hz, or 2–14 dB over baseline (Note: for hydrophone 45, maximum increases in *SPLpk* and the 12.5 kHz *BL* were 7–12 dB over baseline). And fluctuations in the other select decidecade bands were less than 3 dB. However, at this range, the maxima in *SPLpk* could no longer be exclusively attributable to survey activity.

Undoubtedly, orientation of the vessel to the hydrophone also plays a major role in received sound levels since the main transmission beam of the MBES is strongly directional (1° aperture), downward-propagating, fan-like and oriented perpendicularly to the ship's axis. This likely accounts for many inconsistencies to the generalized patterns identified here based on a range-only explanation. Not only is the transmission directional, but there are multiple lobes that make up the transmission pattern. The main lobe of the transmission is by far the loudest and is generally directed vertically toward the seafloor, whereas side lobes are transmitted at oblique angles to vertical and are typically on the order of 20–30 dB lower than the main lobe. Thus, some of the variability in the detection of the EM 122 signal in the sound level time series was related to (1) the orientation of the survey vessel as it approached and/or departed the

hydrophone, and (2) whether the hydrophone was exposed to the main transmission beam, or to a side lobe. Nonetheless, no EM 122 signal could be discerned beyond a range of 17 km.

Although other signals and periods of elevated levels from non-survey activity could be detected on the hydrophones, the survey activity was by far the most common and salient source of acoustic events identified during the study period. The survey vessel alone was detected on seven of the nine hydrophones examined (not on hydrophones 14 or 70), and discernible for 1 (hydrophones 63 and 85) to 3.5 h (hydrophone 45) of the VO period. The survey activity during the VM period was intermittently discernable in the sound level time series for 7 h and 22 min hours on average, ranging from as few as 5 h (hydrophone 19) to at most 11 h and 45 min (hydrophone 45).

It is worth noting that the impact of the same mapping survey discussed herein was also examined with respect to the spatio-temporal foraging behavior of Cuvier's beaked whales (*Ziphius cavirostris*) at the SOAR in Kates Varghese et al. (2020, 2021). The results of those studies clearly showed that the mapping survey did not adversely affect Cuvier's beaked whale foraging. Animals stayed on the SOAR and continued to forage during the mapping survey in 2017, as well as during a second mapping survey with the EM 122 carried out in 2019. The characterization of the sound levels during the 2017 mapping survey as presented herein provides important context to those whale behavior observation works. Despite high sound levels transmitted by the MBES, no adverse changes were observed in a critical life behavior of a species that has been previously shown to be adversely affected in a very significant way by other sonar sources with significantly wider transmission lobes and longer signals (McCarthy et al. 2011; Manzano-Roth et al. 2016). The findings by Kates Varghese et al. (2020, 2021) are corroborated by the results presented here: the ensonification by the MBES mapping activity is confined to a limited space (defined by a narrow angular sector for the main beam and widespread sidelobes at lower levels) around the mobile survey vessel and thus can only have a transient effect on any single location; this is still reinforced by the low values of the signal durations and ping rates.

## Conclusion

This time series review proved to be an essential step for understanding the complex acoustic data obtained from recording a deepwater MBES mapping survey on an array of bottom-mounted hydrophones. Despite the limitations raised by the signal clipping upon reception, the exercise confirmed the expected temporal and spatial dependence of the survey activity contribution to the soundscape. The change in sound levels was closely tied to the specific radiation pattern of the MBES around the mobile survey vessel (short narrow-band signals inside a fan-shaped main sector of high intensity and widespread sidelobes at lower levels), which meant the temporal impact at any given location was also confined to a usually brief time period that the vessel was in the corresponding area.

- The EM 122 signal was detectable above baseline sound levels in the acoustic records only when the survey vessel was within 17 km of a hydrophone receiver (visible faintly in spectrograms up to 20 km from a hydrophone receiver).
- Clipping of received signals occurred at times when the survey vessel with transmitting EM 122 was less than 6 km from a hydrophone, preventing their true sound levels from being measurable at these ranges.
- Of the sound level metrics examined, the EM 122 signal most clearly and consistently manifested in the elevated 12.5 kHz decidecade band levels, and was often – but not always – associated with the maxima in the peak sound pressure level time series.
- Neither the EM122 nor the Sally Ride's other sonar systems or own radiated noise were the only detected sources during the survey. There was consistently biological activity, other vessels passing on or near the array, as well as other unidentified sound sources.
- The sound level characterization of the MBES mapping survey provides important descriptive and explanatory context for simultaneous observation works of marine mammal behavior during the same MBES survey.

**Abstract**

Noise pollution in marine ecosystems has increased during the last decades. In the Pacific Ocean, like in other ocean basins, the most continuous anthropogenic source that contributes to the ambient acoustic environment is maritime transport. Noise produced by ships reduces the communication space of marine species and has various immediate and chronic effects. The study area for this project was the

Gulf of Tribugá – a breeding ground for one of the humpback whale distinct population segments. The goal of the project was to quantify the contribution of humpback whale sounds and other acoustic sources to the soundscape, as well as to document the baseline soundscape. Acoustic samples were recorded at Morro Mico and Nuquí in 2018 and 2019. Both sites were dominated by biophony. In 2019, humpback whale song activity (minutes with song activity) peaked in the mornings at the Morro Mico site and in the evenings at the Nuquí site. This study has revealed that the Gulf of Tribugá demonstrates relatively lower presence of acoustic pollution generated by boats in comparison to other documented oceanic regions. Nonetheless, it is advisable to avoid increasing boat traffic during peak times of the humpback whale song cycle and tailored to the specific site.

## Introduction

Marine pollution produced by anthropogenic activities is closely related to the increase of human populations in coastal areas and domestic, agricultural, and industrial activities (Garay et al. 2001). There are different types of pollution, such as chemical pollutants, microplastics (Chitrakar et al. 2019), microbiological toxins (Zappalà et al. 2012), and noise (Shannon et al. 2016). Specifically in the last five decades, noise has increased significantly in the Pacific Ocean and one of the primary contributors to this problem is maritime transport (Hildebrand 2009; McDonald et al. 2006).

Noise produced by ships is a key contributor to reduced communication space of many marine species, from marine mammals to fish, likely causing chronic effects on individuals and populations (Putland et al. 2018). Ships have been considered the reason for a roughly 12 dB increase in low-frequency background noise levels in the Pacific Ocean (Hildebrand 2009), contributing to the masking of natural sounds (Kaplan and Mooney 2015). Noise produced by small boats, for instance from whale-watching vessels that stay generally close to shore to view easily accessible cetaceans, varies according to the flow of tourists since this parameter influences the number and size of boats used on ecotourism trips (Sprogis et al. 2020). In general, more and larger boats will create more noise pollution, particularly near ports (Chen et al. 2017).

A soundscape includes three fundamental elements: (1) anthropophony, which includes sounds associated with human activity; (2) biophony, which includes sounds produced by animals, like vocalizations (e.g., the song of whales) and nonvocal acoustic signals (e.g., feeding sounds of mollusks) (Kitting 1979); and (3) geophony, which are the sounds generated by physical events such as waves, earthquakes, rain, or storms (Krause 1987; Montgomery and Radford 2017; Pijanowski et al. 2011; Wang et al. 2019).

Some sources of noise, such as those from tourism boats, can have predictable activity cycles from predetermined schedules, while weather events (a natural source of masking) can be more sporadic (Fournet et al. 2018). Inconsistent source cycles

cause inconsistent sound level fluctuations in various frequency bands of the soundscape. In some cases, noise level changes could be driven by biological sound sources and in others by anthropogenic sources (Haver et al. 2019; Seger et al. 2015).

Many marine organisms, including invertebrates, fish, and mammals, contribute to the soundscape, with natural sounds such as whale vocalizations and fish stridulations (Pijanowski et al. 2011). This and many more examples showcase how a healthy soundscape is vital for many animals, allowing them to detect predators/prey, as well as navigate or protect young, thus facilitating critical interactions and dynamics of the ecosystem (Merchant et al. 2015; Remage-Healey et al. 2006). Marine mammals such as whales and dolphins use acoustic signals to facilitate some vital functions like communication, navigation, foraging, breeding, and predator avoidance (Haver et al. 2019; Richardson et al. 1995). Noise can affect them at individual and population levels. For example, physiological stress can inhibit developmental, reproductive, and/or immune functions (McDonald et al. 2008; Rolland et al. 2012).

The humpback whale (*Megaptera novaeangliae*) is a cosmopolitan species, found in all oceans (Clapham and Mead 1999). Humpback whales migrate long distances between tropical breeding areas and polar feeding areas (Clapham 1996, 2000). Individuals from Stock G (International Whaling Commission 1998) arrive in coastal waters of the Colombian Pacific to mate, give birth, and suckle their young (Flórez-González 1991).

Humpback whales produce considerable acoustic activity including songs emitted only by males, mostly during the breeding season, and social sounds, produced by individuals of both sexes and all age classes (Payne and McVay 1971; Rossi-Santos 2015; Stimpert et al. 2012). The song of the humpback whale has been studied, leading to various hypotheses regarding its functionality (Herman 2017). It has been proposed that the song could be used to mediate interactions between males, establish dominance (Darling and Bérubé 2001), attract females (Frankel et al. 1995; Tyack 1981; Winn and Winn 1978), maintain male spacing (Frankel et al. 1995), promote ovulation in females (Baker and Herman 1984), and assist in locating other whales (Frazer and Mercado 2000).

Some behavioral changes have been reported in humpback whales and other cetacean species in response to noise from whale-watching boats (Parsons 2012). For example, Scheidat et al. (2004) reported an increase in swimming speed of humpback whales in Isla de la Plata, Machalilla National Park, Ecuador, in response to tourism vessels. In Bahía Málaga in the Colombian Pacific, an increase in the speed of displacement was reported in correlation with the presence of boats, which was interpreted as avoidance behavior and could incur an additional energetic cost (Avila et al. 2015). Reactions to underwater noise can vary by source (Erbe 2012).

The Colombian North Pacific (specifically Chocó and the Gulf of Tribugá) is one of the most biodiverse areas in the world with high ecological value and complex climatic, geological, and biological histories (Velandia and Díaz 2016). However, the construction of a port in the area has been under consideration for some time. If the project is carried out it would create changes in the soundscape since underwater noise particularly increases near ports and along shipping routes due to a greater abundance of large boat traffic (Chen et al. 2017).

The purpose of the research reported here was to quantify the baseline soundscape and the diel and seasonal patterns of the humpback whale song in the Gulf of Tribugá under the current level of whale-watching and small fishing boats. The goal is to ultimately evaluate any changes in years to come no matter what infrastructure changes occur. This information could also serve to update management plans and environmental impact assessments by including acoustics, which was a topic not considered in the previous permit applications for the port.

## Methods

### Study Site

This study was conducted in the Colombian North Pacific and the sampling sites were: (1) Morro Mico (adjacent to the southern border of Utría National Natural Park), a tiny island reef a few hundred meters from the coast in the north of the Gulf of Tribugá, and (2) Nuquí, a village in the department of Chocó with a large river outpouring and the location of the airport that connects the area with the interior of the country (Fig. 1). The sites were chosen because of the presumed differences in their maritime traffic schedules as advised by experienced researchers in the area. Nuquí is a more central and commercial area while Morro Mico is closer to the Utría National Natural Park and is less traversed. Because of its relatively pristine condition largely to do its remoteness from large shipping lanes and its containing little

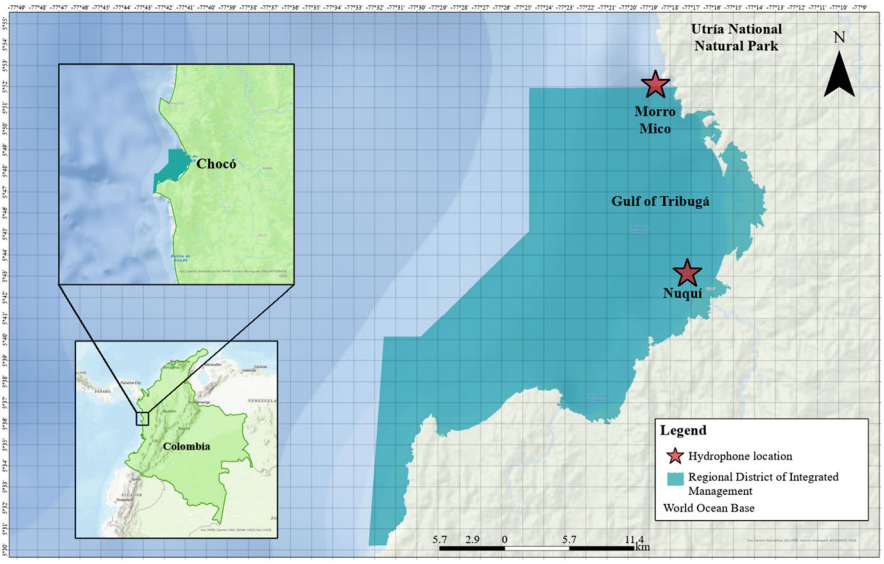

**Fig. 1** Study area in Colombia located in the department of Chocó. The stars indicate the locations (sites) of the recorders in Morro Mico and Nuquí

infrastructure, the entire Gulf of Tribugá was designated a Hope Spot by Mission Blue in 2019. Hope Spots are special places scientifically identified as critical to the health of the ocean. Additionally, Tribugá was named a Biosphere Reserve by UNESCO in 2023, signifying it as a "learning place for sustainable development."

Additionally, weather differences could potentially have been captured between these two sites, specifically differences in rainfall. The Gulf of Tribugá is characterized by being one of the rainiest regions in the world with average annual rainfall around 5000–7000 mm (Velandia and Díaz 2016). There is a trend that rainfall increases South to North across the Gulf of Tribugá, so a more northern study site could experience more sound from rain than a more southern study site, even though weather patterns in the Gulf are patchy microclimates (Velandia and Díaz 2016).

The Gulf of Tribugá Cabo Corrientes Regional District of Integrated Management Area has 60,183 ha and is administered by Codechocó, the policymaking entity responsible for managing natural resources based on sustainable human development with community participation. Therefore, conservation actions are combined with sustainable resource uses like whale-watching tourism. The national park and local conservation-minded people are interested in best practices of whale-watching boats to ensure that they protect the artisanal fishing economy of the area.

## Acoustic Data Collection

Acoustic data were collected using an Ecological Acoustic Recorder (EAR, Oceanwide Science Institute) in Morro Mico and Nuquí in 2018 and 2019 (Table 1). The instrument was programmed to record for 10 minutes on and 20 minutes off, or a 33.3% duty cycle. The sampling rate was 15.625 kHz. The hydrophones on the EARs had a sensitivity of 193.5 dB re 1 V/Pa with a 47.5 dB preamp.

## Spectrogram Analysis

Acoustic recordings were analyzed using spectrograms (Rossing 2007) generated in Raven Pro (version 1.5; Cornell Laboratory of Ornithology, Ithaca, New York) with a temporal resolution of ten minutes and a Fast Fourier Transform (FFT) of

**Table 1** Acoustic data collected in 2018 and 2019 at both sites

| Site | Year | Recorder | GPS | Dates | Days w/Data |
|---|---|---|---|---|---|
| Morro Mico | 2018 | EAR | 05°52′10.1″N 77°18′40.7″W | 22/10 to 28/11 | 38 |
| Morro Mico | 2019 | EAR | 05°52′10.1″N 77°18′40.7″W | 31/07 to 9/10 | 71 |
| Nuquí | 2019 | EAR | 05°43′12.2″N 77°17′10.1″W | 31/07 to 7/09 | 39 |

512 along with an overall bandwidth analysis. The representation in the form of a spectrogram displays time on the horizontal axis, frequency on the vertical axis, and the relative power at each time and frequency as a color depiction using a color scale within the spectrogram. The ten-minute files were manually analyzed every 6 h at 12:00, 18:00, 00:00, and 06:00. Any presence of the following six sound types were tallied in each minute: humpback whales, dolphins, fish, shrimp, wind/rain, and small boats engines. This per-minute tally of sound classifications provided presence time series of six sound types. These time series were then examined to identify the presence of biological cycles, such as diel patterns. Furthermore, a comparison was made between the compositions of the soundscape at each site, and the calculation of "noise budgets" was performed to illustrate the percentage that each type of sound was relatively present at each site. Because noise budgets are not yet widely used in policy decisions (Merchant et al. 2017) and considering that reports concentrating on anthropogenic noise emphasize the creation of these budgets (National Research Council 2003), the goal was to establish a measure of usable relative activity of sound sources at each environment. Percentages of total time when a sound source is present yields itself to an easily accessible pie chart that could be reasonably be tracked over the years to provide policymakers with a reference for how human noise fits into the overall noise budget of each region as time changes the infrastructure of the area (Merchant et al. 2020). For monthly comparisons, the sounds were divided by the total samples within each group, resulting in the generation of a presence rate.

### Statistical Analysis

To identify whether there was a significant difference between the monthly occurrence of each sound type at each site, chi-square tests were performed. Because the expected frequencies in some cells were too small to use the chi-square distribution, a Monte Carlo simulation was performed (Verzani 2014). The null hypothesis ($H_0$) stated that there would be no relationship between the months and the proportion of each sound's presence, while the alternative hypothesis ($H_1$) stated that there would be a relationship between the months and the sound source proportions. Statistical analyses were performed using R software (version 3.5.2). The chosen significant p-value was 0.05.

## Results

For both years (2018 and 2019) and both sites (Morro Mico and Nuquí), sounds from humpback whales, fish, shrimp, wind/rain, and small ecotourism/artisanal fishing and shrimping boats were detected. Time series of these sounds are shown for descriptive results to provide the reader with a "feel" for each year's and site's soundscape. The qualitative results are important, because they represent relevant observations that will allow for comparison of soundscape aspects into the future.

**Table 2** Sampling schedule for each year at both sites

| Site/Year | Month | Sample |
|---|---|---|
| Morro Mico 2018 | October | 76 |
| | November | 222 |
| Morro Mico 2019 | July | 4 |
| | August | 248 |
| | September | 240 |
| | October | 68 |
| Nuquí 2019 | July | 4 |
| | August | 248 |
| | September | 54 |

The recording months were different in each year and location due to climatic and logistical conditions. In 2018, 1681 recordings were collected over 38 sampling days at Morro Mico; in 2019, 3675 recordings were collected over 71 sampling days. In Nuquí the recorder failed in 2018, but in 2019, 1804 recordings were collected over 39 days. The sampling schedule for each year at sites Morro Mico (MM) and Nuquí (NQ) is presented in Table 2.

## Spectrogram Analysis

For both sites, the sources of anthropophony came primarily from small boats as well as from shrimping boats and the associated mechanical sounds of their net chains (Fig. 2). This was evident because these boats occupied a large part of the frequency band and had the typical u-shape indicative of the Lloyd's mirror effect observed in passing vessels. Geophony sounds came from wind or rain (Fig. 3). The sounds of storms (Fig. 3a) and raindrops (Fig. 3b) occupied a large part of the frequency spectrum, and the amount of rain was reflected in the intensity of the spectrograms. Finally, biophony came from the vocalizations of humpback whales (Fig. 4) and sounds of fish and snapping shrimp (Figs. 5 and 6). Neither dolphin clicks nor whistles were detected in any of the years or at either sites.

Between both sites differences were observed in the relative amount of contribution from snapping shrimp to the soundscape. Their presence in Morro Mico (Fig. 6a) for the 2 years was higher than at Nuquí (Fig. 6b), where they were barely evident in most of the acoustic samples. The cavitation sounds produced by the shrimp at Morro Mico for the 2 years were ever-present in the above 4.5 kHz band (Fig. 6a).

## Analysis of Soundscape

The dominant sound source in the 2018 (Fig. 7a) and 2019 (Fig. 7b) soundscapes at Morro Mico was snapping shrimp, followed in descending order by sounds produced by fish, humpback whales, wind/rain, and boats. The snapping shrimp sounds

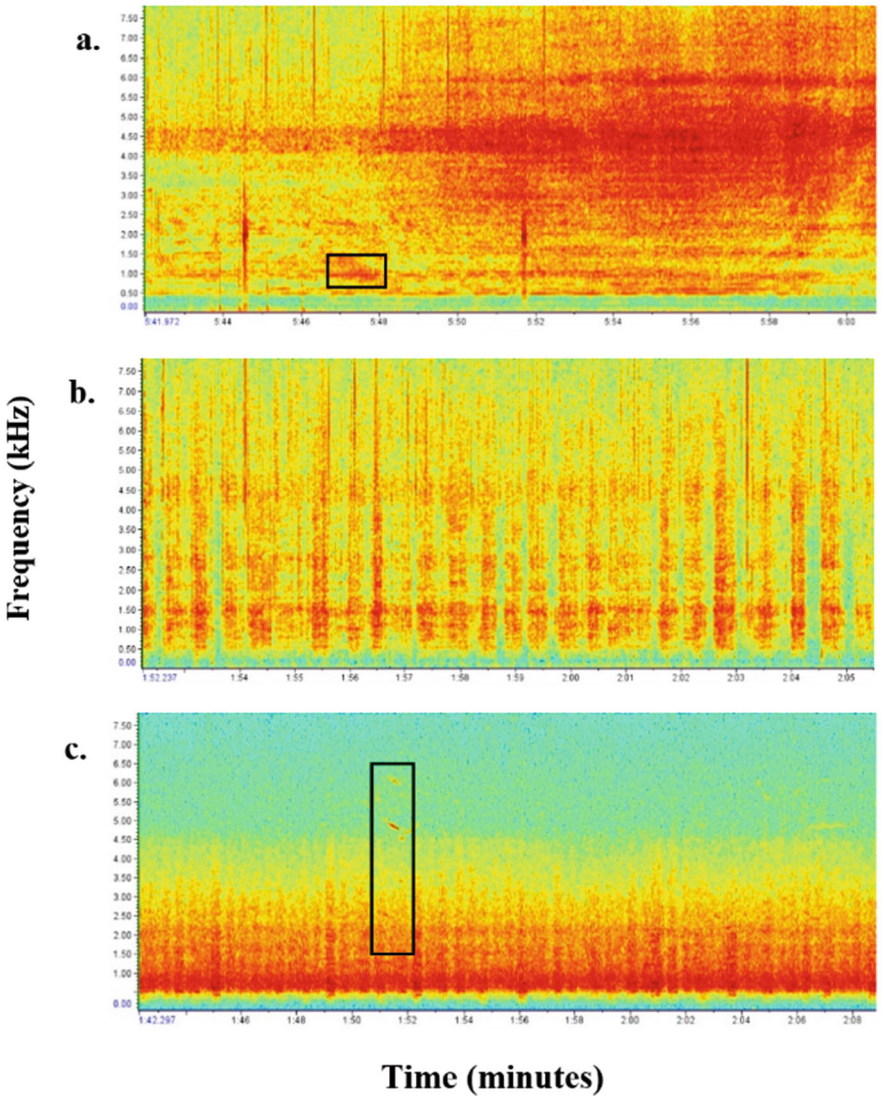

**Fig. 2** (**a**) Spectrograms of small ecotourist/artisanal fishing boats at Morro Mico on 08/09/2019 12:00 hours and (**c**) Nuquí on 08/09/2019 at 06:00 hours. (**b**) Shrimping boats at Morro Mico on 08/28/2019 at 00:30 hours. Black squares denote social calls of humpback whales

were nearly constant. On the other hand, for Nuquí in 2019 (Fig. 7c), the dominant sounds were humpback whales, followed by sounds produced by fish, boats, wind/rain, and shrimp. While the relative proportions of the different categories of sounds did not vary between years in Morro Mico, they did vary between the locations of

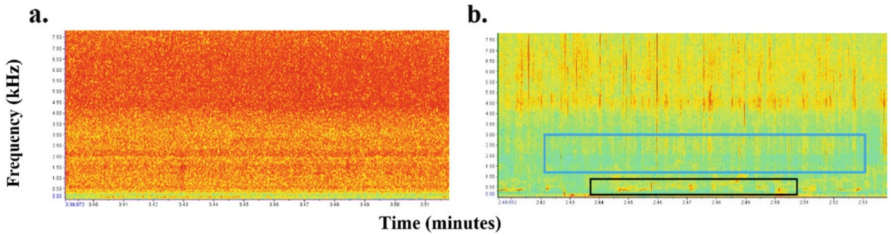

**Fig. 3** (**a**) Spectrograms of a storm at Morro Mico on 08/06/2019 at midnight and (**b**) rain drops at Morro Mico on 08/19/2019 at 18:30. The blue box denotes the drops, while the black rectangle denotes the song of at least one humpback whale (from 0–1 kHz). Sound energy above 4 kHz is primarily from snapping shrimp at Morro Mico

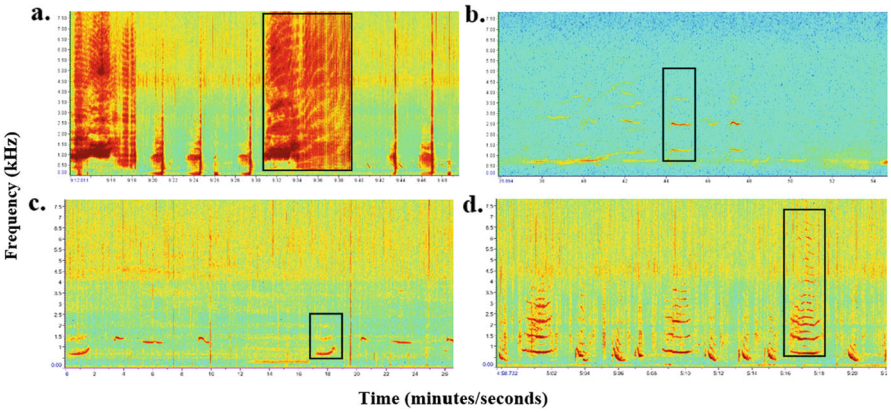

**Fig. 4** Spectrograms of some humpback whale song units (framed in black boxes)

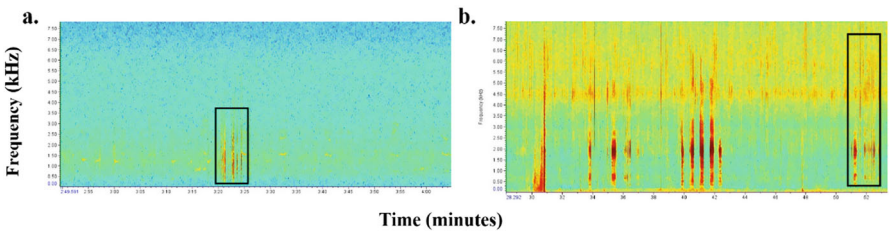

**Fig. 5** (**a**) Spectrograms of sounds produced by fish at Nuquí on 08/01/2019 at midnight and (**b**) at Morro Mico on 08/24/2019 at 12:00 hours, framed in black boxes

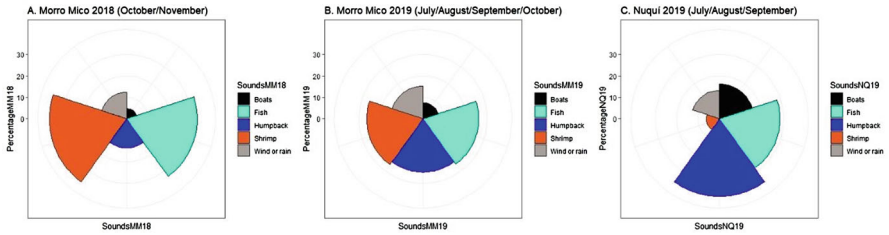

**Fig. 7** (**a**) Pie charts (or proportions) of sounds found in Morro Mico for the year 2018, in the combined months of October and November; (**b**) Morro Mico 2019 in the months of July, August, September, and October; and (**c**) Nuquí 2019 in the months of July, August, and September

**Table 3** Sound source presence percentages (rates) for Morro Mico and Nuquí in 2018 and 2019

| Site | Year | Humpback (%) | Fish (%) | Shrimp (%) | Wind/Rain (%) | Boats (%) |
|---|---|---|---|---|---|---|
| Morro Mico | 2018 | 14 | 33 | 35 | 12 | 5 |
| Morro Mico | 2019 | 25 | 26 | 26 | 15 | 8 |
| Nuquí | 2019 | 36 | 28 | 6 | 13 | 16 |

Morro Mico and Nuquí. The proportional values for each sound source across site and year are shown in Table 3.

Presence rates, which correct for sampling bias toward some months (Fig. 8), show that humpback whales were less prominent later in the year, so overall noise budgets (Fig. 7) of a season do not necessarily represent noise budgets per month.

In 2019 at Morro Mico (Fig. 8b), October compared to November would suggest a large difference in sound source types in the soundscape, but in 2018 all months July–October were relatively similar in their noise budgets. This illustrates that a potential soundscape shift at Morro Mico begins in November, which does coincide with humpback whale southward migration commencing.

In 2019 at Nuquí, July to September (Fig. 8c) had relatively stable noise budgets. However, a peak in snapping shrimp activity in August occurred and could be studied in the future when year-round data can be collected.

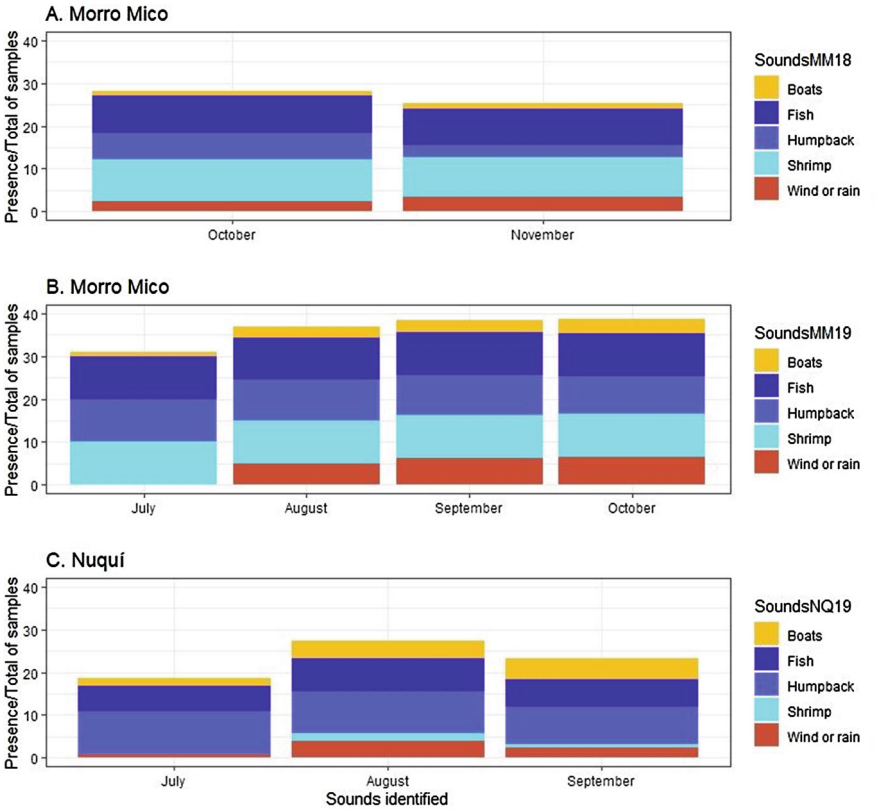

**Fig. 8** Presence rates for each sound source in total samples per month for Morro Mico in (**a**) 2018 and (**b**) 2019, and (**c**) Nuquí for 2019

In brief, for Morro Mico in 2018, presence rates were similar between months except for humpback whale sounds, which occurred less often in November. For Morro Mico in 2019, rates were also similar between months except for July when boats had lower presence rates than the other months. For Nuquí in 2019, the same lower presence rate of boats in July was detected, likely because of fewer recording days. Wind/Rain presence rates were different between months insomuch that they peaked in October or November at Morro Mico but in August at Nuquí. This could be because Nuquí was not sampled in October or November and/or it shows the existence of microclimates in the Gulf of Tribugá. Anecdotally, a common joke is that each village in the Gulf "has its own cloud," and the collected data show that could be true. Presence rates for each sound source in total samples per month are shown in Table 4.

A chi-square test ($X^2_x = 0.994$, $p < 0.05$) revealed that there was no statistically significant relationship between the sound rates of each group and the months at each

**Table 4** Presence rates for each sound source in total samples per month for both sites

| Site/year | Month | Shrimp | Fish | Humpback whales | Wind/ Rain | Boats |
|---|---|---|---|---|---|---|
| Morro Mico 2018 | October | 9.8 | 8.8 | 6 | 2.4 | 1.1 |
| | November | 9.3 | 8.6 | 2.7 | 3.5 | 1.3 |
| Morro Mico 2019 | July | 10 | 10 | 10 | 0 | 1 |
| | August | 9.9 | 9.7 | 9.5 | 5.1 | 2.7 |
| | September | 9.9 | 9.9 | 9.3 | 6.3 | 2.9 |
| | October | 10 | 10 | 8.8 | 6.6 | 3.3 |
| Nuquí 2019 | July | 0 | 6 | 10 | 0.8 | 1.8 |
| | August | 1.9 | 7.8 | 9.8 | 3.8 | 4.3 |
| | September | 0.6 | 6.4 | 8.9 | 2.5 | 4.7 |

site. In brief, the rates of sound sources that occurred did not vary significantly between months.

In 2018 at Morro Mico, the highest absolute amount of humpback whale vocal activity (primarily singing but occasionally social calls) was detected in 180 of the November files recorded at 18:00 hours (Fig. 9a). In 2019, the highest number of files with detected humpback whale sounds (613) occurred at 06:00 hours in August (Fig. 9b). Despite humpback whales having a lower presence rate in November than in October 2018 (Fig. 9a), their sounds filled more files in November than in October. Morro Mico in 2018 had a slight diel cycle for humpback whale songs with a sunset peak. Morro Mico in 2019, however, did not exhibit this same evening peak of activity, but had a slight sunrise peak instead. In 2019 at Nuquí (Fig. 9c), the highest number of files with humpback sounds (620) were detected at 18:00 hours in August. This is the same month as the peak at Morro Mico, but the opposite time of day. In summary, the diel cycle of singing of humpbacks (previously documented in Hawaii [Au et al. 2000] and Mexico [Seger 2016] as more active near midnight and less during the day) was more evident in Morro Mico in 2018 than at either site in 2019, but at dusk instead of midnight.

The number of boat sounds detected at Morro Mico in 2018 (Fig. 10a) filled 376 files and were most commonly detected at midnight. At Nuquí (Fig. 10c), there was a total of 1317 files with boat sounds and they were most common during the day. It is important to consider that, for the year 2019, in both Morro Mico and Nuquí, the recordings from the month of July are only from one day because deployment occurred on 31 July and recordings began at 12:00 hours, preventing any data from existing at midnight and 6 am for July.

## Discussion

This study provides qualitative and quantitative descriptions of soundscapes at two sites located in the Gulf of Tribugá. Both sites have relatively few contributions from noise generated by tourism and fishing boats. Currently, there are no published

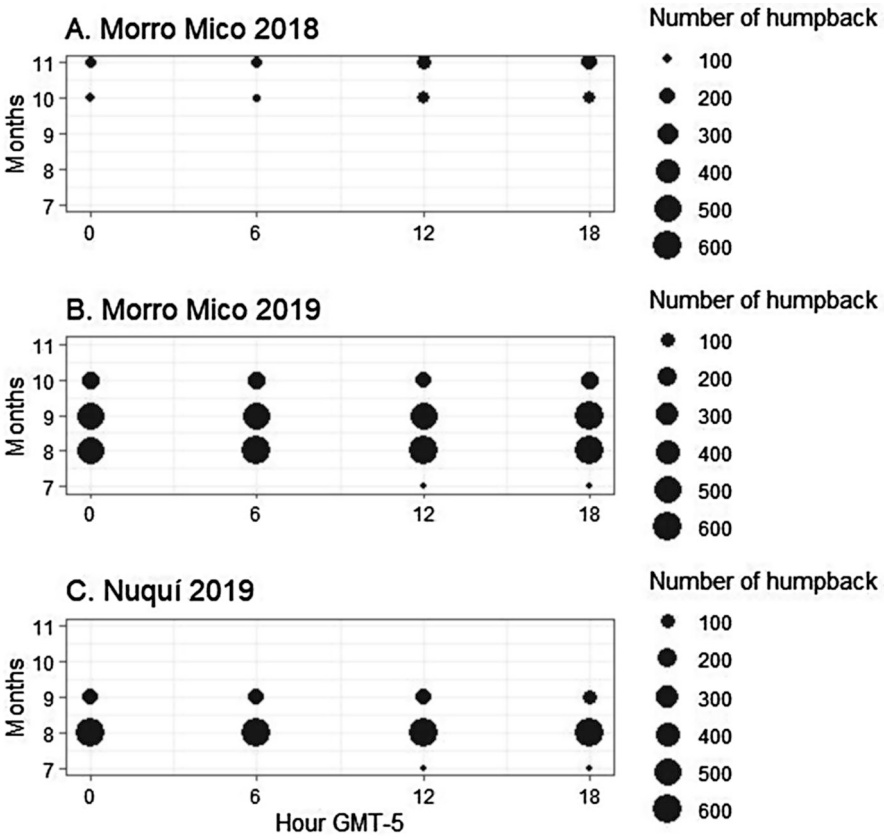

**Fig. 9** Number of files with humpback whale sounds (usually songs) detected during four time periods (00:00–00:10 and 00:30–00:40, 6:00–06:10, 12:00–12:10, and 18:00–18:10). The number of files of the intervals were added, plotted, and represented in the top hours for each of the months sampled by site. From top to bottom: Morro Mico 2018 (October and November), Morro Mico 2019 (July, August, September, and October), and Nuquí 2019 (July, August, and September)

studies about the Gulf of Tribugá's soundscape and the singing cycle of humpback whales that inhabit the Gulf during the boreal summer months. However, behavioral responses of humpback whales have been studied in the presence of whale-watching boats in Bahía Málaga in the Colombian Pacific (Avila et al. 2015), as well as in other South American countries such as Ecuador and Brazil (Scheidat et al. 2004; Sousa-Lima and Clark 2008, 2009). These previous studies are relevant to the current one since the whales that visit the Gulf of Tribugá may cross on the same feeding grounds near Antarctica.

A pattern was evident in Morro Mico's soundscape for both years sampled. Shrimp, fish, and humpback whale sounds were nearly equally dominant until November (2018) when the contribution of humpback whale song reduced, likely due to their migration to Antarctica commencing (Clapham and Mead 1999). The

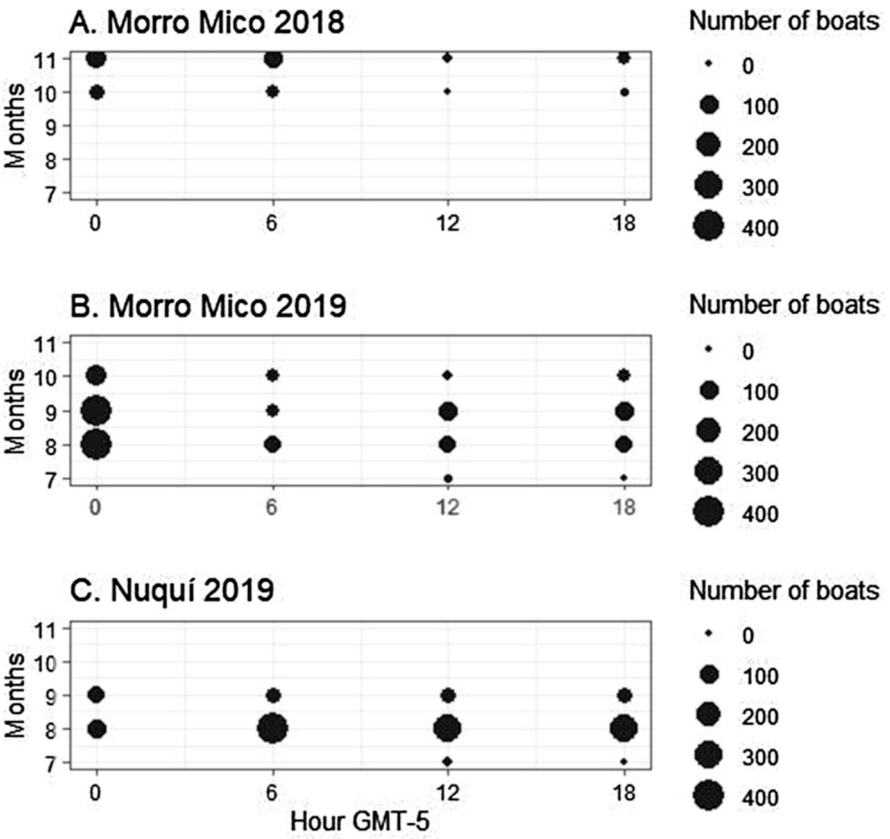

**Fig. 10** Number of files with boat sounds detected during four time periods (00:00–00:10, 06:00–06:10, 12:00–12:10, and 18:00–18:00) for each of the months sampled at (top) Morro Mico 2018 (October and November), (middle) Morro Mico 2019 (July, August, September, and October), and (bottom) Nuquí 2019 (July, August, and September)

peak humpback whale acoustic presence was in July, and then their vocal activity was relatively constant in the Gulf of Tribugá from August until sometime in October. Most previous photo ID research in the area that visually tracks humpback whale demographics has ended by October (Acevedo et al. 2017), so it was assumed that the whales also migrated en masse in October. But comparing October 2018 and 2019 to November 2018 at Morro Mico, it now appears that the mass migration south commences sometime in November.

The soundscape of Morro Mico in 2018 contained consistent snapping shrimp acoustic activity. The presence of shrimp can be a bioindicator for habitat quality and a way to monitor the conditions of the soundscape and the ecosystem. The sounds in a reef could reflect significant ecological changes (Watanabe et al. 2002). For example, the snapping activity of shrimp and the relationship with changes in temperature and dissolved oxygen concentrations have been studied in other

ecosystems (Watanabe et al. 2002). Because this project is the first acoustic study of the Gulf of Tribugá, it provides a baseline amount of activity, but not comparison to assert the relative health of Morro Mico and Nuquí ecosystems. However, if a port is built or if other infrastructure is built in the future, or as climate change continues, this study will serve the important purpose of being that which future studies can be compared against for relative health assessments of the ecosystem(s). Tracking physical variables of the ecosystem, too, like pH or temperature or the sound speed profile, would aid in tracking soundscape shifts into the future.

Finally, sounds of dolphins were not detected at either location, and possible explanations for this are that (1) the location of the hydrophone was not near where dolphins tended to be as they have been documented further south and away from the coast (Noreña 2020), or (2) the sampling rate of 15,625 Hz was too low to capture their whistles and clicks.

Nuquí in 2019 was distinguishable from Morro Mico by having a more variable soundscape. Although, in the absence of anthropogenic disturbances, it was quieter and more monotonous than Morro Mico. This is likely because in Nuquí the seabeds are mostly sedimentary but near Morro Mico they are rocky (Velandia and Díaz 2016), so there are no small coral communities for snapping shrimp and fish to live near Nuquí and contribute to its soundscape. Furthermore, sound attenuation should be greater around Nuquí because sediments with lower porosity and smaller particles (like mud and clay) create greater attenuation (absorb sound waves more) than sediments with higher porosity and larger particles (like rocks and gravel) (Buckingham 1997).

The cycles of humpback whale singing were different between Nuqui and Morro Mico, which was a key interesting discovery in this project. There are a number of reasons why this could be the case. In 2019, samples with whales' songs peaked during the mornings in Morro Mico but in the evenings in Nuquí. This may be an indication that the whales are shifting locations up and down the coast to sing in different places during the night and day, where further north in the Gulf is a better singing location in the morning, but further south is a better singing location in the evening. This is not impossible as whales are mobile animals and can easily cover the distance between Morro Mico and Nuquí in a few hours. If song is a territorial display, though (Seger et al. 2016), and the singers are not moving along the coast to sing in various locations, but choosing to sing at the same location day after day, males within recording range of Morro Mico may prefer to sing more in the mornings than males within recording range of Nuquí. Finally, there could be a binary onshore/offshore trend like documented in Munger et al. (2012) where all singers near Morro Mico are doing so closer inshore in the mornings but singing closer inshore to Nuquí in the evenings. Since there is an uptick in vessel traffic at Morro Mico in the middle of the night and at Nuquí in the middle of the day, singers in each area could be shifting to sing near shore during the relatively lower boat traffic hours at each location. Whether different diel cycles exist at each site (16.9 km apart), or the singing whales shift between the two locations on a daily schedule cannot be determined from single recorders, but would be an interesting future project if arrays or vector sensors can be deployed.

Another possible explanation in these different peak times of singing activity at each recording location is that singer distribution and activity is driven by the locations of other humpback whales and not from an individual singer's decision-making process. Nuquí could be a location where the mothers and calves go at night once the daily peak in boat traffic has slowed down, and they return to Morro Mico in the mornings to avoid the increase in vessel traffic coming out from the largest village of the region. If the males are using song to attract these females, their singing activity may follow the daily routes that mothers take with their calves. However, this would be counter to the theory of "aural camouflage" described by Seger et al. (2015) whereby grey whale mothers with calves seek out areas with high snapping shrimp activity to use as a masking device to be able to communicate at close ranges with their calves but not be detected by males in the immediate vicinity. If mothers and calves preferred areas with lots of snapping shrimp sounds, and males sang in areas close to adult females, song would be concentrated only in Morro Mico and not in Nuquí. A third explanation could be based on the observation that males stop singing when they join with other males (Darling et al. 2006; Tyack 1981) and start singing when they disaffiliate into singletons (Kobayashi et al. 2021). If Nuquí is at the center of the Gulf, then there may be more male whales joining and stopping to sing each morning, causing a dip in singing activity after sunrise but an increase in the evening near Morro Mico when they spread out again to sing. These possible explanations all make assumptions about singing trends that cannot be corroborated with visual surveys because previous work in the Gulf of Tribugá has not tracked movement patterns overnight, has not investigated whether there are temporal patterns of resightings of animals between the two monitoring locations of this research, and has not expanded past the Gulf's borders to determine whether the humpback whale song may have a broader trend that cannot be captured with just two recording stations. Further research, including a count of songs within each time frame, would be required to distinguish between the presence/absence of singing activity in the files.

Overall, the sounds that substantially dominated the Nuquí soundscape's noise budget were those of humpback whales, fish, and boats. Humpback whale songs were detected more often at Nuquí than at Morro Mico and represented a larger percentage of the noise budget. The lack of snapping shrimp at Nuquí is likely what leaves room in the noise budget for humpback whales to occupy a larger percentage of it. A possible explanation for the greater detection of songs in Nuquí is that, in the absence of boats, the acoustic environment was quieter, so a whale song would be easier to detect if there wasn't snapping shrimp to mask its reception like at Morro Mico. Even though song from whales and noise from boats would both be attenuated by the muddy sediments, the higher attenuation of sound at Nuquí compared to Morro Mico might also reduce the amount of noise from far away boats and whales reaching the EAR, making it easier to detect whales within detection range when there were no boats within detection range.

The coincidence that a larger portion of the Nuquí noise budget being humpback whale song implies that the area with the highest humpback whale vocal activity detected in the Gulf of Tribugá is also the area with the highest boat activity. Thus,

high human activity appears to be overlapping with a critical singing area for the whales. The effect of this might be seen in the different diel cycles of humpback whale song at each site. This analysis found that the diel singing cycle of humpback whales was more evident at Morro Mico in 2018 than at Nuquí or Morro Mico in 2019 but was backward since the peak did not occur at midnight like in other locations around the Pacific Ocean–Hawaii and Mexico (Au et al. 2000; Seger 2016). Instead, Morro Mico in 2018 had more singing activity at 12:00 and 18:00 hours than at 00:00 and 06:00 hours. Some authors suggest that vision in daylight plays a key role in the formation of competitive groups, but at night males can focus effort on vocal activity as the main mating strategy (Au et al. 2000; Helweg and Herman 1994). If true, high boat activity during peak singing hours could cause the humpback whales to either relocate to an area with less boat traffic, or to shift their diel singing cycle to peak when there is less disturbance. The shift to more singing in the daylight hours at Morro Mico in 2018 exemplifies this latter possibility as it does coincide with a potential avoidance of the higher nighttime boat traffic at Morro Mico. However, this trend did not hold true in 2019 as Morro Mico still had the most boat traffic at 00:00 hours, but there was no clear diel singing cycle from the whales. The closest thing to a peak in singing activity that occurred at Morro Mico in 2019 was that a large number of files with song present in them occurred at 06:00 hours, but only in August. The lack of a midnight-peaking singing cycle is interesting given that the midnight peak in boat activity is obvious.

Nuquí in 2019 similarly showed no clear diel singing cycle even though boat activity there did drop overnight. The most acoustic files containing singing activity was centered at 18:00 hours in August, again suggesting that even some boat noise at night might be too much for humpback whales to maintain a midnight-peaking singing cycle at Nuquí. According to Seger (2016), it was observed that their site of study with the most boat activity did not contain a diel singing cycle, either, so humpback whales may have a threshold of masking from boats that causes them to adjust their singing cycle accordingly or to vacate an area with too much disturbance. A final explanation could be that humpback whales from the Southern Hemisphere, or at least from Stock G, have a naturally different diel singing cycle than those from the Northern Hemisphere that breed in Hawaii and México.

The noise generated by boats was higher at Nuquí than in Morro Mico both in terms of percent of the noise budget and in absolute counts of files with boat noise present. In Caribbean marine parks, it was found that, the lowest percentages of time that vessel noise existed in their soundscapes were between 20% and 30% but did sometimes reach up to 99% (Heenehan et al. 2019). The most that boat noise was detected at Nuquí in 2019 (the highest for this study) was 16% of the time, which is still considerably lower than that documented in some marine parks in the Caribbean area. Therefore, the Gulf of Tribugá can be characterized as an area with relatively low levels of noise pollution compared to the Colombian Caribbean coast, which in some areas has operations that produce intense underwater noise through seismic testing, platform construction, and the constant drilling and removal of the land (Vásquez 2019). This emphasizes the claim that Tribugá is still a "relatively pristine" environment as compared to the current status of vessel traffic in other areas of the

world today. To the best of current knowledge, no scientific investigation has compared soundscapes between Colombia's Pacific and Caribbean coast waters.

The Gulf of Tribugá is part of the administrative area of Chocó, which is one of the places in the world with highest rainfall and associated winds (Velandia and Díaz 2016). This is evident in the monthly precipitation reports for the year 2019 by the Institute of Hydrology, Meteorology, and Environmental Studies (IDEAM- acronym in Spanish) (Instituto de Hidrología, Meteorología y Estudíos Ambientales (IDEAM) 2019). Because of the rain, the communication space for marine animals may be masked by natural hydrological and geophysical factors. The results of this research showed there were more acoustic files with rain sounds during 2019 than 2018. According to the IDEAM monthly report, for the months of August, September, and October of 2019, the monthly amount of precipitation was above that observed for the same months in 2018 (Instituto de Hidrología, Meteorología y Estudios Ambientales (IDEAM) 2019). The sound of rain occupied the entire frequency spectrum when present, sometimes intensely enough to mask sounds even as intense as humpback whale song. Also, it is known that wind is an important source of contribution to soundscapes (Wenz 1962) as it makes the surface of the ocean choppier, producing more bubbles, and causing their cavitation sounds to radiate downward with cosine directionality. Waves also have a sharp pressure pulse when they impact the surface, followed by the resonance of the gas bubbles generated by the impact (Hildebrand 2009) contributing to the overall geophony.

Within the data there were many instances of biological sounds and boat sounds that occurred at the same times, illustrating temporal, spatial, and spectral superpositions and causing masking effects in the communication not only of marine mammals (Clark et al. 2009; Cholewiak et al. 2018; Erbe et al. 2016, 2019), but also of fish (Smott et al. 2018). This could generate combined masking effects by the rain on the ocean surface and the sound of the boats, potentially masking biologically relevant signals by two sound sources at once (Montgomery and Radford 2017). Since boat sound decreased at night, the combined masking effect could be more intensely present for longer periods of time in the daylight hours, with the effects of wind and/or rain only persisting through the nighttime hours. This would mean the reduction of the communication space of singing humpback whales would vary throughout a 24-h period.

Within the datasets of this paper, fish sounds were consistently present at both sites and years. Even though neither the fish nor the whales notably stopped calling/singing completely at any time in the datasets, possible impacts such as increase in stress hormones from receiving high noise levels could affect vital functions and change communication functionality, as has been found in right whales (Rolland et al. 2012). Future work investigating stress levels of whales during days and times with lower or higher sound levels close to the Morro Mico or Nuquí sites would help answer this question. Also, more in-depth studies about specific acoustic reactions of fish and whales when boats are nearby compared to when they are not would be useful to understand how much and in what ways animals are responding to fluctuations in background noise levels in their soundscapes.

To that end, Rey-Baquero et al. (2021) used a subset of these data to determine whether humpback songs changed after a boat pass compared to the song structure and rhythm before the boat passed. They found that song structure changed roughly 50% of the time during a boat pass, so was not statistically significant in terms of a reaction to boat noise, but the song units and space between song units had a statistically significant difference after a boat passed as compared to before. Also, Brown et al. (▶ Chap. 76, "Frequencies of Humpback Whale Song Units (*Megaptera novaeangliae*): Adjustments to Small Boat Noise") tested whether humpback whales in the Gulf of Tribugá changed the frequency content of their songs during and after boat noise as compared to before it was present. They found that out of 38 comparisons, song frequencies significantly changed nine times. Similar studies on frequency content would be important to provide a more holistic understanding of humpback whale singing reactions to boat noise.

More boats or larger vessels in the Gulf of Tribugá, especially if an international port were to be built, would increase background noise levels in the soundscape. In fact, Huertas-Amaya et al. (▶ Chap. 77, "Acoustic Models to Consider Noise Pollution from a Possible Port on Humpback Whales in the Gulf of Tribugá, Colombia") quantified how much more area of the waters off Colombia could be ensonified by new shipping lanes. Noise produced by large vessels has been found to impact acoustic-based interactions for whales, fish, and other marine animals, especially in protected areas or areas of special biological interest such as sanctuaries and marine parks (Hatch et al. 2008; Stanley et al. 2017). Also, disturbances and impacts from smaller vessels, such as fishing and whale-watching boats, have been reported because they contribute to masking (Rey-Baquero et al. 2021). Thus, with both large and small vessels, the effect of heightened background noise would be cumulative (Cholewiak et al. 2018). Vessels have been found to have the ability to reduce the communication space for fish and whales, even though there is natural variability in background sound (Putland et al. 2018; Rey-Baquero et al. 2021).

The impacts of tourism whale-watching boats have been studied in different marine mammals and places around the world (Parsons 2012). Some of the changes studied in humpbacks are acoustical (Erbe et al. 2019) while others are behavioral (Avila et al. 2015; Sousa-Lima and Clark 2009; Schuler et al. 2019). In feeding areas, it has been found that the noise of the boats can affect foraging, causing impacts at the individual and population levels (Blair et al. 2016). Although the effect of boats on the humpbacks in Tribugá is unknown, the impacts could be similar to other places, affecting ecological, reproduction, and breeding processes. In addition, whale-watching of marine mammals has gained great economic importance, especially in the interior of the Gulf of Tribugá (Velandia and Díaz 2016). If the industry grows, the masking effect could increase due to the number of boats and frequency of tours, so responsible whale-watching practices should include acoustic considerations in their guidance. This is considered a relatively easy lift in the area since boat operators already receive training that they largely abide by, so adding acoustical considerations would also likely receive high compliance.

## Conclusions and Perspectives

Both the study years and sites were dominated by biophony, arising from sound sources such as the songs and social calls of humpback whales, and sounds of shrimp and fish. Overall, this study has shown that the Gulf of Tribugá contains relatively low presence of boat noise/acoustic pollution as compared to other documented areas of the oceans. Monitoring is recommended to document any increase of human noise disturbances, especially in sites such as Nuquí which present greater potential for more contributions from sounds of boats as the population of Chocó grows. Interestingly, the humpback singing cycle peaks did not follow the midnight peaks of other Pacific breeding grounds, which could be attributed to: (a) the coincident peak boat activity that would make it harder to detect song even when peaking; (b) a behavioral shift toward the time of day when there were fewer boats, thus illustrating a possible adaptation to the human noise diel cycle; or (c) a possibility that Stock G whales from the Southern Hemisphere may naturally sing on a different diel cycle than their Northern Hemisphere counterparts.

Communicating the results of this study could help in regulating noise levels and keeping them to a minimum as infrastructure grows along the Pacific Coast of Colombia. A key recommendation would be to avoid an increase in boat traffic at peak times of the humpback song cycle – a time that would depend on the site. For future studies, it is recommended to evaluate the effects of anthropophony on the soundscape, using other metrics such as percentiles in decidecade or one-third octave bands (Wang et al. 2019). Including percentiles or analyzing more hours could better represent the soundscape components and more easily identify the intensity contributions of each group and help determine where and when the humpback whales are singing most of the Gulf of Tribugá. Finally, continuing with passive acoustic monitoring allows management authorities to prioritize protection of conservation areas before possible disturbances due to human activities, especially when any proposals for the construction of a mega maritime port or other large infrastructure project exists.

Future studies should extend the acoustic sampling season to times when humpback whales are in their feeding grounds (November–May). Visual observations from local fishermen and tourist boats have recently documented pilot whales and killer whales in the Gulf of Tribugá, so it would be interesting to determine if sounds from these animals become more prevalent, or are at least more detectable, when humpback whales are not around. Sampling rates of the recorders would need to increase to capture the delphinid contribution to the soundscape, though. Future work would benefit by having more than one recorder at a single site so that locations of boats and all sound sources can be determined.

**Acknowledgments** We would like to express our gratitude to the people of Chocó, Colombia, for opening their homes to our research efforts. To Fundación Macuáticos Colombia and Dr. Natalia Botero Acosta for the wonderful job she does monitoring the humpback population each year and for making this research possible. To Checa and Cruz, for being our captain and keeping us housed and fed. Thank you to Marc Lammers and the Oceanwide Science Institute for loaning us the EARs. To Lili (Kákiri Estación de Buceo) for the help in the dives and installation of hydrophones. To Juana Perea, this manuscript is dedicated to you. The fieldwork would not have been possible without the approval of local councils Consejo Comunitario Los Riscales and Consejo Comunitario Coquí.

**Abstract**

The St. Lawrence Estuary is renowned for the abundance and diversity of marine mammals that come to feed in summer or live all year round in its waters. It is also a major seaway linking the Great Lakes to the Atlantic Ocean. Due to the high maritime traffic in this seaway, negative impacts on marine mammals are an issue to be studied. In the current context of sustainable development and protection of marine species at risk in Canada, such as the beluga whale (*Delphineptarus leucas*) and blue whale (*Balaenoptera musculus*), it is essential to determine the noise levels to which these species are exposed. In this chapter, the underwater soundscape recorded from August to October 2021 by the Marine Acoustic Research Station (MARS) – consisting of four vertical arrays of three hydrophones deployed in the middle of the Laurentian Channel – is analyzed. In addition to recording the ship's signatures, they continuously acquire ambient noise created by all traffic and cetacean emissions to provide a complete picture of the acoustic context of the St. Lawrence Estuary. An analysis of the relative contribution of wind and traffic noises to ambient noise at three different 1/3-octave bands has been achieved. At low frequencies (50 Hz), used by blue whales' long-range communication signals, traffic noise dominates the soundscape. At mid-frequencies (300 Hz), used by humpback whales' short-range signals, a mixed regime is observed. At high frequencies (6300 Hz), used by belugas' whistles, wind noise dominates the soundscape.

## Introduction

### Whales and Shipping Lane in the St. Lawrence

The importance of the Estuary and Gulf of St. Lawrence for the abundance and diversity of marine mammals has long been recognized. The abundance of marine mammals in the Gulf was first reported by Jacques Cartier during his voyage to the New World in 1534. The diversity of marine mammals in the St. Lawrence Estuary is composed of two orders: cetaceans (Mysticetes and Odontocetes) and pinnipeds (Odobenidae and Phocidae). Up to 16 species of cetaceans and pinnipeds may visit the Estuary in any given season. The region boasts resident populations of beluga and harbor seals (*Phoca vitulina*), as well as migratory populations of minke whales (*Balaenoptera acutorostrata*), humpback whales (*Megaptera novaeangliae*), fin

whales (*Balaenoptera physalus*), and blue whales (*Balaenoptera musculus*), which use the Estuary as a summer feeding ground due to its high concentrations of forage species. These species frequent the Estuary and contribute to its underwater soundscape (Kingsley and Reeves 1998; Edds et al. 1987). The St. Lawrence system is also a major shipping lane linking the Atlantic Ocean to the Great Lakes which has effects on local marine life, including exposure to underwater noise (Chion et al. 2017; Gervaise et al. 2015; Gervaise et al. 2012) and collisions with marine mammals (Krause 2008).

## Effects of Noise on Whales

In the current context of sustainable development and the protection of species at risk in Canada, such as the North Atlantic right whale (*Eubalaena glacialis*) (Gervaise et al. 2021; Meyer-Gutbrod et al. 2018; Brillant et al. 2017; Elvin and Taggart 2008), blue whale, fin whales, and the beluga whale (*Delphineptarus leucas*) (Lesage 2021; Vergara et al. 2021; Fisheries and Oceans Canada 2020; Bailleul et al. 2012a, b; Department of Fisheries and Oceans 2012), there is a need for research that investigates the effects of noise on marine mammals.

## MARS Project

The MARS project (http://www.projet-mars.ca) is an applied research project that aims to understand and measure the underwater noise radiated by ships to propose relevant methods for its reduction, in synergy with Canadian shipowners. The MARS project scientific program is based on the development and deployment of world-class instrumentation in the St. Lawrence Estuary near Rimouski (Fig. 1). An underwater acoustic recording station for measuring the acoustic signature of ships operating on the St. Lawrence, hereafter called "the station" (Fig. 2), was deployed in the middle of the Laurentian Channel from August to November 2021. It is a cabled instrument that records continuously for a frequency between 5 Hz and 50 kHz. Data is sent via the surface buoy, which establishes a connection with Rimouski via the cell phone network. In addition to measuring the acoustic signature of ships, this data also enable observation of the local soundscape.

## Sound Levels Recorded by the MARS Station

The underwater soundscape is very rich with sounds generally classified into three categories: biophony, geophony, and anthropophony (Krause 2008). The objectives of this chapter are to quantify the sound levels in the St. Lawrence recorded by the MARS station during the 3 months of the operating period and to identify the main sources that generate them. To achieve these objectives, the ambient noise will be first analyzed, and the sound levels measured at the station will be quantified by frequency band. Then, the sources responsible for these sound levels (geophony or anthropophony) will be identified and the environmental parameters best describing

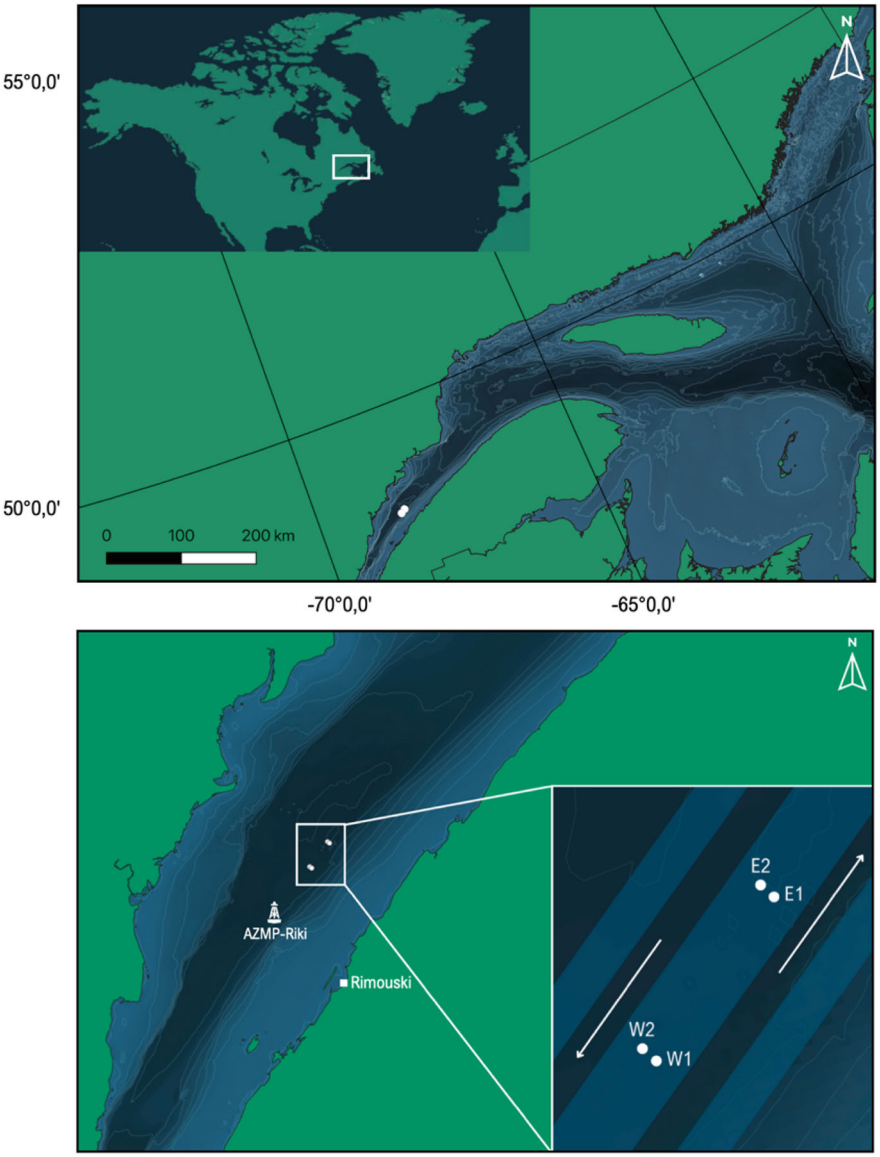

**Fig. 1** Implementation of the MARS acoustic station in the center of the traffic separation lane of the St. Lawrence seaway, offshore Rimouski. *Up:* the white points are the location of the hydrophones. *Below:* the white arrows illustrate trajectories of ships. AZMP-Riki is an oceanographic and meteorological buoy designed by Multi-Electronics (MTE) and operated by Fisheries and Oceans Canada for the Atlantic Zone Monitoring Program (AZMP), located 9 km away from the station (Pêches et Océans Canada – Fisheries and Oceans Canada 2022). The bathymetric datasets come from NASA.

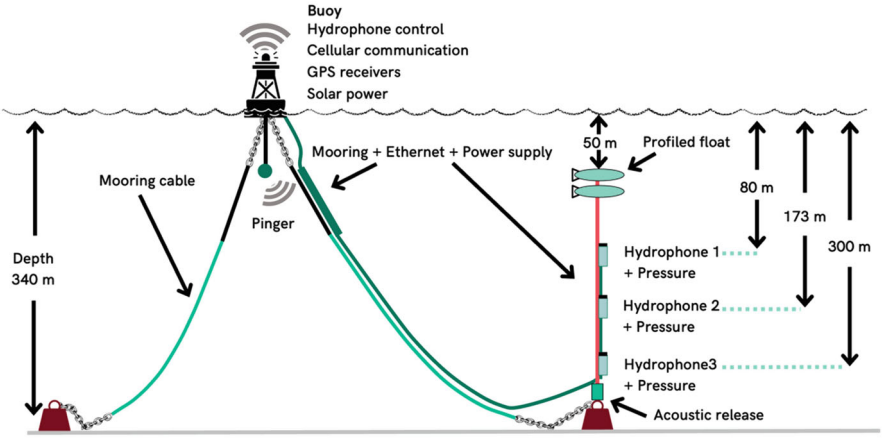

**Fig. 2** Geometry of a MARS station antenna

them will be defined: surface wind speed for geophony and distance to the nearest ship for anthropophony. The sound levels will be described in the three chosen 1/3-octave bands (50 Hz, 300 Hz, 6300 Hz), representative of the wide bandwidth covered by cetacean sounds.

## Materials and Methods

### AIS Data

Traffic data were collected using an Automatic Identification System (AIS) receiver, installed on shore at 20 km from the station, allowing detection of ships within 100 km. Time series of longitude, latitude, and speed over ground have been collected as well as other relevant information such as length, width, draft, type, and age of each vessel. A speed criterion was applied to remove vessels with a speed less than 2 knots to avoid bias caused by vessels stopped in nearby harbors. From the position of each vessel, the distance between the acoustic station and the nearest vessel was calculated with a time resolution of 5 min. To focus on traffic noise only, data collected when wind noise is not prevalent (wind speed $<5$ m.s$^{-1}$) was considered for analysis.

### Wind Speed Data

Wind speed was recorded by the AZMP-RIKI oceanographic and meteorological buoy (Fig. 1) designed by Multi-Electronics (MTE) and operated by Fisheries and Oceans Canada for the Atlantic Zone Monitoring Program (AZMP) located 9 km away from the station (Pêches et Océans Canada – Fisheries and Oceans Canada 2022). From August to October 2021, time series of the 60-s average surface wind

speed was extracted with a time resolution of 30 min. From the wind speed recorded by the PMZA-RIKI buoy, a 120-min moving average was applied. To focus on wind-generated noise only, data collected in the absence of nearby ship, when the nearest vessel was at least 30 km away from the station, was considered for analysis (Fig. 5b).

## Acoustic Recordings

The acoustic station has been designed to be ANSI/ASA S12/64-2009 compliant (ANSI/ASA 2009). It consists of four moorings (E1, E2, W1, W2) forming two gates spaced eight kilometers apart anchored between the two shipping lanes of the St. Lawrence, off Rimouski at approximately 48°N and 68°W (Fig. 1). It records continuously during its operating period. Each mooring consists of a surface buoy and a vertical array of three acoustic recorders (Fig. 2). The buoy provides energy to the recorders and communication with the shore. The acoustic recorders are calibrated and placed at 80 m, 173 m, and 300 m, respectively, along a vertical array. The line is held vertically by floats. Floats and cables are profiled to reduce current-induced vibrations. The moorings themselves generated underwater noise. This noise takes the form of periodic knocking and oscillations, and it is more intense during periods of high current. The proportion of noiseless measurements varied between 18% (antenna W1, bottom hydrophone) and 68% (antenna E1, bottom hydrophone). The E1 mooring had noise-free measurement proportions of 52%, 62%, and 68% for the three hydrophones from top to bottom. In this chapter only the data collected by the bottom (300 m) hydrophone of E1 mooring was analyzed. It is composed of an AURAL M3 recorder developed by MTE-OpDAQ comprising a Geospectrum hydrophone with a sensitivity of $-174.5 \pm 3$ dB re 1 V/μPa for a frequency between 5 Hz and 50 kHz, a gain of 18 dB, and an acquisition scale $\pm 2.5$ V, 24 bit. The raw acoustic data files from all four moorings were transmitted once per week through the cellular network. The complete acoustic dataset was also accessed after recovery of the system at the end of the operating period. It is composed of 20,308 5-min .wav files, sampled at 16 kHz, representing ~1692 h (~70 days) of recordings and 326.22 GB. For this chapter, noise levels in third octave bands (Third Octave Level (TOL), dB re 1 μPa) were extracted using the PAMGuide software (Merchant et al. 2015), using a 1-s Hann windows and 50% overlap. The minimum TOL value on a 5-minute sliding window was extracted to provide a smoothed time series of the background noise level. Central frequencies of the three 1/3-octave bands are, respectively, 50 Hz, 316 Hz, and 6309 Hz. Spectrograms were generated using Matlab (0.5 s Hann window, 50% overlap) to allow visualization of the dataset.

## Focus on Three Third Octave Bands

For this chapter, the analyses focused on three 1/3-octave bands. The low frequencies (50 Hz) are representative of the frequencies used by the large baleen whales: the blue whale and the fin whale. The medium frequencies (300 Hz) are representative of the frequencies used by the other baleen whales: the humpback whale, the

North Atlantic right whale, and the minke whale (*Balaenoptera acutorostrata*). And the high frequencies are representative of the frequencies used by the toothed whales: sperm whale (*Physeter macrocephalus),* northern bottlenose whale (*Hyperoodon ampullatus*), killer whale (*Orcinus orca*), Atlantic pilot whale (*Globicephala melas*), beluga whale, Atlantic white-sided dolphin (*Lagenorhynchus acutus*), white-beaked dolphin (*Lagenorhynchus albirostris*), and harbor porpoise (*Phocoena phocoena*), and seals: harbor seal (*Phoca vitulina*), harp seal (*Pagophilus groenlandicus*), and gray seal (*Halichoerus grypus*). The construction of scatter plots of sound pressure level (SPL) in dB re 1 µPa versus wind speed, distance from the nearest vessel and SPL versus wind speed for vessels located more than 30 km from the station were performed to describe the recorded noise levels for these three 1/3-octave bands in relation to these covariates.

## Results

### Sound Pressure Levels

The median and percentile distributions of the noise levels recorded by the station were calculated (Fig. 3). A ~10 dB re 1 µPa dispersion between the SPL values of the 25th and 75th percentiles of the third-octave band 300 Hz and 6300 Hz was observed, which is consistent with previous observations in the area (Simard et al. 2010). The typical spectral slope of wind noise is visible at all percentiles of the distribution in the high frequencies, from ~500 Hz (Fig. 3), and the median level was

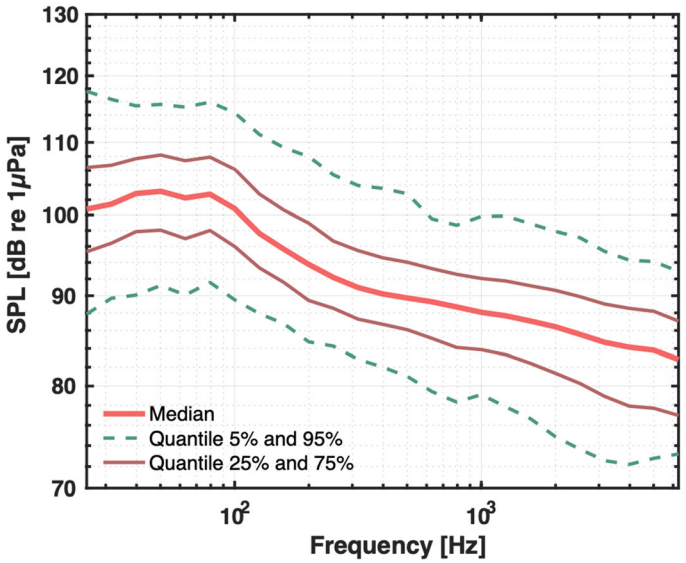

**Fig. 3** Percentiles of noise levels recordings by the station from August to October 2021 with the median received noise level in the 25 Hz–6 kHz band (black dotted line)

82.8 dB re 1 μPa in the third-octave band 6300 Hz. The typical signature of maritime traffic noise centered at 50–100 Hz (Wenz 1962) is visible on all percentiles of the distribution, and the median level, 103.1 dB re 1μPa, in the third-octave band 50 Hz corresponds to the values proposed for heavy traffic noise by the Wenz curves (Wenz 1962) (Fig. 3). A strong contribution of traffic noise to our observations is to be expected, the station being positioned between two shipping lanes, at 2 km from each, with a daily traffic in the Lower St. Lawrence Estuary during the 3-month period of about 22 ± 3 ships per day in both directions (Gervaise et al. 2012).

## Wind Noise

The correlation between the time series of noise level and wind speed − calculated with the *corr* Matlab function (MATLAB Version: 9.11.0.1809720 (R2021b) Update) − shows three frequency ranges where the relationship between TOL and wind speed appears to differ: 10–100 Hz, 100 Hz–1000 Hz, and the frequencies >1000 Hz (Fig. 4). Noise levels at 50 Hz, 300 Hz, and 6300 Hz were analyzed with regard to surface wind speed (Fig. 5a). At low frequencies, no tendency is noticed, and the dispersion of ~25 dB re 1 μPa is coherent with the dispersion of the ship source level observed by Simard et al. 2016, in the area. The tendency is partial at mid-frequencies and the pattern observed is more complex: at reduced wind speed (<5 $m.s^{-1}$), noise level is dominated by traffic noise (~25 dB re 1 μPa spread and no trend); at high wind speed (>5 $m.s^{-1}$), noise level is clearly influenced by wind speed (Fig. 5a). At high frequencies, wind-generated noise dominates the soundscape, therefore, noise level increases noticeably with wind speed as previously observed (Cauchy et al. 2018; Mathias et al. 2016; Vagle et al. 1990; Wenz 1962) and the observed tendency (Fig. 5a) suggests that at 50 Hz the wind noise is weak and is masked by anthropophony. While at 300 Hz, wind noise is masked by anthropophony for wind <5 $m.s^{-1}$ and wind-generated noise dominates the soundscape at 6300 Hz.

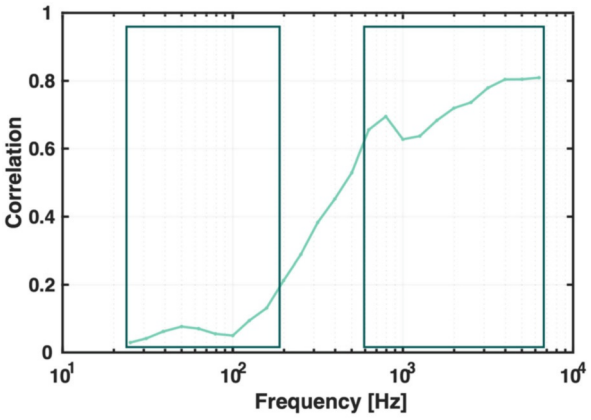

**Fig. 4** Correlation between the wind speed and observed noise levels recordings by the station from August to October 2021 based on 1/3rd octave band

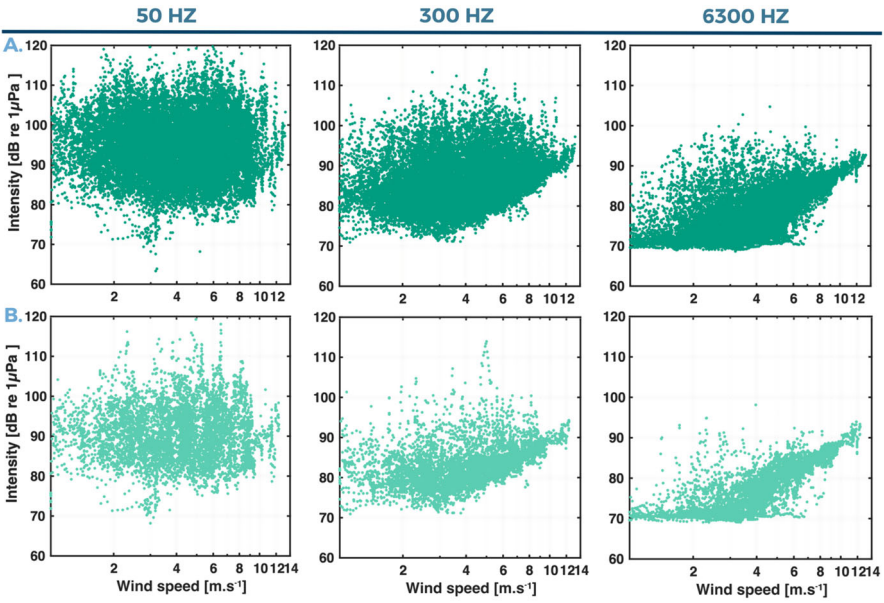

**Fig. 5** Distribution of noise levels at 1/3-octave bands 50 Hz, 300 Hz, and 6300 Hz as a function of wind speed recorded by AZMP-RIKI (**a**) complete dataset, (**b**) in the absence of ships in 30 km around the station (central frequencies of the three 1/3-octave bands are, respectively, 50 Hz, 316 Hz, and 6309 Hz)

The influence of the wind in the low frequencies is still not visible with the cleaning data, noise level likely being dominated by distant traffic, as stated by Wenz (1962). At medium frequencies, the relationship between wind speed and noise level becomes clearer: noise generated by local traffic is removed and the dependency of noise level with high wind speed (>5 $m.s^{-1}$) is highlighted. Finally, the dependency of high-frequency noise level with wind speed stays clear.

## Traffic Noise

Noise levels at 50 Hz, 300 Hz, and 6300 Hz were analyzed with regard to the distance of nearest ship to the station (Fig. 6). The noticeable spreading of the noise levels, of ~25 dB re 1 µPa, is coherent with the dispersion of ship source level observed by Simard et al. (2016) in the area. Despite a low tendency, distance to the nearest vessel seems to partially explain the SPLs considering the logarithmic decrease in noise levels with distance from the nearest vessel to the station in the three frequency bands. In fact, as the ship moves further away, noise levels decrease up to a certain limit, different for the three frequencies considered (Fig. 6). Therefore, other parameters must be considered such as the high variability of emitted noise (Simard et al. 2016) and the number of ships within a given radius (Magnier and Gervaise 2020).

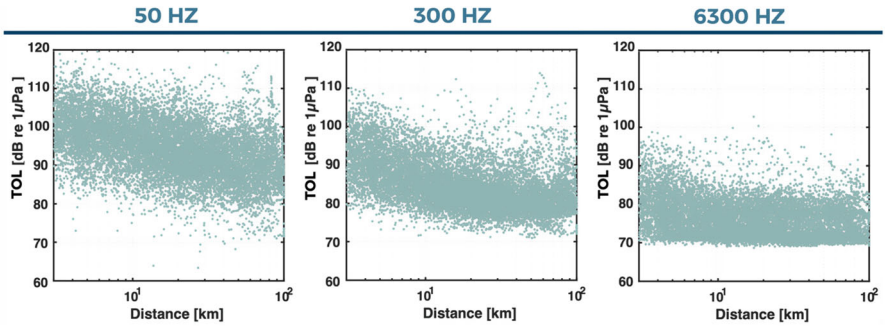

**Fig. 6** Distribution of noise levels at 1/3-octave bands 50 Hz, 300 Hz, and 6300 Hz as a function of distance of the nearest vessel from the station in wind speed $<5$ m.s$^{-1}$ conditions

## Discussion

### Distant Maritime Traffic Noise Dominant Above 200 Hz

Noise from distant traffic dominates the observed soundscape up to 200 Hz in all weather conditions. It is more complicated at mid- and high frequencies because the wind sometimes dominates. Further analysis will allow estimation of vessel's acoustic footprint, as the range over which vessel-generated noise exceeds the natural ambient noise (wind-generated), and the noise generated by ship category.

### Wind Noise Dominant Above 500 Hz

Co-located observations of wind speed and underwater noise level show a clear relationship above 500 Hz. Further analysis could consider wind direction to account for effects of a developed sea state, a fully developed sea being only possible at the station location under NE or SW winds, along the direction of the St. Lawrence Estuary. Tidal currents should also be considered to analyze their influence on sound levels. Access to similar recordings from the MARS hydrophones deployed at 80 and 170 m depths will provide valuable information regarding the depth dependency of wind-generated noise (Cauchy et al. 2018; Vagle et al. 1990).

### What Noise Levels Are St. Lawrence Whales Exposed to?

Up to 16 marine mammal's species use the St. Lawrence throughout the year (McComb-Turbitt et al. 2021; Druskat et al. 2019; Simard et al. 2019; Ramp et al. 2015; Teloni et al. 2008; Richard et al. 1990). The diversity of marine mammals in the St. Lawrence Estuary is composed of migratory populations of humpback whales, minke whales, blue whales, and fin whales, which use the estuary as a

summer feeding ground due to its high concentrations of forage species (Edds et al. 1987; Kingsley and Reeves 1998), and St. Lawrence resident populations of beluga whales and harbor seals (*Phoca vitulina*), which use the estuary as a summer feeding ground due to its high concentrations of forage species. In fact, this is the region with the highest krill aggregation documented to date in the Northwest Atlantic (Simard 2009). Six species have been identified in this chapter: blue whales (18–90 Hz), fin whales (15–100 Hz), humpback whales (100–710 Hz), minke whales (50–2000 Hz), sperm whales (1–30 kHz), and beluga whales (2–150 kHz) (Fig. 7).

The MARS station is important for two types of analysis. First, a long-term acoustic observatory such as this can provide means of monitoring animal populations, i.e., their seasonal occurrence patterns, migration timing, and relative abundance. And secondly, given the wide range of frequencies used by whales (15 Hz–150 kHz), it is ecologically important to know what levels of noise they are exposed to. Impacts of underwater noise on whales such as belugas include behavioral changes affecting foraging efficiency, such as avoidance and disturbance (Gomez et al. 2016), changes in vocalization behavior (Lesage et al. 1999), communication masking affecting the animal's ability to socialize and locate prey (Erbe et al. 2016), and hearing loss (Finneran et al. 2002; Schlundt et al. 2000).

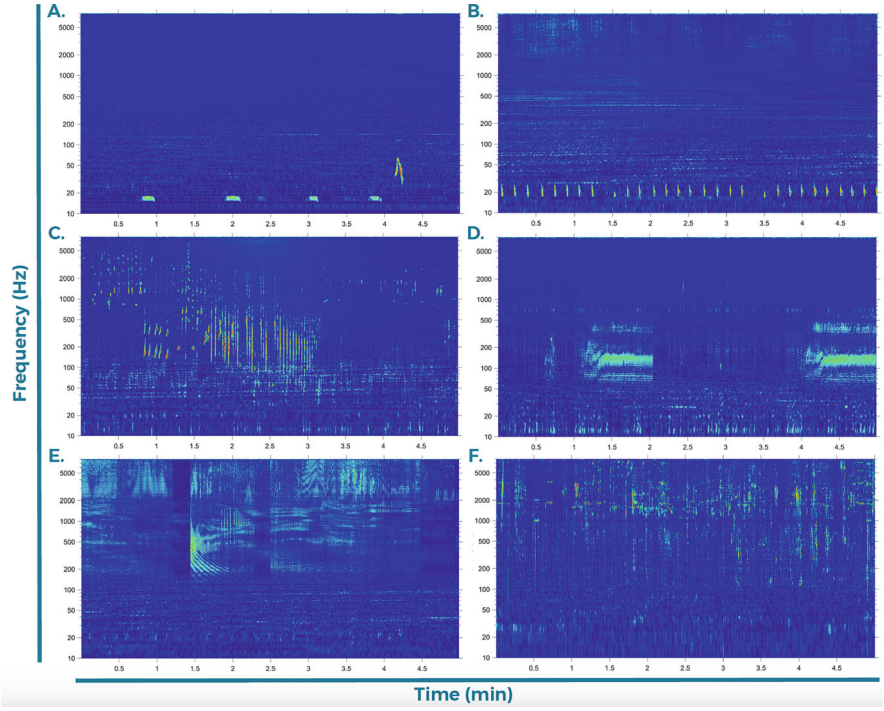

**Fig. 7** Spectrograms of cetacean sounds detected by the MARS station. (**a**) Blue whale, (**b**) Fin whale, (**c**) Humpback whale, (**d**) Minke whale, (**e**) Sperm whale, and (**f**) Beluga whale

Most of these studies have used behavioral attributes such as changes in site frequentation, dive patterns, swimming speed, movement orientation, herd cohesion, and dive synchronization to indicate possible disturbance or stress caused by marine traffic (Richardson et al. 2013). Numerous studies have examined the effects of high levels of underwater noise on the vocal behavior and hearing ability of marine mammals (Southall et al. 2008, 2019; National Marine Fisheries Service 2018; Lesage et al. 1999) and consensus has emerged; while less consensus has been established on behaviors and masking (Erbe et al. 2022). Given that marine mammals rely on the acoustic sensory channel for many of their activities, it is even more important to improving our knowledge of their tolerance thresholds and listening range, to target the frequencies at which anthropogenic noise needs to be attenuated to limit the effects on their functions that depend on underwater ambient noise levels.

## Conclusion

### Influence of Sound Sources in the St. Lawrence Soundscape

The influence of local traffic and wind speed on noise level at low (50 Hz), medium (300 Hz), and high (6300 Hz) frequencies have been assessed. The main results of this study are that distant maritime traffic noise is dominant above 200 Hz and wind noise is dominant above 500 Hz. In conditions of wind $<5$ m.s$^{-1}$ the traffic noise dominates and wind $>5$ m.s$^{-1}$ the wind noise dominates. For the high-frequency whistles and echolocation clicks of belugas, the wind noise dominates the soundscape.

### What Knowledge Can Provide the MARS Project?

The MARS project simultaneously deployed 12 acoustic loggers at four locations and three different depths in the Laurentian Channel. Three months of acoustic recordings from one hydrophone were analyzed to provide a qualitative description of the soundscape observed at the station. These data were compared to meteorological data (wind speed) and anthropogenic activities (shipping traffic) in the St. Lawrence. Analyses based on acoustic recordings from the MARS station provide a basis for studying the evolution and variations of the soundscape of the St. Lawrence. They also include preliminary studies for analyses of sound propagation, the acoustic footprint of ships, and the effect of anthropogenic sound on marine mammal communications and listening ranges.

**Acknowledgments** The MARS project is funded by the *Ministère de l'Économie, de l'Innovation et de l'Énergie du Québec*, Transport Canada, shipowners (Algoma, CSL, Desgagnés, Fednav), OpDAQ, MTE Instruments, and the Société de développement économique du Saint-Laurent. Weather observations were provided by AMZP-RIKI buoy from the Atlantic Zone Monitoring Program of Fisheries and Oceans Canada (Pêches et Océans Canada – Fisheries and Oceans Canada 2022). The author would like to sincerely thank the committee of the conference AN2022 for their generous conference support.

**Abstract**

Anthropogenic noise is known to influence acoustic environments and the habitats of marine species. Acoustic indices used to evaluate relative contributions of and trends in anthropogenic noise have had mixed success when applied to marine environments. This study assessed which acoustic metrics represent the level of anthropogenic activity within Abrolhos Bank, the most important humpback whale (*Megaptera novaeangliae*) breeding site in the western South Atlantic. Metrics included power spectral density (PSD), long-duration false-color (LDFC) spectrograms, ribbon plots, and nine acoustic indices. Metrics were calculated within a control area with low vessel traffic and a treatment area with high vessel traffic. Contributing sound sources included vessels, humpback whales, and fish species. The treatment area had higher PSD levels, indicative of high vessel noise conditions. Normalized difference soundscape index (NDSI), acoustic events (EVN), and acoustic complexity index (ACI) scored lower for higher levels of anthropogenic noise. ACI was influenced by high levels of humpback vocal activity and should be used with caution as a diversity proxy. LDFCs clearly confirmed the presence of singing humpbacks, fish choruses, and vessels, but only humpback songs were evident in ribbon plots. Findings in this chapter confirmed that PSD and spectral probability density plots are the current best way to characterize anthropophony within marine soundscapes.

## Introduction

A major challenge we face today is finding how to evaluate both biodiversity and human disturbance in the mosaic of natural to urban areas to determine conservation priorities in a world that is suffering rapid changes due to anthropogenic impacts. This task is especially hard for cryptic species and remote habitats, for whom classical ecological measurements are time-consuming and limited by human and financial resources (Sueur et al. 2008). In this perspective, acoustic recordings play an increasingly important role in monitoring trends within environments, both in terrestrial and marine ecosystems (Gasc et al. 2013; Pieretti et al. 2017; Lindseth and Lobel 2018; Alcocer et al. 2022).

For decades bioacoustic research focused on specific species and/or vocalizations. However, different passive acoustic monitoring (PAM) technologies have gained greater autonomy and are now capable of recording at higher sampling rates continuously for long periods of time (Sousa-Lima et al. 2013; Havlik et al. 2022). This scenario enables and forces us to look not just at a specific species but at the ensemble of sounds emanating from a whole ecosystem. These sounds may be derived from animals (zoophony, sensu Ferreira et al. 2018), from geophysical

events (geophony) or from human activities (anthropophony) (Krause 1987), and the sum of all these acoustic events is called "soundscape," defined as "the temporal and spatial distribution of sound through a landscape, reflecting important ecosystem processes and human activities" (Pijanowski et al. 2011).

The main challenge of using a soundscape scale is the choice of the adequate method to use, as analytical metrics continue to be developed and improved. Traditional measurements include broadband sound pressure level (SPL) and spectral analysis such as power spectral density (PSD) and fractional octave band levels (1/3 octave band) (Merchant et al. 2015). A more recent approach is the use of acoustic indices to summarize some aspect of the spectral-temporal distribution of acoustic energy in a recording (Towsey et al. 2014; Alcocer et al. 2022). The indices may be derived from waveforms, spectrograms or can be based on the relative contribution of the components of a soundscape (zoophony, geophony, and anthropophony), aiming to reflect different ecological aspects of a soundscape.

So far, results have been showing that weighted combinations of indices yield more ecologically useful information than single ones (Towsey et al. 2014). However, acoustic indices have shown inconsistent performance of correlation with diversity metrics (Alcocer et al. 2022), being influenced by transitory or permanent background noise (Sueur et al. 2014; Gasc et al. 2015; Bohnenstiehl et al. 2018). Another bias is the fact that the studies developed so far were mainly designed for terrestrial environments, despite the ecological importance of sound for several marine species (Tucker et al. 2014; Sueur et al. 2014; Fuller et al. 2015; Ferreira et al. 2018; Havlik et al. 2022). Furthermore, most of the studies performed in marine habitats were directed to coastal and shallow areas (having fish and crustaceans as major contributors to zoophony), concentrated in the northern hemisphere, with very little inspection of mammal contributors (Staaterman et al. 2013; Kaplan et al. 2015; Harris et al. 2016; Bertucci et al. 2016; Havlik et al. 2022; Alcocer et al. 2022). In addition, a visualization tool called long-duration false-color (LDFC) spectrogram was developed to facilitate the ecological interpretation of long-duration audio recordings (Towsey et al. 2014) and has nearly not yet been applied to marine ecosystems.

Hence, the goal of this study was to analyze how different acoustic indices react to two levels of anthropophony in a marine environment, guiding future uses of such measurements. For this purpose, PSD and LDFC analyses were included, and recordings made simultaneously in two areas were compared: one with high level of vessel traffic (treatment) and another outside the main navigation route (control). The low-frequency recordings (up to 1000 Hz) show male humpback whale (*Megaptera novaeangliae*) singing as the major contributor to zoophony, while vessel noise is the major contributor to anthropophony. This low-frequency spectrum is interesting because it is where major acoustic overlap between biotic and abiotic sources (geophysical and human-generated noise) occurs and hence may help elucidate to what extent each index is affected by abiotic noise rather than by biological sounds, a troubling factor already highlighted before for aquatic environments (Parks et al. 2014).

## Material and Methods

### Study Area

Study area was situated at the Abrolhos Marine National Park, a national protected area inside the northeast portion of the Abrolhos Bank (IBAMA/FUNATURA 1991). Abrolhos Bank is a sediment-capped volcanic bank in the east coast of Brazil (16°40′–19°30'S) with an approximate area of 30,000 km$^2$ and shallow mean depth of 30 m (Fainstein and Summerhayes 1982). It consists in an enlargement of the continental shelf with the bottom covered of coral reefs, mud, sand, and calcareous algae, and it comprises the most extensive and richest area of coral reefs in the Southwestern Atlantic (Leão and Kikuchi 2001). Abrolhos Bank is also the most important humpback whale breeding site in the western South Atlantic Ocean (Siciliano 1997), being a preferred concentration area of this population, estimated to be around 20,400 individuals (Bortolotto et al. 2017). Inside the national park, fishing is forbidden, and there are some restrictions for vessel traffic that mainly consists of small touristic boats (IBAMA/FUNATURA 1991; Hoyt 2001).

### Sound Data Acquisition

The sound data used in this study was acquired during the year 2005 (Sousa-Lima et al. 2018). Approximately one-third of the Abrolhos Marine National Park (314 km$^2$) was acoustically monitored using two arrays of four marine autonomous recording units ("MARUs" developed by the K. Lisa Yang Center for Conservation Bioacoustics of the Cornell Laboratory of Ornithology) fixed at the bottom floor at depths of around 20 m. The arrays were deployed northwest of the Abrolhos archipelago, one at an area of high level of vessel traffic (treatment, at 38°43′3.785"W, 18°0′47.237"S) and another in an area of little to no vessel traffic (control, at 38°43′43.777"W, 17°56′21.061"S) (Sousa-Lima et al. 2018), and one recorder from each array was selected for analysis (Fig. 1). Recording areas, though relatively close, were considered independent since low-frequency sounds are

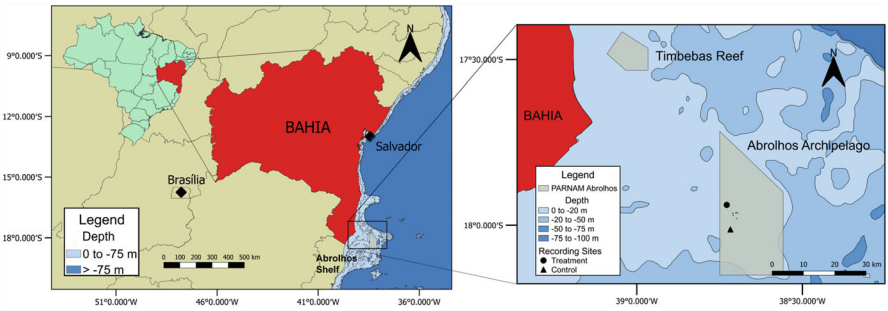

**Fig. 1** Map of the study area. Location of the recording sites, control (triangle, coordinates X 529881 Y 8008340), and treatment (circle, coordinates X 528717 Y 8016522) inside of PARNAM Abrolhos (Abrolhos Marine National Park), Abrolhos Bank, BA/Brazil

greatly attenuated in shallow depths (Forrest et al. 1993) and the same singing humpback whale individual could not be heard simultaneously in MARUs from the two different arrays. The arrays were programmed to record continuously during the breeding season of humpback whales, from 15 July to 01 October of 2005, at a sampling rate of 2000 Hz (Table 1).

## Sound Data Analysis

To produce calibrated measurements and calculate the power spectral density (PSD) of the recordings, the template code *PAMGuide* (Merchant et al. 2015) was used under MATLAB (MATLAB 2022). PSD is a standardized spectrum of sound levels across frequencies, estimating the strength of energy variation as a function of frequency. PSD is considered as one of the most comprehensive analyses of the sound-level distribution (Merchant et al. 2015; Lindseth and Lobel 2018). In *PAMGuide*, the following settings were used: Mh of −165 dB re: 1 Vrms/1 μPa, gain of 23.5 dB, vADC of 1.414 (estimated value), chunk size of 300 s, linear scale, Hamming window, and Welsh average of 1200s, resulting in a 10-min resolution analysis of the 79 days for each area.

For the calculation of acoustic indices and generation of LDFC spectrograms, the open-source software *QUT Ecoacoustics Analysis Programs* was used under Windows Command Prompt (Truskinger et al. 2014; Towsey et al. 2018); the indices used are listed in Table 2 (see Towsey 2017 for detailed information on indices calculation). LDFCs are based on three indices known to capture distinct characteristics of sound that are mapped to red-green-blue colors and displayed in spectrogram-like format. The calculation of the acoustic indices and production of LDFCs were performed for each 24 h using a 1-minute resolution (hence, each day was primarily split in 1440 1-minute segments), using the following settings: FFT length of 512, Hamming window, low-frequency bound of 100 Hz, mid-frequency bound of 900 Hz, high-frequency bound of 1000 Hz, and 0% overlap. LDFCs were based on ACI, temporal entropy (ENT), and EVN: ACI is more sensitive to complexly structured calls having multiple levels of amplitude modulation, ENT responds to acoustic events of

**Table 2** Definition and properties of the acoustic indices calculated for the investigation of anthropophony influence on acoustic index performance in a marine soundscape. See Towsey (2017) for detailed calculation

| Index | Name/formula (if available) | Definition/calculation |
|---|---|---|
| **ACI** | Acoustic complexity index (degree of complexity)<br>$ACI[f] = \sum i\lvert A_{if} - A_{i-1,f}\rvert / \sum iA_{if}$<br>$i$ index over frames<br>$f$ index over freq. bins | The average absolute fractional change in spectral amplitude between two adjacent intensities, presented as an average of all frequencies, widely used as a measure of diversity. See Pieretti et al. (2011) for index idealization, though Towsey (2017) modifications were used on the index calculation performed (only the mid-band is used) |
| **BGN** | Background noise | An estimate of the background noise in each 1-minute recording. It is set equal to the mode of the energy distribution in the waveform envelope, according to the method of Lamel et al. (1981) |
| **SNR** | Signal-to-noise ratio | The decibel difference between the maximum envelope amplitude and the background noise in any minute segment |
| **ACT** | Acoustic activity | The fraction of noise-reduced decibel envelope which exceeds 3 dB above the level of background noise |
| **ENT** | Temporal entropy (acoustic energy concentration in time)<br>$H[t] = -(\sum ipmf_i \, x \, log_2(pmf_i))/log_2 N$<br>$ENT = 1 - H[t]$<br>$pmf$ probability mass function<br>$i$ index over frames<br>$N$ number of frames | The squared amplitude values in each frequency bin are normalized to unit area and treated as a probability mass function; classically it is a measure of energy "dispersal" through time, and here it is converted into a measure of energy concentration (ENT = 1 – H[t]). Derived from the noise-reduced amplitude envelope |
| **EVN** | Acoustic events (Count of Acoustic events per minute)<br>$\theta = 3$ dB | The number of acoustic events (decibel value in a bin that crosses a 3 dB threshold) per minute in each noise-reduced frequency bin. Derived from the decibel envelope |
| **EAS** | Entropy of the averaged spectrum<br>EAS = 1 – H[a] | Calculates the average of the mid-band spectra then calculates its entropy as described for temporal entropy. A measure of the "concentration" of mean energy through the spectrum, expected to be like the Gini index. Derived from the noise-reduced frequency spectrum |
| **NDSI** | Normalized difference soundscape index (index of health quality)<br>NDSI = (zoophony – anthropophony)/(zoophony + anthropophony) | Estimates the level of anthropogenic disturbance on the soundscape by computing the ratio of anthropophony to zoophony in a sound file. Ranges between −1 (prevalence of anthropophony) and 1 (prevalence of zoophony). See Kasten et al. (2012) for index idealization and calculation |

(continued)

**Table 2** (continued)

| Index | Name/formula (if available) | Definition/calculation |
|---|---|---|
| **SPD** | Spectral peak density (Density of peaks in Spectrum) | A measure of the average number of cells in the mid-frequency band of a 1-minute spectrogram that is identified as being local maxima (when its decibel value exceeds a 6 dB threshold, being greater than the values in the frequency bins on either sides). Derived from the decibel spectrogram. Considered as an "ecological index" that attempts to be an acoustic measure of species richness (Towsey 2017) |

concentrated energy such as pulses or croaks, and EVN responds to high pulse rates (Towsey et al. 2018). False-color spectrograms were built with 2345 frames (frame duration = 25.58 ms) and 256 frequency bins (frequency resolution of ~3.91 Hz).

In addition, ribbon plots of the 79 days were made for control and treatment areas. Ribbon plots are a vertically stacked series of 24-hour LDFCs whose vertical resolution is reduced (1440 × 32-pixel ribbons), in a way that is possible to attach and visualize several months of audio recordings (Phillips et al. 2017). Hence, it is possible to reveal progressive patterns of changes occurring over time at the cost of losing detailed information contained in LDFCs.

## Statistical Analysis

For a description of the areas, a general inspection of daily spectrograms was performed, and the proportion of minutes containing the presence of vessels and humpback whale sounds was estimated based on visual and aural inspection of audio files in 2-minute window spectrograms with no overlap and 1024 FFT.

To understand how the acoustic indices respond to different levels of anthropophony and zoophony, a customized dataset consisting of recordings with different proportions of anthropophony (vessel noise) and zoophony (humpback whale vocalization) was generated. Recordings from the complete, real dataset were used to create ten 1-minute samples of each of these combinations: V100 (100% of the recording with vessel noise), V75W25 (75% of the recording with vessel noise and 25% with humpback whale vocalizations), V5W5 (50% of the recording with vessel noise and 50% with humpback whale vocalizations), V25W75 (25% of the recording with vessel noise and 75% with humpback whale), and W100 (100% of the recording with humpback whale). All the acoustic indices (Table 2) for the customized dataset were calculated, and the results were compared with those from the real dataset.

After exploratory data analysis (Zuur et al. 2010) indicating heterogeneity and temporal autocorrelation of data, a Wilcoxon signed-rank test was used to test for pairwise differences between the areas. For such, a random minute was selected every 3 h (to avoid autocorrelation of the same singing whale, following the procedure in Sousa-Lima and Clark 2008), and 30 random days of the entire recording period were

sampled for pairwise comparison, using a significance level of 0.05. Statistical analysis was performed under R statistical program (R Development Core Team 2022) using the packages dplyr (Wickham et al. 2022), cowplot (Wilke 2020), and ggplot2 (Wickham 2016). A synthesis of the performance of each acoustic index for each area was also generated, as recommended by Lindseth and Lobel (2018).

## Results

A total of 1896 h were analyzed for each sampled area. In the control area, 0.31% of the minutes had the presence of boat noise, while 98.79% of minutes had the presence of humpback whale sounds; in the treatment area, 8.28% of the minutes had the presence of boat noise, while 97.22% had the presence of humpback whale sounds. Hence, both areas were highly dominated by humpback whale vocalizations in the period recorded, whereas the main difference between them was the anthropophony level due to vessel traffic.

In addition, other acoustic events were found through the visual inspection of daily standard spectrograms. Those were continuous events that lasted hours (from 2 to 6 h), found in both areas during the nighttime, usually presenting 3 or 4 harmonics between 50 and 300 Hz. The events were identified as fish choruses, although further confirmation by specialists is recommended (Mcpherson et al. 2016; Pieretti et al. 2017).

## Power Spectral Density (PSD)

Power spectral density analysis resulted in a different pattern for both areas, highlighted by the spectral probability density (SPD) (Fig. 2). Below 400 Hz, the

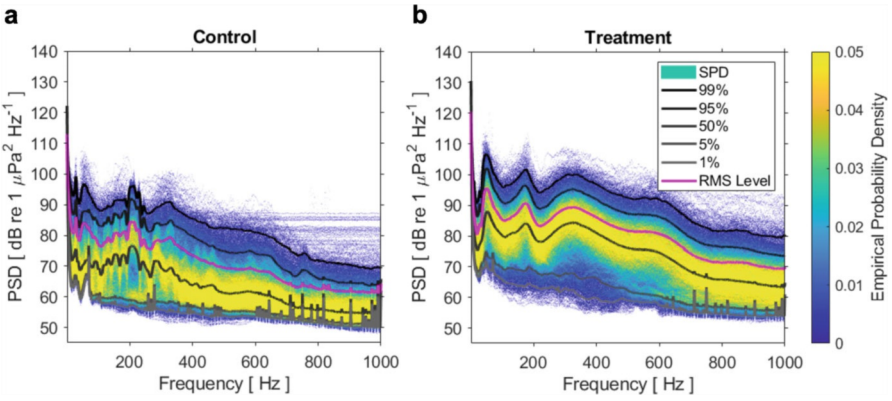

**Fig. 2** Power spectral density (PSD) analysis for control and treatment areas. PSD was calculated over the range of 0–1000 Hz using a 10-min resolution average of the long-term soundscape data from Abrolhos Bank/BR. Two recording areas were used, (**a**) control (lower level of vessel traffic) and (**b**) treatment (higher level of vessel traffic). RMS (root-mean-square) level: pink line; percentiles, gray-colored lines; spectral probability density (SPD), color-graded (yellow are values more likely to occur while dark blue are values less likely to occur)

treatment area showed higher sound levels, with three peaks of ~90 dB re 1 $\mu Pa^2$ $Hz^{-1}$ at around 50 Hz, 180 Hz, and 350 Hz, while the control area showed an irregular pattern of several small peaks between 100 and 300 Hz and bimodality of the spectral probability distribution at 200 Hz (two different sound levels with similar probabilities, around 60 and 80 dB re 1 $\mu Pa^2$ $Hz^{-1}$). Above 400 Hz, SPD of the control area indicated sound levels likely to be around 60 dB re 1 $\mu Pa^2$ $Hz^{-1}$, while in treatment sound levels were higher at around 80 dB re 1 $\mu Pa^2$ $Hz^{-1}$ until falling to ~65 dB re 1 $\mu Pa^2$ $Hz^{-1}$ above 650 Hz.

## Index Performance on the Customized Dataset

In the customized dataset, ACI was the index that best separated the categories, increasing its values consistently with increase of zoophony proportion on the recording (Fig. 3). Other indices that presented such a tendency were EVN, ENT, SPD, ACT, and signal-to-noise ratio (SNR), while entropy of averaged spectrum

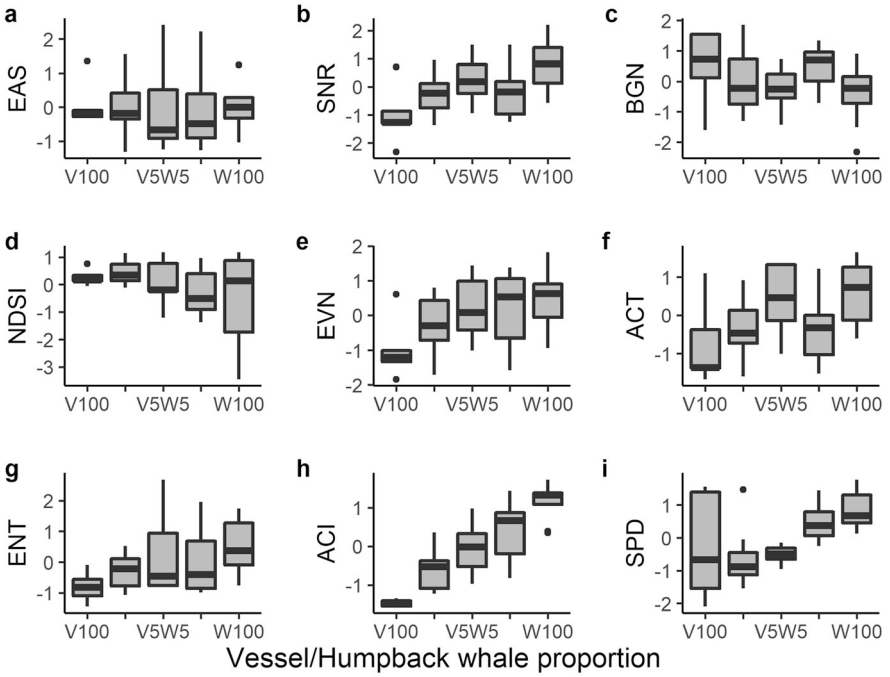

**Fig. 3** Acoustic index performance in different proportions of anthropophony and zoophony: V100 (100% vessel noise), V75W25 (75% vessel noise and 25% humpback whale vocalizations), V5W5 (50% vessel noise and 50% humpback whale vocalizations), V25W75 (25% vessel noise and 75% humpback whale), W100 (100% humpback whale). Indices results are normalized to mean 0. (**a**) Entropy of averaged spectrum (EAS), (**b**) signal-to-noise ratio (SNR), (**c**) background noise (BGN), (**d**) normalized difference soundscape index (NDSI), (**e**) acoustic events (EVN), (**f**) acoustic activity (ACT), (**g**) temporal entropy (ENT), (**h**) acoustic complexity index (ACI), (**i**) spectral peak density (SPD)

(EAS), NDSI, and background noise (BGN) showed a rather constant or inverted result between the levels (e.g., higher scores in V100 level).

## Index Performance on the Complete Dataset

EVN ($p = 0.017$), EAS ($p = <0.001$), and NDSI ($p = <0.001$) showed higher levels in the control area, despite having a lot of overlap between the results of both areas (Fig. 4). ACI had higher values in treatment ($p < 0.001$), as well as SPD ($p = <0.001$) and ACT ($p = <0.001$). SNR ($p = 0.58$) and ENT ($p = 0.66$) did not show any significant difference between the areas, although ENT had higher scores in control when compared to treatment (note the skewed distribution of ENT data). Table 3 is a summary of the performance of each acoustic metric.

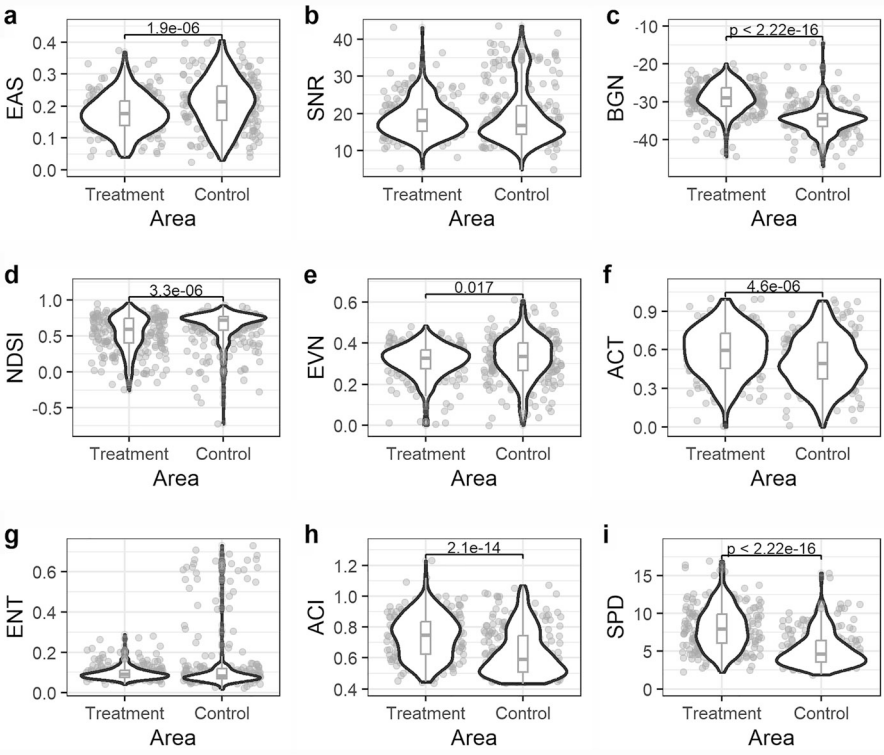

**Fig. 4** Wilcoxon pairwise comparison of index performance in control and treatment areas. Indices results are normalized to mean 0. (**a**) Entropy of averaged spectrum (EAS), (**b**) signal-to-noise ratio (SNR), (**c**) background noise (BGN), (**d**) normalized difference soundscape index (NDSI), (**e**) acoustic events (EVN), (**f**) acoustic activity (ACT), (**g**) temporal entropy (ENT), (**h**) acoustic complexity index (ACI), (**i**) spectral peak density (SPD)

**Table 3** Summary of acoustic metrics in control and treatment areas of Abrolhos Bank/BR during humpback whale breeding season (data by minute)

| Acoustic metric | | Control (N = 113,760) | Treatment (N = 113,760) |
|---|---|---|---|
| **EAS** | Mean ± SD | 0.22 ± 0.09 | 0.18 ± 0.06 |

## LDFCs and Ribbon Plots

When visually comparing standard spectrograms with false-color spectrograms (Fig. 5), the pattern of humpback whale singing activity is easily identifiable in both plots (marked boxes), but even more so in LDFCs, where whale singing appears as a broadband pattern with predominantly yellow (interaction between ACI/red and ENT/green) and pink (interaction between ACI/red and EVN/blue). Vessel passages and fish choruses were detected by the blue color of the EVN index. Also, in LDFCs, electrical interferences generated by the recording system are visible as ENT/green marks, especially in the upper and lower frequencies.

Ribbon plots evidenced the lack of periodicity in the presence of humpback whale singing activity, as these events are found in both areas at any time of the day (Fig. 6). It is also possible to see that the treatment area has brighter and stronger pink colors than control, indicating stronger singing activity of humpback whales (Fig. 6).

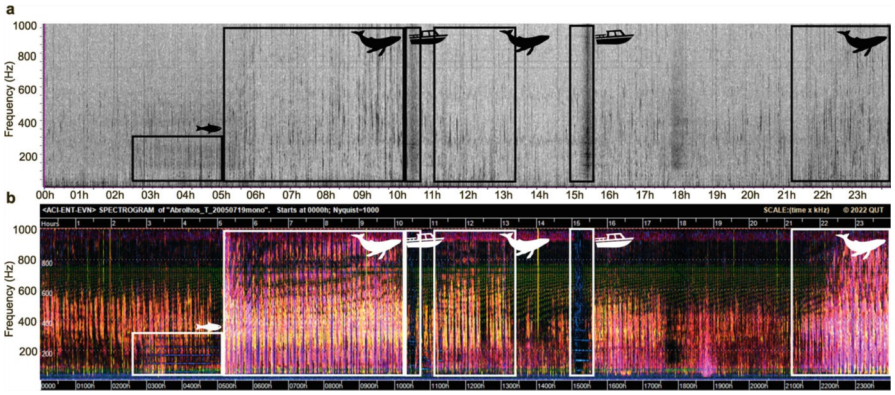

**Fig. 5** One day of recording from the treatment area is represented as a standard spectrogram (**a**) and long-duration false-color (LDFC) spectrogram (**b**). Boxes are drawn around sound events in each recording caused by fish choruses, vessel passages, or male humpback whale singing activity. For both representations, x-axis = time (24 h), y-axis = frequency (1000 Hz). For LDCFs, z-axis = ACI, ENT, and EVN index values assigned as red-green-blue code; for standard spectrograms, z-axis = acoustic energy in dB (gray color-coded), FFT = 512

On the other hand, ribbon plots did not show any of the temporal patterns expected to be visible in this long-duration recording period, such as a variation between night and day or any influence of moon and tidal cycles in the soundscape (shown in Sousa-Lima and Clark 2008). Also, the expected patterns of diurnal vessel noise and nocturnal fish choruses were not evident. These blue events were much more subtle than humpback singing events and were probably missed when the LDFCs lost frequency resolution to generate the ribbon plot.

## Discussion

The field of ecoacoustics has been exploring ways to assist the monitoring of terrestrial and aquatic environments. Acoustic indices that summarize soundscape characteristics have shown mixed performance on capturing ecological information. Results in this chapter support the need of using a combination of different acoustic metrics for marine soundscape characterization. Other studies have also used a combination of acoustic indices and standard acoustic measurements (Pieretti et al. 2017; Blondel and Hatta 2017), describing sound levels and its variations over different bandwidths and timescales (Merchant et al. 2013).

PSD and SPD patterns obtained for Abrolhos marine soundscapes corroborate that complementary metrics are useful in revealing the underlying noise-level distribution of different habitats. In this study, treatment and control areas presented different peaks of SPD in the frequency band of 100–600 Hz, with the treatment area also showing higher sound levels (Fig. 2). This result was expected once this is the

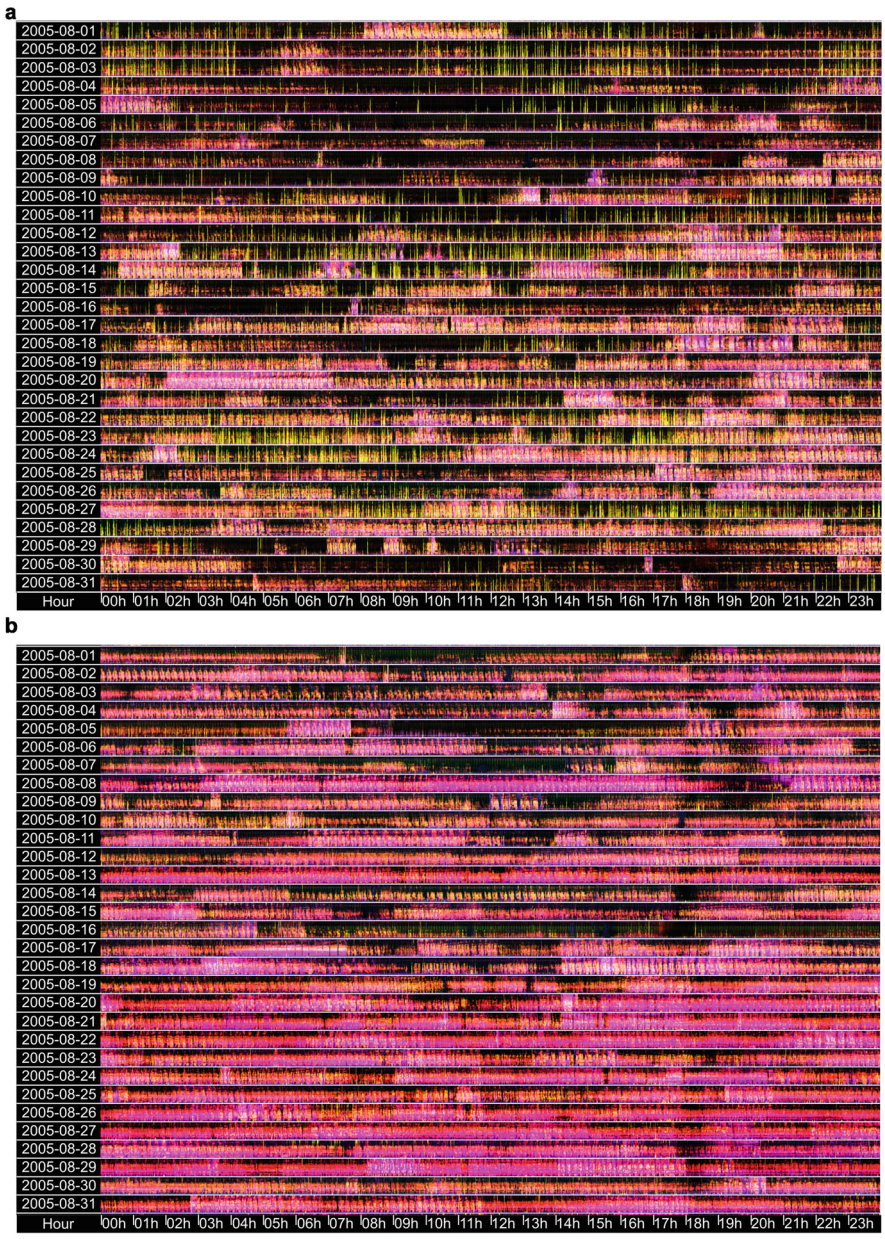

**Fig. 6** Ribbon plots of one month of continuous recording of Abrolhos soundscape for control (**a**) and treatment (**b**) areas. X-axis, time (hour); y-axis, frequency (1000 Hz as 32-pixel resolution; each string is a recording day); z-axis: ACI, ENT, and EVN indices with values assigned to red-green-blue code

frequency range where vessel noise is more intense (Urick 1983; Hildebrand 2009; Fernandes 2014; Mcpherson et al. 2016). In the control area, there was a bimodality in the SPD distribution at frequencies around 200 Hz (where engine noise is greater) that might be explained by the transient occurrence of vessel noise dragging the modal tendency ~20 dB greater than the primary mode, whereas in the treatment area vessels are more frequent and result in a unique mode with higher levels (Merchant et al. 2013). In addition, the control area had several small peaks between 100 and 300 Hz, which can be the reflection of a higher diversity of animal signals (zoophony).

Acoustic index performance was variable. In the complete, real dataset, NDSI, acoustic events (EVN), and entropy of the averaged spectrum (EAS) showed higher values in the control area (Fig. 4). The NDSI had mostly positive values in both areas, correctly demonstrating that both areas had a high level of biological sounds due to humpback whale vocal activity, yet the control area showed an overall higher score, probably due to less masking of humpback whale sounds. This result, even for such a narrow-frequency bandwidth, initially corroborates with the applicability of this index as an estimate of the level of anthropogenic disturbance also in marine soundscapes (Kasten et al. 2012; Machado et al. 2017; Alcocer et al. 2022). However, the same index did not perform as well in the customized dataset, showing relatively similar values between the different proportions of anthropophony/zoophony and only a higher variability in the 100% zoophony recordings. This inconsistency is probably due to the frequency bands selected for the present analysis, with the midband having a major overlap between zoophony and anthropophony (in contrast to the usual bands selected for terrestrial environments, anthropophony at 1–2 kHz and zoophony at 2–8 kHz), indicating an obvious caveat when selecting frequency bands according to the sampling frequency of each specific study (Kasten et al. 2012). EVN (a measure of the number of acoustic events) performed well for both complete and customized datasets, scoring higher for higher zoophony, although LDFCs showed that the index was also capturing the noise of vessel engines (see discussion below), yet with lower scores. As for the spectral entropy (EAS – a measure of energy concentration in the frequency spectrum), the control area showed higher and more variable values. However, in the customized dataset, EAS showed similar values in all levels. This result agrees with the reduced reliability already discussed for the classical H index (a measure of acoustic dispersion and not acoustic concentration) when measuring communities with a few sonic species (e.g., a single species producing sounds covering a broad frequency spectrum, which is the case in this study) (Sueur et al. 2008). Arguably, H has been one of the best performing indices in capturing ecologically relevant information (Alcocer et al. 2022), so it is possible that its applicability is useful in environments where animals produce broadband signals and the analyses' bandwidth is limited, as in this study.

The acoustic complexity index (ACI), background noise (BGN), activity index (ACT), and spectral peak density (SPD) showed higher values at the treatment area, indicating that anthropophony has biased these indices (Fig. 4). BGN is a simple measure of ambient background noise, showing expected higher levels for the area

with higher anthropogenic noise (treatment area). ACT is a simple measure of the number of acoustic events with a high sound level. These levels might be due to both biological and non-biotic sound sources, which can explain the higher score in treatment. However, ACI is the index most widely used for biodiversity appraisal in marine ecosystems (McWilliam and Hawkins 2013; Staaterman et al. 2014; Blondel and Hatta 2017; Lindseth and Lobel 2018; Bohnenstiehl et al. 2018; Alcocer et al. 2022). ACI assumes that biotic sounds are complex and amplitude modulated, whereas human-generated noise are usually constant (Pieretti et al. 2011). ACI has already demonstrated concerning biases such as being sensitive to geophony (Pieretti et al. 2011), to species identity (Gasc et al. 2015), to specific vocalization features (e.g., call rate and call type), and to the spectral resolution of analyses (Bohnenstiehl et al. 2018). Some authors have already suggested new indices derived from adjustments of ACI, such as the Acoustic Variability Index, which proved to be a good indicator of shipping noise (Mcpherson et al. 2016). For terrestrial habitats, background noise effects could be mitigated with threshold cutoff filters (Farina and Pieretti 2014); this simple approach is almost always impossible for marine ecosystems where there is a lot of overlap between biological and non-biological sound sources (Parks et al. 2014), especially at limited frequency ranges. At a first glance, the results in this chapter might suggest that ACI was incorrectly accounting for vessel noise as biological sounds, yielding unreliable higher values for the treatment area. Nonetheless, a clearer interpretation is achieved with the help of LDFCs to visualize features of interest with manual inspection and validation of the long-term recordings.

One of the main benefits of using LDFCs is that it enables a rapid identification of prominent soundscape features without having to listen to hours of recording (Phillips et al. 2017). Through this visualization, it was quite clear that humpback whale singing activity was the major feature dominating Abrolhos Bank soundscape during the recorded period, both in the control and treatment areas. However, vessel noise was not as evident as expected, nor were fish choruses, which were relatively easy to observe through standard spectrograms. Both events appeared as subtle blue events (captured by EVN) in LDFCs (Fig. 5), clarifying that ACI did not account for vessel noise, but rather, to a possible higher intensity of whale singing activity in the treatment area. The customized dataset also helped assign higher ACI scores to a high proportion of zoophony and lower ACI scores to a high proportion of anthropophony. According to Fernandes (2014), the treatment area within the Abrolhos Bank shows high concentration of vocally active whales (which is also the same area that overlaps with the highest vessel traffic). Hence, ACI might be biased by specific species and its call rate (humpback whales, in this case) and hence should be used with caution as a proxy for richness and diversity, as suggested by other studies (Gasc et al. 2015; Bohnenstiehl et al. 2018; Alcocer et al. 2022). The same might have influenced SPD, which was developed to be a measure of acoustic richness.

SNR and ENT showed no distinction between the study areas. However, in the customized dataset, there was a gradual increase with increasing zoophony proportion for both indices. This suggests that the result of the indices on the complete

dataset was possibly driven by the prevalence of humpback whale signals in both areas, despite higher anthropogenic noise and humpback whale vocal activity in the treatment area. Also, ENT presented a skewed distribution to higher levels in the control area, in accordance with the significant result seen for EAS (another similar index but calculated from the frequency spectrum while ENT is derived from the amplitude envelope). These indices have been used in weighted combination with others in a finer temporal resolution to create detectors of specific long-duration acoustic events, showing useful applications (Towsey et al. 2014).

The temporal patterns of the Abrolhos soundscapes studied in this chapter were visually assessed by the ribbon plots. Ribbon plots highlighted constant humpback whale singing activity, emphasizing the continuous occurrence of long-duration singing events throughout the 24 h. As reported by Sousa-Lima et al. (2018), humpback whale singing activity in Abrolhos ranges from 30 min to 20.5 h nonstop. This visualization tool might be only useful for spotting seasonality in longer datasets. It would be interesting to compare recordings made year-round, including humpback whale nonbreeding periods, when fish choruses should have a more important role in the Abrolhos soundscape.

## Conclusion

This chapter shows that a combination of traditional acoustic measurements with acoustic indices is recommended for the analysis of underwater soundscapes, in agreement with previous studies (Staaterman et al. 2013; Lindseth and Lobel 2018). PSD and SPD analysis proved to be useful in revealing the underlying noise-level distribution of different habitats and should be included in soundscape characterization. Among the acoustic indices, NDSI and ACI appeared to be less useful to account for anthropophony but are potentially useful to measure zoophony. However, ACI was impacted by humpback whale singing activity and should be used with caution as a measure of diversity within single-species acoustically dominated soundscapes. LDFCs highlighted humpback whale singing activity and demonstrated to be an interesting tool for the interpretation of index performance, and future applications should take into consideration different indices' combinations.

This study represents a step toward establishing robust protocols for long-term acoustic monitoring, fulfilling the passive acoustic monitoring promise of being an easy and accessible tool for conservation.

**Abstract**

The fundamental problem with current noise exposure criteria (e.g., ISO 1999) is their reliance on an energy metric to quantify an exposure, which completely ignores the effects of temporal characteristics of noise exposure known to be important in affecting noise-induced hearing loss (NIHL). Noise usually has a rather complex temporal structure, which can be expressed as a combination of continuous steady-state noise and various transient impulsive noises. A large number of animal experiments and epidemiological studies have shown that complex noise presents a greater hearing loss risk than continuous noise. Therefore, a metric is needed to account for this increased risk when analyzing hearing loss caused by complex noise. Over the last 20 years, multi-national collaborative teams have addressed the issue of complex noise exposure. Both animal and human research studies have found that the kurtosis statistic, a metric that describes the

probability for a noise signal to include high-level impulsive events, can account for the risks observed for groups with complex exposures. Kurtosis holds great promise in addressing the complexity associated with measuring and characterizing such exposures. Many issues focused on kurtosis can be applied not only to terrestrial mammals but also to marine mammals. A better understanding of the role of the kurtosis metric in NIHL may lead to its incorporation into a new generation of more predictive hearing risk assessments for noise exposure.

Noise-induced hearing loss · Complex noise · Kurtosis of noise exposure · Kurtosis-adjusted noise exposure level

## Introduction

Noises of the same or similar energies and spectra can have very different effects on hearing because of their different temporal structures. Studies (e.g., Hamernik and Qiu 2001; Hamernik et al. 2003, 2007; Qiu et al. 2007, 2013) have shown that temporal variables need to be considered to adequately assess the effects of non-Gaussian complex noise on hearing. High levels of complex noise exposure are common in industrial environments. Complex noise exposure cause much more damage to hearing than continuous steady-state noise at the same equivalent sound level, and existing noise standards (e.g., ISO 1999) underestimate hearing loss due to complex noise. (Zhang et al. 2021a). Numerous animal experiments have shown that exposure to complex noises produces more sensory cells loss than exposure to equivalent level steady-state continuous noise (e.g., Dunn et al. 1991; Lei et al. 1994; Lataye and Campo 1996; Hamernik and Qiu 2001; Harding and Bohne 2004; Hamernik et al. 2003, 2007; Qiu et al. 2006, 2007). The results of animal experiments have been confirmed by epidemiological studies (e.g., Sulkowski et al. 1983; Taylor et al. 1984; Theiry and Meyer-Bisch 1988; Zhao et al. 2010; Xie et al. 2016; Zhang et al. 2022). These results also prompt us to re-examine the application of the equal-energy hypothesis (EEH), which forms the basis of current noise exposure standards (e.g., ISO 1999). The issues raised above, while directly relevant to humans and other terrestrial mammals, are also relevant to marine mammals and might even be considered for fishes (e.g., National Marine Fisheries Service 2016). While this kind of work has not been done for marine mammals, it might be highly relevant and should be examined.

Industrial workers are often exposed to complex noise environments. Complex noise consists of a background Gaussian noise with embedded high-level transients, as shown in Fig. 1. Transients can be impacts or noise bursts. These transients usually have different peak intensities, inter-transient intervals, and durations. These noise characteristics are known factors that affect the outcome of noise exposure.

Since current noise standards only use energy measures and do not include the temporal characteristics of noise, and since there are countless noise exposures with the same energy and spectrum but very different temporal structures, the inclusion of

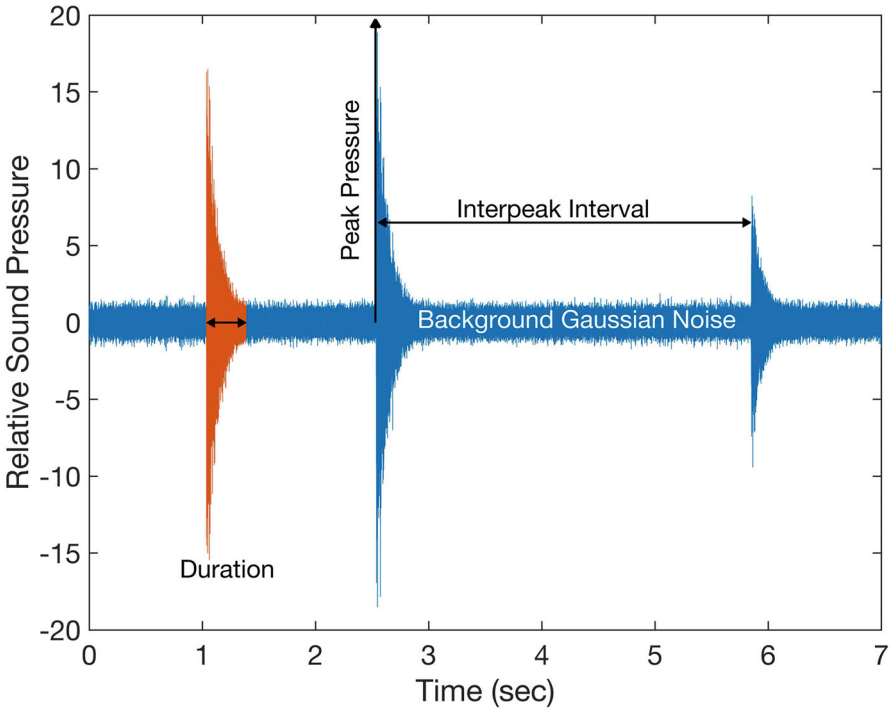

**Fig. 1** An example of complex non-Gaussian noise. Compound noise is composed of Gaussian background noise and various high-level transients superimposed. The transients could be impacts or noise bursts of varying peak intensities, inter-transient intervals, and durations. (Adapted from Qiu et al. 2020)

a metric related to the temporal variables of noise would be a useful adjunct to the energy metric. One such metric is kurtosis.

## The Definition of Kurtosis

Kurtosis is a statistical measure that describes the extreme value of the data relative to the two ends of the Gaussian distribution. In the case of noise, kurtosis describes the impulse property of noise, i.e., the degree of deviation from continuous, steady-state noise (Murphy and Qiu 2021). Theoretically, kurtosis is defined as the ratio of the fourth-order central moment to the squared second-order central moment of a distribution. For a sample of $n$ values, the kurtosis of noise ($\beta$) is calculated as:

$$\beta = \frac{1}{n}\sum_{i=1}^{n}(x_i - \bar{x})^4 \Big/ \left(\frac{1}{n}\sum_{i=1}^{n}(x_i - \bar{x})^2\right)^2$$

where $x_i$ is the $i$th value of noise amplitude and $\bar{x}$ is the sample mean.

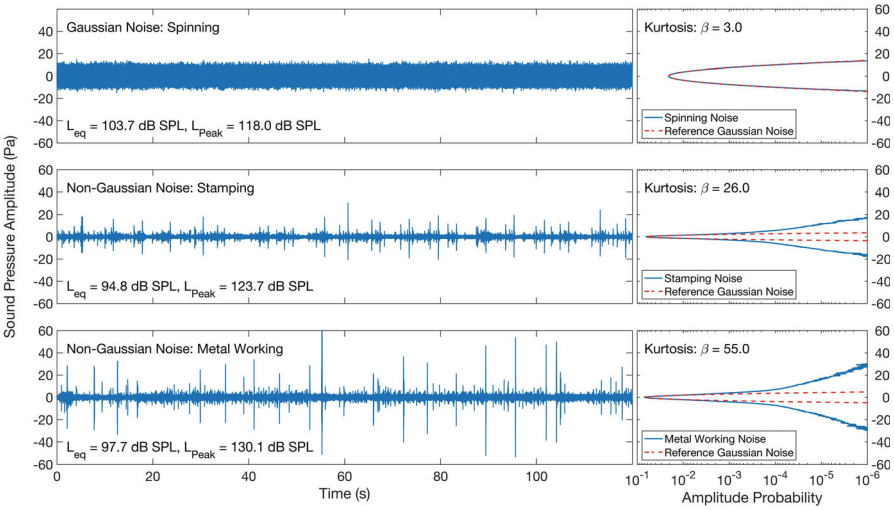

**Fig. 2** Comparison waveforms (left) and amplitude probabilities (right) from three industrial noises. Note: $L_{eq}$ is the equivalent sound pressure level of noise, and $L_{peak}$ is the peak sound pressure level of noise. (Adapted from Qiu et al. 2020)

All the variables that characterize a non-Gaussian noise, such as transient peaks, inter-transient intervals, transient durations, crest factor, etc., affect the kurtosis value. The kurtosis of a continuous steady-state (Gaussian) noise is 3. The kurtosis value of complex noise is greater than 3. Figure 2 shows three examples of industrial noise waveforms, their kurtosis values, and corresponding amplitude probability histograms.

## Evidence of Kurtosis Differentiating Hearing Loss Caused by Complex Noises with Different Temporal Structures

Qiu et al. (2013) designed animal (chinchilla) experiments to determine to what extent auditory system trauma, as quantified by sensory cell loss (percentage of outer hair cell loss, %OHC Loss) is affected by differences in the temporal structure of various complex noise exposures all having the same spectral energy. Four groups of animals ($n = 8$ for each group) were exposed to an overall SPL of 97 dB(A) noises (for 19 days) with different noise kurtosis values equal to 3, 25, 50, and 100, respectively. The 19 days of exposure simulated 3 weeks of typical occupational noise exposure, i.e., 8 h a day, 5 days a week. The results are shown in Fig. 3. The figure clearly shows that noise with the same sound pressure level but a different temporal structure can produce different degrees of hearing loss. From the chinchilla model, hearing loss is proportional to kurtosis in that threshold shift, and hearing loss increase as kurtosis increases for a fixed noise energy level. In other words, noise

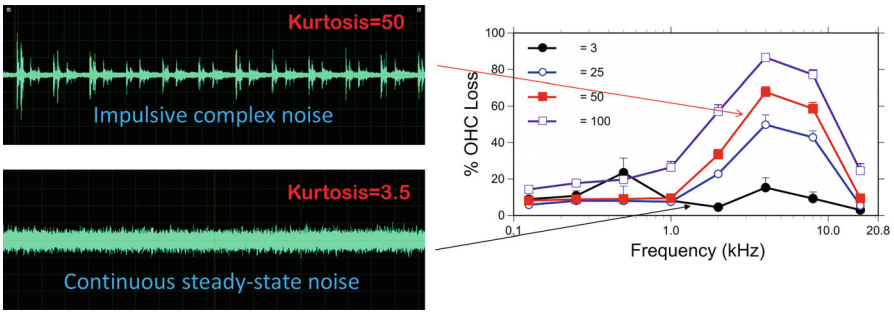

**Fig. 3** The group mean percent outer hair cell loss (% OHC loss) for groups exposed to the $\beta(t) =$ 3, 25, 50, or 100 complex noise at 97 dB SPL for 19 days. The right panel of the figure was adapted from Qiu et al. (2013)

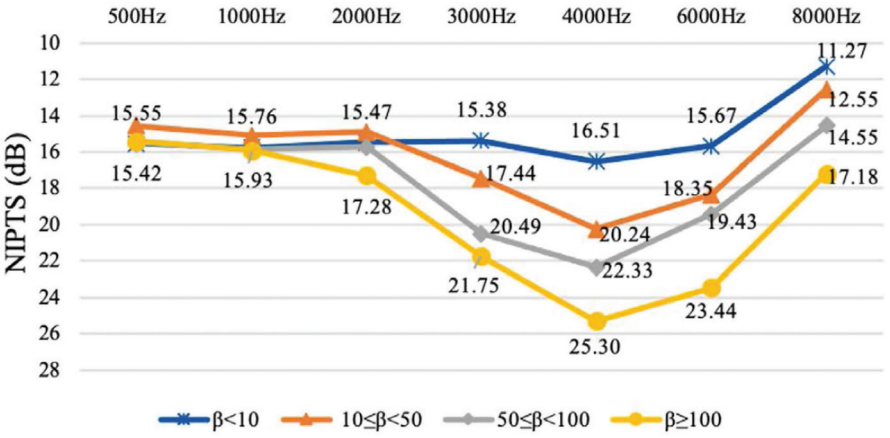

**Fig. 4** The relationship between noise-induced permanent threshold shift (NIPTS) and kurtosis category for the cumulative noise exposure in the range of 85 to 100 dBA·year. (Adapted from Zhang et al. 2021b)

kurtosis differentiates the degree of hearing loss caused by complex noise with the same energy but different temporal structures.

An epidemiological study was conducted in China by Zhang et al. (2021b) to investigate the relationship between occupational noise-induced hearing loss (NIHL) and the kurtosis of noise. The data of workers from six industrial settings were collected. Figure 4 shows the relationship between noise-induced permanent threshold shift (NIPTS) and kurtosis category for the cumulative noise exposure in the range of 85 to 100 dBA·year ($n = 1962$). The NIPTS at 3, 4, 6, and 8 kHz were sorted according to the level of kurtosis. Put another way; the NIPTS increased with the increase of kurtosis level, which is consistent with the results of animal experiments (as shown in Fig. 3). It follows that kurtosis, as an adjunct to the energy metric, is a potentially effective metric for assessing hearing loss caused by complex noise exposure.

## Kurtosis Metric Needed in the Evaluation of Hearing Hazards Associated with Industrial Noise Exposure

Zhang et al. (2021a) analyzed hearing measurements and shift noise exposure data for 2333 workers from 34 industries in China. These workers were exposed to various types of noise ranging from 85 to 100 dBA, and their exposure durations ranged from 1 to 35 years. Figure 5 shows the age, exposure duration, noise level exposed, and noise kurtosis distributions of workers.

The effects of noise level and kurtosis on the measured NIPTS for two exposure durations are shown in Fig. 6. For the D $\leq$ 10-year group, the measured NIPTS increased with the increase of kurtosis at similar noise levels. For the D $>$ 10-year group, the effect of kurtosis on measured NIPTS was no longer as pronounced as it was during the first 10 years of exposure. However, the measured NIPTS in the highest kurtosis group ($K_4$) were still significantly higher than those in the other three lower kurtosis groups. The results show that the kurtosis value plays a more important role in evaluating the NIHL of workers with exposure time less than or equal to 10 years compared to workers with exposure time greater than 10 years. However, when the kurtosis value is greater than a certain value ($\beta > 75$, namely, high impulsive noise), the damage to hearing caused by this type of noise is not only rapid but also continues with the extension of noise exposure duration.

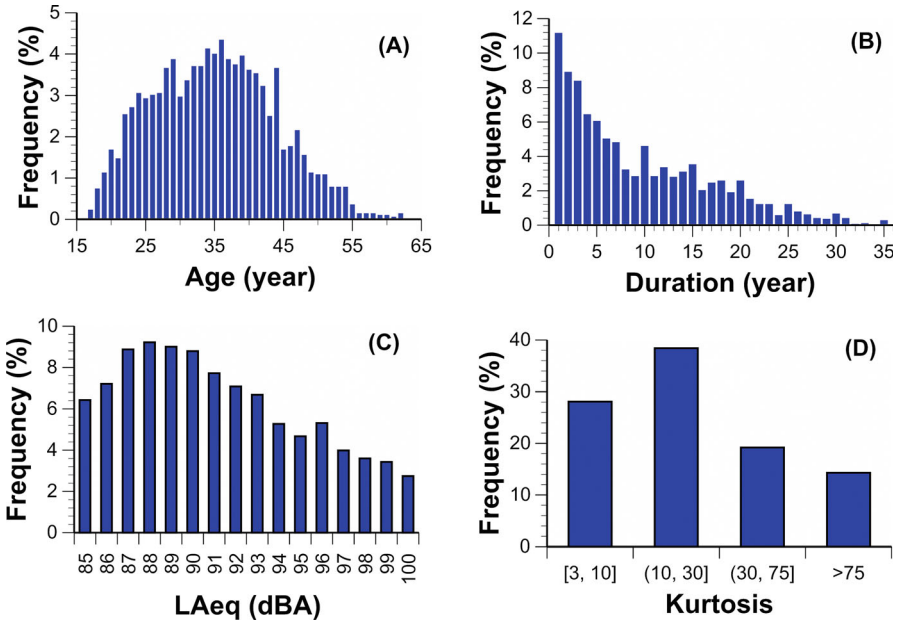

**Fig. 5** Distributions of (**a**): age; (**b**) exposure duration; (**c**) A-weighted equivalent sound pressure levels ($L_{Aeq,8h}$); and (**d**) kurtosis level in the 2333 noise-exposed workers. (Adapted from Zhang et al. 2021a)

## How to Use the Kurtosis Metric in the Evaluation of NIHL in Industrial Settings

In order to practically use the kurtosis metric for hearing protection purposes in industrial settings, the following issues need to be addressed:

1. How to measure noise kurtosis in industrial settings?
2. What is the optimal window duration for kurtosis calculation?
3. How should kurtosis be normalized to converge over work shifts?
4. How to use the kurtosis metric in NIHL evaluation?

### How to Measure Noise Kurtosis in Industrial Settings

To obtain noise kurtosis, the noise waveforms must be recorded. The recording needs to have high fidelity: at 48 kHz sampling rate, 32-bit resolution in our studies, and a microphone capable of measuring the high-intensity sound levels typical of occupational noise exposures.

### What Is the Optimal Window Duration for Kurtosis Calculation

Tian et al. (2021) investigated the correlation between window duration for kurtosis computation and the accuracy of NIHL prediction using a Chinese industrial

database ($n = 2110$). Workers were divided into high- and low-kurtosis groups based on kurtosis values calculated over different window durations. Two algorithms were used to find the optimal window duration. Algorithm 1 applied the Mann-Whitney U test to compare the difference in group hearing threshold levels to obtain the optimal window duration to best distinguish these two groups. Algorithm 2 used a support vector machine to predict the NIHL under different window durations and found the optimal one by testing the performance of the model through the area under the curve. The results showed that 60 s was an optimal window duration.

## How Should Kurtosis Be Normalized to Converge Over Work Shifts?

A sampling rate of 48 kHz is used for noise recording. The length of the calculation window for the recorded noise signal kurtosis is 60 s, and the shift-long noise is calculated without overlap. For a sample of n values, kurtosis can be calculated as:

$$\beta_j = \frac{1}{n}\sum_{i=1}^{n}(x_i - \overline{x})^4 \Big/ \left(\frac{1}{n}\sum_{i=1}^{n}(x_i - \overline{x})^2\right)^2$$

where $x_i$ is the $i$th value of noise amplitude and $\overline{x}$ is the sample mean.

The mean of the measured kurtosis values, $\beta_j$, at every 60 s is calculated

$$\beta_{\mathrm{N}} = \frac{1}{N}\sum_{j=1}^{N}\beta_j$$

and used as the kurtosis of noise exposure ($\beta_{\mathrm{N}}$).

## How to Use the Kurtosis Metric in NIHL Evaluation?

An algorithm using kurtosis to adjust the measured equivalent A-weighted 8-h noise exposure level ($L_{\mathrm{Aeq,8h}}$) proposed by Goley et al. (2011) is applied. The formula is as follows:

$$L'_{Aeq,8h} = L_{Aeq,8h} + \lambda \log_{10}\frac{\beta_N}{\beta_G}$$

where $\beta_{\mathrm{N}}$ is the kurtosis of noise, $\beta_{\mathrm{G}}$ is the kurtosis of Gaussian noise, which is equal to 3, and $\lambda$ is the adjustment coefficient. The Goley's model uses noise kurtosis to directly correct the measured noise energy. The greater the kurtosis, the greater the amount of correction. Goley et al. (2011) found the adjustment coefficient $\lambda = 4.02$ when using the chinchilla data from Auditory Research Laboratory, SUNY Plattsburgh.

Using NIPTS at test frequencies 3, 4, and 6 kHz ($\mathrm{NIPTS}_{346}$) as the indicator of NIHL, Zhang et al. (2022) found the optimal kurtosis adjustment coefficient ($\lambda = 6.5$)

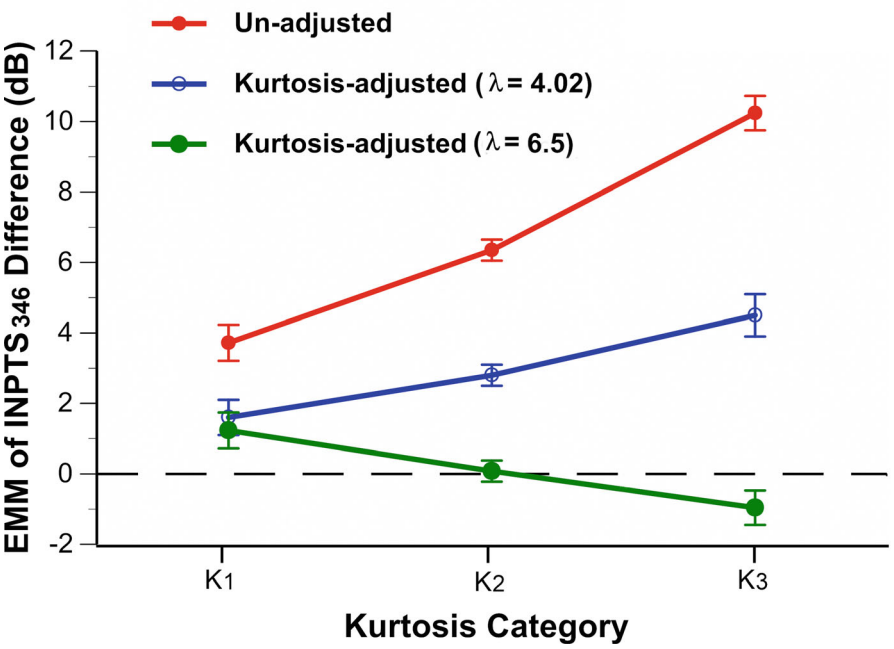

**Fig. 7** The estimated marginal mean of underestimated $NIPTS_{346}$ by ISO 1999:2013 model for three kurtosis levels under un-adjusted and kurtosis-adjusted noise levels. Error bars: standard error. The kurtosis value ranges are $K_1$:3 $\leq \beta_N \leq$ 10; $K_2$: 10 $< \beta_N \leq$ 50; $K_3$: $\beta_N >$ 50. (Adapted from Zhang et al. 2022)

for Goley's formula based on noise recordings and hearing measurements collected from workers ($n = 2601$) in industrial settings. Figure 7 displays the estimated marginal mean (EMM) of underestimated $NIPTS_{346}$ for each kurtosis level before and after kurtosis adjustment. It can be seen from Fig. 6 that the unadjusted kurtosis levels (red line) exhibit an increasing error in the prediction of $NIPTS_{346}$ as kurtosis increases. The EMM of underestimation can reach as high as 10 dB for the high kurtosis group. The kurtosis adjustment using $\lambda = 4.02$ (from the chinchilla model) provides a better estimate than the unadjusted noise levels but still exhibits an increasing error as kurtosis increases (blue line). The best-fit value, $\lambda = 6.5$ (from human data), exhibits an error of about $\pm 1$ dB (green line) as the kurtosis level changes. The kurtosis-adjusted $L_{Aeq,8h}$ with an adjustment coefficient of 6.5 can predict the high-frequency NIHL more accurately.

## Conclusion

Because non-Gaussian complex noise is common in the industry, the temporal characteristics of noise (i.e., kurtosis) must be taken into account in evaluating occupational NIHL. The temporal characteristic (i.e., kurtosis) can be used to adjust

noise level (via Goley's formula). The greater the value of kurtosis, the larger amount of the adjustment, which means the higher risk of hearing loss. The results of the epidemiological study demonstrated that these adjustments are feasible and necessary.

**Abstract**

Anthropogenic disturbance is affecting the sensory environment. Acoustic, visual, and chemosensory modalities are changing, impacting information use of animals across taxa. In order to effectively mitigate these impacts, we need to understand how disturbance in those sensory modalities are similar, and where they diverge. Animal information use follows the general principle of a cue that is produced by a sender and perceived by a receiver, which may alter its behavior in response to that cue. At the same time, acoustic, visual, and chemosensory modalities diverge in whether parts of this process involve active production and in whether the receiver is actively creating cues that it can perceive. Sensory pollution can take place through masking and changes in signal processing speed, which overarches sensory modalities. Getting better understanding of how acoustic, visual, and chemosensory pollution affect animal information use will help unravel the general mechanisms underlying the effects of sensory disturbance on information use in animals.

## Introduction

The increased industrialization of human society is changing acoustic, visual, and chemosensory modalities in the environment (Frisk 2012; Naidu et al. 2021; Sanders et al. 2021). Since the Industrial Revolution, ambient noise levels in both terrestrial and aquatic environments have increased due to human-generated sounds (Miksis-Olds and Nichols 2016; Slabbekoorn 2019). At night, the sky and the ocean are illuminated through artificial light sources (Falchi et al. 2019). Chemical pollution has changed the composition of lakes and rivers (Håkan Olsén 2011).

These changes have an impact on information use in animals. For instance, increasing noise levels lead to masking of intraspecific communication (Erbe et al. 2016; Slabbekoorn et al. 2010), artificial light at night increases conspicuousness of prey to predators (Delhey and Peters 2017; Santos et al. 2010), and decreases in seawater pH levels affect the use of chemosensory cues by fish (Ferrari et al. 2011). On top of that, animals often have to cope with an accumulation of impacts from multiple sensory disturbances at the same time (Crain et al. 2008). This highlights a need for understanding how animals are disturbed by various forms of sensory pollution.

While the sensory modalities in which animals operate can vary, there are general mechanisms that underlie the way animals use these sensory cues (Sebeok 1977). A cue or signal is – inadvertently (cue) or intentionally (signal) – produced by a sender or abiotic factor and is received by a receiver (Laidre and Johnstone 2013). The receiver processes the cue and potentially adjusts its behavior. This process can only take place if the sender is able to produce the cue and the receiver is able to perceive the cue produced by the sender – which depends in part on the spectrum of sensitivity and the intensity threshold (Fay 1974). If one of those conditions is not met, the cue is not perceived. Humans, for example, cannot perceive the UV-color cues present on flowering plants, because UV light falls outside of their spectrum of perception (Silberglied 1979).

Similar to sensory information use, disturbance through sensory pollution is governed by mechanisms that overarch sensory modalities (Dominoni et al. 2020). The knowledge that various forms of sensory information use and sensory pollution operate through the same mechanisms gives us the opportunity to examine how they are the same, and more importantly, where they diverge.

## The Sender

The sender can either actively – by production – or passively – by reflection – use a sensory modality to send a signal. Acoustic and chemosensory signals are typically actively produced (Bossert and Wilson 1963; Busnel 1977). An animal produces a

call or releases a chemical compound (e.g., pheromones (Karlson and Lüscher 1959)) that transmits through the environment to hopefully reach a receiver. In addition to direct transmission, chemosensory signals can also be left to linger on other objects, giving the sender the possibility of sending the signal without actively being present to send it (Bossert and Wilson 1963). Terrestrial animals often use this kind of chemosensory signaling to mark territory boundaries (Campos et al. 2017). There are only few species that actively produce light to send a signal, most of them in the marine environment (Haddock et al. 2010). Light is usually used passively, by changing the way the light reflects off a body through coloration, through movement, or by changes in posture (Hailman 1977). For instance, cichlids (*Labeotropheus fuelleborni*) use body coloration to signal their potential to be a mate (Pauers and Mckinnon 2012).

In contrast to light, sound and chemicals are only rarely used passively to send signals. One example of passive acoustic signaling comes from plant-animal interactions. Bat-dependent plant species have evolved leaf shapes that can act as acoustic reflectors (Schöner et al. 2016). In the marine environment, no such intentional passive acoustic signals are known. Rather, fish and cephalopod prey may inadvertently reflect the sound of echolocating toothed whales, thereby betraying their position (Au 1997). Given the ubiquity of sound use in the marine environment, and the relative absence of light, one would expect more species to use acoustic reflection for sending signals. Are there biological trade-offs that negate the benefit of such a signal type? Or are we simply unaware of such examples?

## The Receiver

Signal reception is usually passive, although animals can actively enhance their probability of receiving a signal. They can do so in multiple ways, for instance, by moving away from potentially masking noise sources, by turning toward the sound source (Dent et al. 1997), by having directional sensing organs (Ebata et al. 1968; Von Békésy 1964), or by moving toward a location with better signal reception, i.e., closer to the source or to a point with higher propagation potential (Brumm and Slabbekoorn 2005). One notable exception to this rule is echolocation (Griffin 1953; Schevill and McBride 1956). An animal that is echolocating actively sends a signal in order to be able to act as a receiver of the echo of that signal (Au and Simmons 2007). In a similar fashion, light-producing animals may use their light source to see by. For instance, lanternfish (*Myctophidae*) are thought to use their bioluminescence to illuminate prey (de Busserolles and Marshall 2017; Herring 1985). Would a similar mechanism be possible in the chemosensory modality? And if so, is it used by animals?

## Disturbance

Both sender and receiver of sensory signals seem to follow general underlying rules, regardless of the sensory modality in which they operate. Senders usually actively produce a signal, while receivers passively receive it. However, upon closer

examination, there are differences between sensory modalities, especially for sending visual signals and receiving chemosensory signals. We should take these similarities and differences into account when we examine the mechanisms of sensory disturbance.

## Masking

One of the ways in which acoustic disturbance can affect animal information use is through masking. Masking is defined as a decrease in signal-to-noise ratio (SNR), such that the signal or cue is no longer discernible from the background noise (Luther and Gentry 2013). A specific requirement for masking in mammals is that the signal occurs in the same frequency band as the noise. If the signal is outside of the frequency range of the noise, it will be detectable regardless of the noise intensity. It is unclear if a similar mechanism applies to fish and invertebrates (Hawkins and Popper 2017; Popper and Hawkins 2019). Masking has been studied extensively for acoustic disturbance, both for terrestrial and aquatic animals (Brumm and Slabbekoorn 2005; Erbe et al. 2016; Popper and Hawkins 2019; Shannon et al. 2016; Slabbekoorn et al. 2018). Many vertebrates evolved coping mechanisms for masking in natural conditions, which work to varying degrees for anthropogenic disturbance (Brumm and Slabbekoorn 2005), but similar mechanisms seem to be absent in invertebrate taxa (Brumm and Zollinger 2011).

Similar to acoustic disturbance, visual disturbance can also act via masking. In aquatic environments, increasing turbidity leads to increased visual noise, which reduces the possibility to detect visual signals. Increased water turbidity mainly impacts visual predators, who are less likely to successfully catch their prey in more turbid waters (Ortega et al. 2020). Water turbidity may increase from material runoff or resuspension of the sediment through extreme rainfall and storms, which are predicted to increase due to climate change (Cózar et al. 2005; IPCC 2014; Schälchli 1992; van der Sluijs et al. 2011; Weyhenmeyer et al. 2016). In contrast to turbidity, artificial light at night (ALAN) will decrease masking of visual cues, which will make prey more conspicuous to visual predators. Nocturnally foraging waders, for example, changed their foraging effort to artificially light experimental sites and changed from mixed foraging strategies to visual foraging (Santos et al. 2010). Similarly, changes in the visual background can increase conspicuousness of prey that use the background as camouflage (Cuthill et al. 2019).

Chemosensory disturbance is often used in the field of ecotoxicology, where changes in behavior are used as biomarkers to assess the toxicity of a chemical compound (Carvan et al. 2008). Masking is one of the mechanisms through which this behavior changes, when an introduced chemical compound masks existing chemical cues from con- or heterospecifics. For instance, female sword-tail fish (*Xiphophorus birchmanni*) lost their preference for conspecific male olfactory cues in polluted stream water (Fisher et al. 2006). However, another possible explanation for the results is a physiological change in the olfactory receptors of the fish due to the pollutant (Fisher et al. 2006; van der Sluijs et al. 2011). In that case, it would not

be masking, but a temporary impairment of the receptive organ that created the effect. Alternatively, it has been proposed that chemical pollutants may change the structure or abundance of chemical cues, which could lead to a decrease in signal detection (Fisher et al. 2006; van der Sluijs et al. 2011). This would decrease the signal to noise ratio by decreasing the amount of signal available. The alternative, an increase in the noise, has not been proposed but could be possible, depending on the specificity of the olfactory receptors and the nature of the chemical disturbance.

## Changes in Signal Processing Speed

Acoustic disturbance has been shown to alter the response latency of multiple animal taxa to cues (Chan et al. 2010; Chan and Blumstein 2011; Simpson et al. 2015, 2016; Voellmy et al. 2014). More specifically, sound can distract animals (Chan and Blumstein 2011; Rosa and Koper 2018), potentially leading to increased predation (Simpson et al. 2016). However, this is not always the case. In some studies, acoustic disturbance was actually found to have an opposite effect: Instead of a longer response latency, the hoatzin bird (*Opisthocomus hoazin*), dwarf mongooses (*Helogale parvula*), prairie dogs (*Cynomys ludovicianus*), and three-spined sticklebacks (*Gasterosteus aculeatus*) all showed a shorter response latency under influence of noise (Karp and Root 2009; Kern and Radford 2016; Shannon et al. 2016; Voellmy et al. 2014). The precise mechanism that operates behind this dichotomy is not well understood. It could be related to the perceived risk of the disturbance, but this has not been tested explicitly (Frid and Dill 2002).

Distraction by visual disturbance has been suggested for nocturnal insects (Owens et al. 2020). Phototactic insects show – sometimes fatal – attraction to artificial light sources, rendering them more vulnerable to predation risk by visual predators that operate close to the light source. Nocturnal moths were equally easily caught with light traps while being exposed to playback of bat sounds as with silent light traps, suggesting absence of the typical acoustic avoidance flight to bat sound when exposed to artificial light (Hügel and Goerlitz 2020). However, conclusive evidence is lacking, as the study did not test whether avoidance flights would be reduced for moths exposed to light and sound as compared to sound alone. Furthermore, the attraction of insects to artificial light sources at night is not typical of the distraction mechanism as seen for acoustic disturbance, where the disturbance influences response latency to another, biologically relevant, cue. The question of changes in signal processing speed induced by visual disturbance therefore remains open.

Chemosensory pollution often leads to changes in signal processing speed of chemosensory cues. Air pollution impaired the learning of olfactory cues in honeybees (*Apis mellifera*) (Leonard et al. 2019). Background odors distracted moths (*Manduca sexta*) from the direction of scented flowers, increasing the time they took to localize the flower (Riffell et al. 2014). Chemosensory pollution might also affect responses to other sensory cues. However, care must be taken to ensure that changes in behavior due to chemosensory pollution are not due to physiological changes caused by the chemical compounds.

## Conclusion

Anthropogenic disturbance can have many different forms, but the ways in which sound, light, and chemosensory pollution impact information use of animals could be similar. Comparing animal information use from a mechanistic perspective helps unravel existing knowledge gaps. If sending and receiving a signal typically works via the same principle, why then do we sometimes see differences between sensory modalities in how signals are used? Is visual perception using bioluminescence as widely used as echolocation, and does it have the same functionalities? Is there a chemosensory equivalent, and if not, why not? Understanding how these mechanisms overlap and where they diverge will give further insight into animal information use, and more importantly, into the disturbance of that information use. This knowledge is necessary to increase the potential for effective mitigation of disturbance in a sensory world.

**Abstract**

Early work has shown that exposure to high-intensity sounds can damage the sensory epithelia of fish ears and impair their hearing. However, experiments suggest that when the acoustic stimulus impinges on the ears from different directions, the damage level varies significantly. Therefore, it was hypothesized that the angle of the incident sound might play a part in the propensity to cause damage. To test the hypothesis and gain insight into the differential movement of the otolith relative to the epithelia, finite element models based on microCT data of the saccular otolith of a bight redfish (*Centroberyx gerrardi*) was built, which modeled the otolith motion to acoustic stimulations from the horizontal and vertical directions. Sound pressure level, relative displacement, acceleration, and shear stress at the surfaces of the otolith and macula (water-otolith boundary) were compared. The results suggest that the incident angle of the sound and the

## Introduction

The bony fishes have two ears with three pairs of otoliths: utricular (lapillus) otoliths, lagenar (asteriscus) otoliths, and saccular (sagittal) otoliths. In most fish species (except for the otophysans), the saccular otoliths are the largest ones. The three otolith organs are involved in hearing, which can be responsive to waterborne sound energy (Popper and Schilt 2008; Braun and Grande 2008; Schulz-Mirbach et al. 2013). The hair cells of the sensory epithelium are connected to the dense calcareous otolith through the otolithic membrane (a gelatinous and fibrous matrix) and lie in sulcal groove along the otoliths. When an acoustic stimulus is imposed on the otolith, due to the different densities between the otolith and macula, a differential motion is generated which causes deflection of the hair cells (Popper and Fay 1999). This deflection creates neural impulses in the innervating eighth cranial nerve that is proportional to the amplitude and direction of hair cell bending (Flock and Wersall 1962; Hudspeth et al. 2000).

Previous behavioral research has shown that continuous noise and pure tones can cause temporary hearing threshold shift (TTS) to fish (Popper and Clarke 1976; Popper et al. 2005). Exposure to high-intensity pure tones (e.g., over 180 dB re 1 μPa) for a period of time may damage the sensory hair cells of the fish ears and eventually impair fish hearing (Scholik and Yan 2001, 2002; Hastings et al. 1996; Smith and Monroe 2016). For example, in the study of McCauley et al. (2003), a group of pink snappers (*Chrysophrys auratus*) were held in cages and were exposed to multiple shots from air gun signals (a short, sharp, low-frequency sound made by venting high-pressure gas). They reported damage to parts of the ears of the exposed fish. The damaged sensory hair cells were not repaired or replaced up to 58 days after air gun exposure. McCauley et al. (2007) studied hearing damage in the tropical gold band snapper (*Pristipomoides multidens*) using fish caught in commercial traps set on the seabed. They also reported that significant damage to the ears of fish was observed when the fish was exposed to a seismic pass.

These experiments were followed up by partly contradictory results of effects on the hearing abilities by the air gun signals. In the first scenario which was the experiment conducted by McCauley et al. (2003), the exposed fish was located at 3 m depth in 10 m water depth, and then a single 20 cui (cubic inch, e.g., 1000 cui = 16.4 L) air gun at 5 m depth passed within 5 m off the fish. There were no constraints on the direction of arrival, horizontal and near vertical primarily from the surface bounce. It was reported that the fish ears were severely damaged, specifically on the dorsal and ventral sides of the macula (McCauley et al. 2003).

By contrast, in the second scenario, the exposed fishes were in small cages held at 7 m depth in 60 m of water. The seismic source, at 5 m depth, passed within 45–800 m of the cages (McCauley et al. 2008). In this case, the only vertical arrival would be the bounce off the seafloor; however, as the seabed was hard limestone, a poor reflector, the energy arriving at the fish from below would have been low compared to the direct horizontal arrival and distorted given the phase shifts from the seabed. Given the shallow nature of the source and receiver, the dominant arrivals were near horizontal with little to no energy arriving from above the fish. The damage level on the fish ears was much lower compared to the first experiment. The received air gun signal pressure metrics were similar between the two experiments. One possible explanation for the partly contradictory results could be the difference in fish species. There could be variations among the species in terms of the shape of the otolith (Dahl et al. 2020; Jenkins et al. 2022). However, the fish species in both scenarios have similar otolith shapes (the caudal groove is narrow and mostly horizontal, located at the midpoint of the otolith); therefore, we hypothesize that the angle of the sound impinging on the saccular otolith affects otolith motion patterns and causes different damage levels to the hair cells.

Here micro-computed tomography (microCT) scanning was performed on the saccular otoliths of a bight redfish (*Centroberyx gerrardi*) and constructed finite element (FE) models to simulate the saccular otoliths' response to the acoustic stimulations from the horizontal and vertical directions. This imaging-based finite element modeling (FEM) has been widely used to study the mechanisms involved in sound production, propagation, and reception in the heads of several animal species, including toothed whales (Aroyan 2001; Cranford et al. 2014; Wei et al. 2017, 2018a, b), baleen whales (Cranford & Krysl 2015; Tubelli et al. 2018), and marine fishes (Salas et al. 2019a, b; Krysl et al. 2012; Wei et al. 2022). It has become an important complementary tool for traditional experimental methods due to its advantage of studying the complex acoustic processes as sounds interact with animals' anatomical structures. Using the modeling techniques, this study computed the motion of saccular otoliths in the presence of horizontal and vertical stimulations, respectively. The sound pressure levels (SPLs), displacement, acceleration, and the shear stress on the surface(s) of the saccular macula and otolith were compared to test our hypothesis, especially with regard to damage to certain regions of the saccular macula observed in earlier studies and the previous partly contradictory results of effects on the hearing abilities of anthropogenic noise.

## Methods

### XCT and MicroCT Scans

Medical CT scanning on the full body of bight redfish specimens was firstly performed. The specimens were purchased from a fish market and were scanned in 3D by X-ray computed tomography (XCT) using a Siemens SOMATOM Definition

AS medical scanner, as shown in Fig. 1a. The scan was conducted using 0.6 mm spiral acquisition, and the slice increment was set as 0.1 mm.

However, after examining the data, it was found that the resolution of the CT data was not high enough to provide detailed geometry information of the saccular otolith (e.g., sulcal groove). Therefore, a dissection was conducted to cut off the otolith within the bony capsule for microCT scanning. The microCT scanning was performed at the Australian Resources Research Centre (ARRC, Kensington, Western Australia) using an Xradia VersaXRM-500 microCT scanner. The Xradia VersaXRM-500 provides high-resolution 3D X-ray imaging with submicron

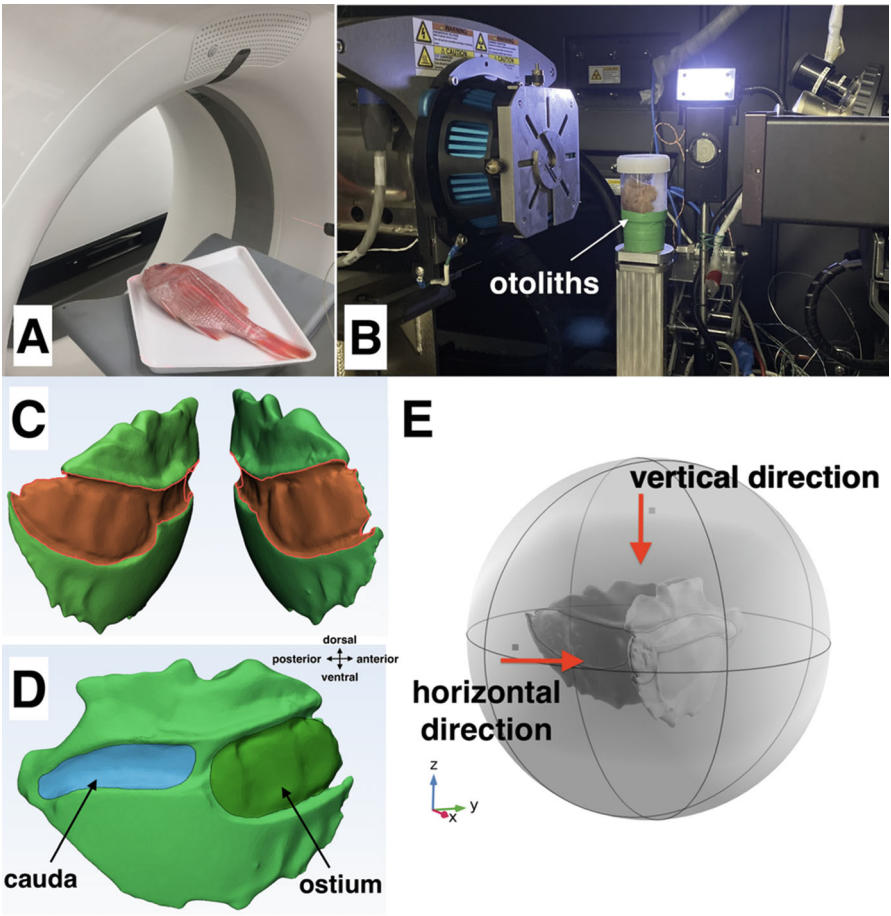

**Fig. 1** CT imaging scans and model reconstruction. (**a**) Medical CT scanning on a full body of fish. (**b**) MicroCT scanning on the fish otoliths within the bony capsule. (**c**) 3D reconstruction of a pair of saccular otoliths of a bight redfish. (**d**) 3D reconstruction of the left saccular otolith. resolution. It facilitates nondestructive observation of the internal structure of objects, such as the saccular otoliths. The otoliths were firmly fixed in a plastic container during the scanning, as shown in Fig. 1b. In the microCT scanning, the isotropic resolution was set as voxel size 29 μm, and the power setting was set as 80 kV × 87 μA. Cone beam reconstruction was performed on the object, and the data was saved on a hard drive as a matrix of 1000 × 1024 pixels per image in TIFF format. The images were converted to DICOM format later and imported into Horos™ (Horos Project, Geneva, Switzerland) for data analysis and 3D geometrical model reconstruction. Figures 1c and d display the 3D reconstruction of the saccular otoliths. The regions in orange are the sulcal grooves. The otoliths were exported as a stereolithography (STL) file after optimization and modification (e.g., smoothing, removing overlapping and self-intersections, etc.).

## Finite Element Model Construction

STL files were imported into the COMSOL Multiphysics modeling software (Stockholm, Sweden) for finite element analysis (FEA) and corresponding data analysis. The microCT data only contains the capsule with otoliths in it, to ensure the saccular otoliths maintain the correct orientation as in an actual live fish; the orientation of the saccular otoliths was carefully adjusted based on the XCT data of the full fish. According to Schilt et al. (2011) and Krysl et al. (2012), most fish tissue has similar acoustic properties (e.g., density and elasticity) to the surrounding water; therefore a water sphere was set outside of the otoliths while the acoustic stimulation arrived, as shown in Fig. 1e. The diameter of the sphere was set as 30 mm, and the center of the sphere was located at the approximate center of the otoliths. A low-reflecting boundary condition (Bérenger 1994) was applied to the sphere, simulating the sound transmitting in free space with minimum boundary reflections. The sound source was located at a distance of 6 mm from the edges of the otoliths on the two main axes (it was assumed that the fish was ideally parallel to the water surface when the incident sounds arrived). As there were no boundary reflections from the water sphere surrounding the otolith, the experimental setup emulated long-range stimulation of the otolith system, while allowing a simplified and realistic model structure. A force was applied at the source to create vibration from the horizontal and vertical directions, creating two cases (horizontal case, H case; vertical case, V case) for later comparisons. The frequency was swept from 25 to 1600 Hz in steps of 25 Hz according to the fish hearing sensitivities and the signal characteristics of the air gun signals (Fay 1988; McCauley et al. 2003; Popper et al. 2005).

COMSOL's free mesher was used to map the entire model using the tetrahedral mesh. COMSOL has built-in detection for small features and narrow regions in a complex geometry. Based on the mesh refinement results, the size of the element was set between 0.12 and 1.6 mm, whereas the minimum wavelength of the impulse sound was 0.93 m in the model, ensuring the solution had sufficient numeric precision.

The finite element Pressure Acoustics-Frequency Domain module coupled with solid mechanics and an Acoustic-Structure Boundary was applied for the models. When acoustic waves propagate within the liquid medium, the longitudinal waves can be written as follows:

$$\frac{1}{\rho_0 c_s^2}\frac{\partial^2 p}{\partial t^2} + \nabla\cdot\left(-\frac{1}{\rho_0}\nabla p\right) = 0 \tag{1}$$

where $p$ is the sound pressure, $\rho_0$ is the density (kg/m$^3$), and $c_s$ is the speed of sound (m/s). The density $\rho_0$ is included in the equation because of its variations in different computational domains within the model. For the harmonic solution of the pressure $p(\boldsymbol{x}, t) = p(\boldsymbol{x})e^{i\omega t}$, with the angular frequency $\omega$ (rad/s), Eq. 1 can be simplified to the following:

$$\nabla\cdot\left(-\frac{1}{\rho_0}\nabla p\right) - \frac{\omega^2 p}{\rho_0 c_s^2} = 0 \tag{2}$$

While the acoustic waves interact with the solid medium, the multiphysics coupling provides and assigns the boundary conditions for the two-way acoustic-structural coupling between the liquid (e.g., water) and the solid (e.g., fish otoliths and bones). The automatic boundary condition set the boundary load $\boldsymbol{F}$ (force/unit area) on the otoliths to the following:

$$\boldsymbol{F} = -\boldsymbol{n}_s p \tag{3}$$

where $\boldsymbol{n}_s$ is the outward-pointing unit normal vector seen from inside solid domain, while on the liquid side the normal acceleration experienced by the liquid is set equal to the normal acceleration of the solid, meaning that:

$$-\boldsymbol{n}_a\cdot\left(-\frac{1}{\rho_0}\nabla p\right) = a_n \tag{4}$$

$$a_n = (\boldsymbol{n}_a\cdot\boldsymbol{u})\omega^2 \tag{5}$$

where $\boldsymbol{n}_a$ is the outward-pointing unit normal vector seen from inside the liquid, $a_n$ is normal acceleration of the solid surface in the liquid domain boundary, and $\boldsymbol{u}$ is the calculated harmonic displacement vector of the solid structure.

The following parameters were set for the models: (a) sound speed values of water outside the otoliths as 1483 m/s, whereas the density values were set as 998 kg/m$^3$. (b) The density and sound speed of the otoliths were set as 2970 kg/m$^3$ and 3000 m/s, respectively (Schulz-Mirbach et al. 2018, 2019; Salas et al. 2019b; Campana and Thorrold 2001). Young's modulus of the otolith was set as 66 GPa (Ren et al. 2013), and Poisson's ratio was set as 0.3, a value commonly used for bone (Tubelli et al. 2014).

## Results and Discussion

Some fish species can detect sound pressure, and all fish species are primarily detectors of particle motion, which can be expressed as displacement, velocity, or acceleration (Popper and Hawkins 2018). The otoliths act as elastic objects to vibrate when they are driven by the incident stimulus, creating displacement between themselves and the coupled hair cells on the macula lying in the sulcus. Figure 2a compares the distributions of SPL and displacement on the saccular otolith surface when the sound wave (frequency = 500 Hz) arrived in the H and V cases. For the SPL distribution, most energy was distributed in the anterior side of the otoliths in the H case, whereas most energy was distributed in the dorsal side of the otoliths in the V case.

Figure 2a also shows that the displacement distribution between the H and V cases is different. In the H case, higher displacement regions were visible around the anterior side of the otoliths and the direction of the displacement toward the midline of the fish. By contrast, in the V case, higher displacement regions were visible around the dorsal side of the otolith and the direction of the displacement toward the

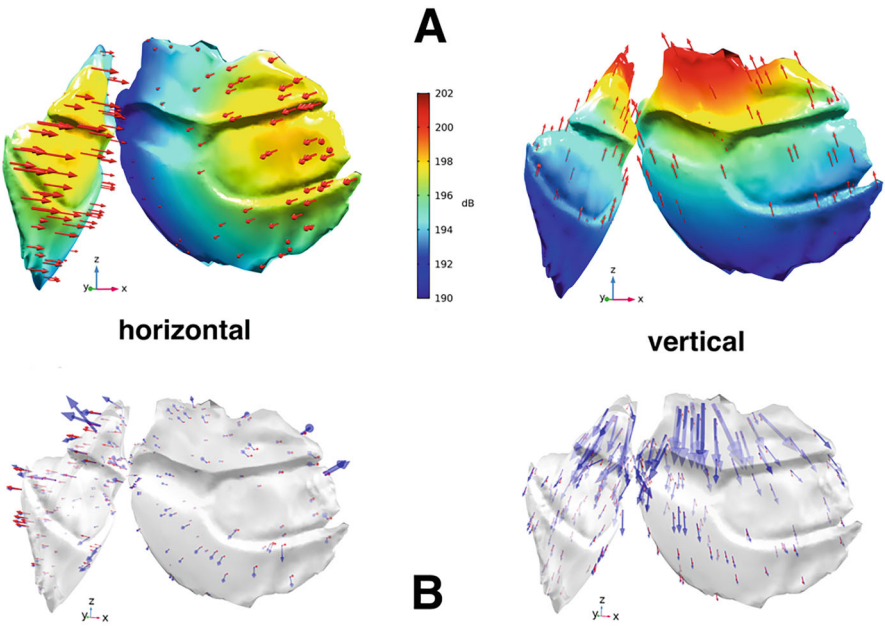

**Fig. 2** Distributions of SPL and displacement of the otolith, as well as the accelerations of the membrane and otolith in two cases (frequency = 500 Hz). The arrows indicate both the direction and magnitude. (**a**) The sound field and displacement field on the otoliths. (**b**) The acceleration distributions of the membrane and otolith. The blue arrows represent the accelerations of the membrane surfaces, and the red arrows represent the accelerations of the otolith surfaces

dorsal side of the otoliths. In both cases, the accelerations of the membrane (blue arrows) were higher than those of the otolith (red arrows). Moreover, the directions of the acceleration between the otolith and coupled membrane were also different in the H and V cases (Fig. 2b). The results demonstrated that the relative motion between the membrane and dense otolith differed between H and V cases when the sound waves arrived.

To further compare the differences of SPL, displacement, and acceleration on the sulcal groove in the two cases, the modeling data was derived to plot the 2D contours on the sulcal groove, as shown in Fig. 3.

Figure 3 displays roughly symmetrical contours. On both otoliths, as sound arrived from the horizontal direction, the regions of maximum SPL and displacement exhibited in the ostium regions. Beyond the maximum regions, the magnitudes decreased along the posterior direction. By contrast, as sound arrived from the vertical direction (Fig. 3a), the maximum regions of SPL and displacement were observed around the dorsal side of the grooves.

The contours of the acceleration on the otolith surface were similar to those of the displacement on the otolith surfaces in the two cases (Fig. 3c). Both cases had significantly different contours compared to the corresponding acceleration contours on the macula (water-otolith) surfaces, showing the differential movement between the saccular macula and dense otolith. For the acceleration distributions on the macula boundary (Fig. 3d), the regions of maximum acceleration were displayed at the edge of the rostrum in the horizontal stimulation. By contrast, the regions of maximum acceleration were distributed at the dorsal and ventral edge of the cauda when the sound wave arrived in the vertical direction.

To better visualize the relative motion between the otolith and saccular macula in two acoustic stimulations, two receiving points were placed on the water-otolith boundary. One point was located in the cauda region (PointC), and one point was located in the ostium regions (PointO) (Fig. 4). The results in Fig. 4 showed that accelerations on the water-otolith (macula) boundary (dashed lines) of corresponding points were all higher than those on the otolith (solid lines) in the two cases, suggesting that the dense otolith lagged behind relative to the motion of the macula due to its inertia (Dijkgraaf 1960; Popper and Lu 2000). When the sound arrived from the vertical direction, the differentials of the acceleration between the otolith and macula of both points were greater than those in the H case, suggesting stronger differential motions between the otolith and macula in both the cauda and ostium regions in the vertical sound arrival. The differential motion deflected the hair cells and, if amplitudes were high enough, may cause damage to the ears. A stronger differential motion might cause more severe damages. It could be one of the reasons causing the partly contradictory results from the previous experiments (McCauley et al. 2003, 2008), in which the severe damages were found in the experiment allowing vertical acoustic stimulation. The fish species used here and in the experiments of McCauley et al. (2003, 2008) had common otolith shapes with a long mostly horizontal caudal groove along the inside otolith side which was comparatively narrow and deep at the midpoint of the otolith. The different shape of otoliths and their caudal groove among other fish species may mean these results do not translate to all fish species.

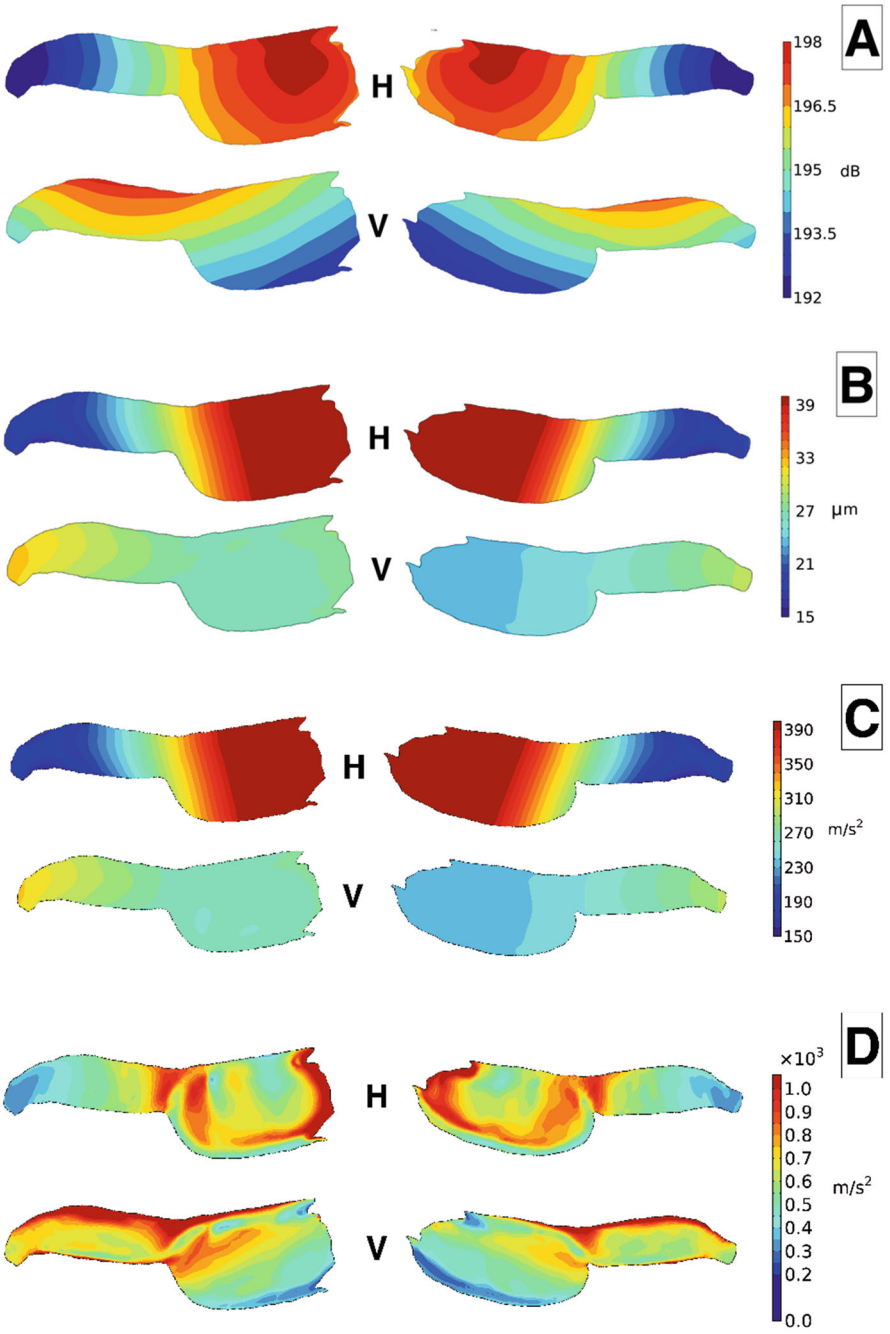

**Fig. 3** Contours of SPL, displacement, and acceleration on the sulcal grooves in the two cases. The color bars show the absolute values. (**a**) SPL contours on the otolith surfaces. (**b**) Displacement contours on the otolith surfaces. (**c**) Acceleration contours on the otolith surfaces. (**d**) Acceleration contours on the macula surfaces

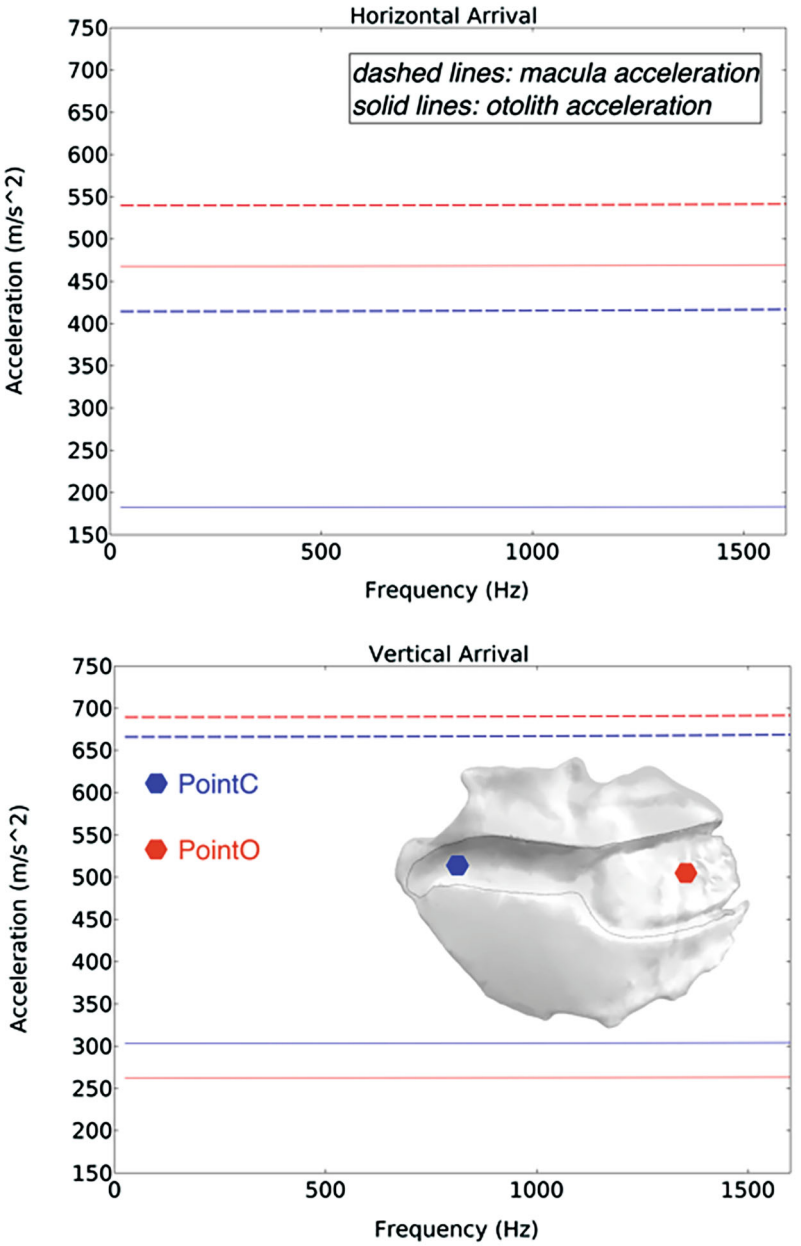

**Fig. 4** Comparison of accelerations of the otolith and macula (water-otolith boundary) from 25 to 1600 Hz in the two cases. The blue lines represent the data from the point in the cauda region, and the red lines represent the data from the point in the ostium region. The dashed lines represent the accelerations on the surface of the water-otolith, and the solid lines represent the accelerations on the surface of the otolith

The otolith is connected to the macula with the hair cells in it through the elastic membrane; the ciliary bundles could be either deflected or compressed as the sound wave impinges from different angles (Schulz-Mirbach et al. 2019). Here a force analysis was attempted to study the stress exerted on the surface of the otolith in the two cases. Figure 5a shows the shear stress distribution on the surfaces of both otoliths. As the sounds arrived from the vertical direction, significantly higher-stress regions were exhibited in the cauda regions of both otoliths. The results matched well with the spatial mapping of the hair cell damage on the exposed fish from the previous experiment (McCauley et al. 2003, Fig. 5b), in which most damage occurred in the cauda region closer to the dorsal/ventral edges when an exposed fish experienced air gun signals with an almost equal vertical to horizontal energy component.

According to the morphometric results obtained from the microCT data, the groove was relatively deep (~0.6 mm) and narrow (~2.4 mm) when looked at from the top and shallow and long (~16.6 mm) when looked at from the front. Because of this biological configuration of the otoliths, when an acoustic stimulation arrives from the horizontal direction, it will tend not to drive the membrane into the sulcal groove edges since there is more space for it to move. By contrast for stimulation in the vertical direction, there is not enough space for the membrane to go except to push against the inside of the sulcal groove. Therefore, the results from this study suggested that fishes with an otolith shape similar to the bight redfish might be able to endure sound energy arriving in the horizontal direction rather than the vertical direction. Again, the results are most likely species-specific; a different fish species with a distinct otolith shape may lead to different results (Smith et al. 2022).

The model in this study only simulated a pair of the saccular otoliths immersed in the water. However, the saccular otoliths of the bight redfish sit inside an otic capsule

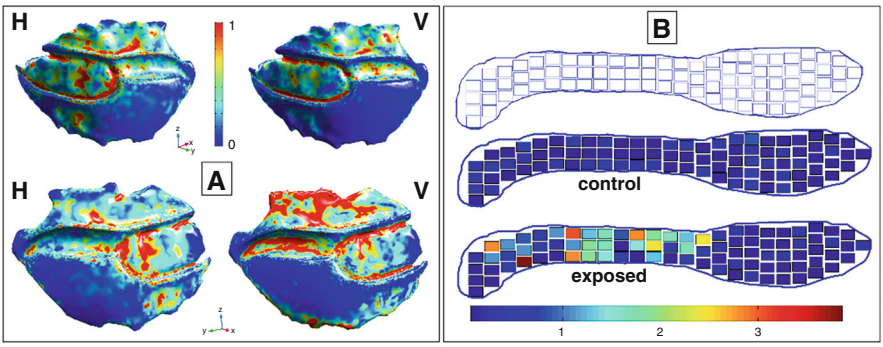

**Fig. 5** (**a**) Comparison of the relative shear stress on the otolith surfaces in the two cases, the color bar represents the magnitude of the normalized shear stress. (**b**) The spatial mapping of the hair cell damage on the pink snapper (*Pagrus auratus*) macula from air gun signals with an almost equal vertical energy component compared with horizontal. (Modified from McCauley et al. 2003, Fig. 2.62). The color code is a scale of severity as the mean number of ablated cells in that grid space (gross hair cell damage only). The middle image shows the results of the control fish, and the lower image represents the results of the exposed fish

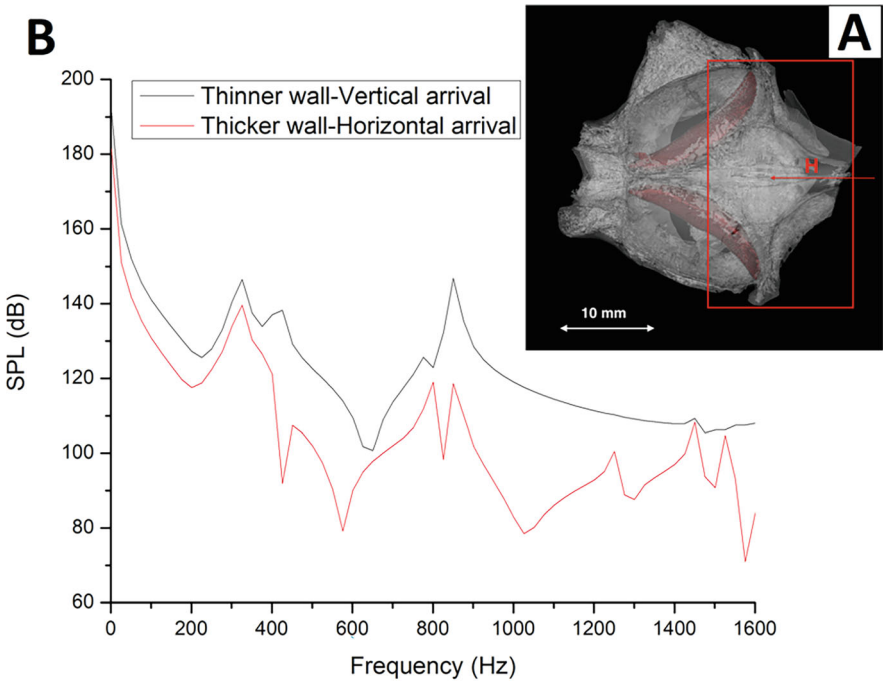

**Fig. 6** (**a**) 3D reconstruction of the capsule (white) containing the saccular otoliths (red). The transparency level represents the different thicknesses. (**b**) Comparison of the SPLs inside the capsule when sound penetrates through the thinner wall (vertical direction) vs. thicker wall (horizontal direction)

(Fig. 6a). The wall of the capsule in the head of the bight redfish is thicker in the horizontal direction compared to the vertical direction, as circled in Fig. 6a. The thickness of the wall could cause different attenuations when the sound penetrates through the capsule. A test was run by setting a receiving point in the center of the capsule and compared the SPLs of the receiving point when sounds arrived from the horizontal direction through a thicker wall and the vertical direction through a thinner wall (Fig. 6b). The results showed that the SPL was reduced in the entire frequency range from 25 to 1600 Hz if the sound penetrated through a thicker capsule wall in the bight redfish's head. This may further explain why less damage to the hair cells was found when the air gun signals were induced from the horizontal direction in the previous experiments.

As noted above, it is important to note that the morphology of fish otolith (e.g., size, geometry, the angle it is tilted in the capsule, etc.) varies among species. Therefore, it would be interesting to model other otolith shapes for this topic and consider what the shapes mean for hearing in different species. The morphology of the otolith may also change in the same species due to different ages and food sources. In addition, there are many other variables, such as the angle of arriving sound energy (caused by the location of the sound source, depth of water, bottom

type), the source of the stimulus (pulsed sound vs. pure tone), the hair cell orientation patterns, etc. It is important to consider these variables in any future studies to gain a deeper understanding of the effect of acoustic stimulus on fish otoliths.

## Conclusions

In this study, 3D finite element models based on the microCT data of a pair of saccular otoliths were constructed to investigate the motion of the otoliths in the presence of acoustic stimulations from the horizontal and vertical directions. The results show that a sound wave that arrives from different directions causes different magnitudes of the differential motion between the sensory macula and otolith in the fish ears. This motion difference plus the geometry of the otoliths plays an important role in terms of how the fish otoliths may respond to incoming sounds. The results from this work may potentially aid researchers in studying the hearing of some key fish species (e.g., commercially important species) and may feed into environmental policy with regard to the management of intense noise sources such as the noise from petroleum seismic survey air gun arrays, which are often in conflict with commercial fisheries.

**Abstract**

Anthropogenic noise negatively impacts the lives of aquatic animals including their ability to reproduce and survive. However, some animals are still able to thrive within these increasingly noisy environments and therefore must have some adaptations that allow them to attend to salient signals within noise. All major classes of vertebrates have cholinergic neurons in the hindbrain that function as auditory efferents, meaning that they project to the inner ear. Even less is known about dopamine neurons that project to the inner ear, but studies in rodents have proposed that one role of both types of efferents is to protect the ear from damage due to noise. Therefore, research in aquatic systems should focus on animals that use acoustic communication in reproductive contexts, like the oyster toadfish (*Opsanus tau*), which are regularly exposed to high levels of anthropogenic sounds. Examining the role of modulatory neurotransmitters, like dopamine, within the auditory system, will provide important insights to understanding neural adaptations for survival in environments exposed to increasing levels of anthropogenic noise.

## Introduction

Noise in the aquatic environment has only increased in the last 60 years (Ellison et al. 2012) and may come from various sources including impact pile driving, seismic air guns, vessels, and wind turbines (Slabbekoorn et al. 2010; Popper and Hawkins 2019). Anthropogenic noise is typically low in frequency and broadband, which is within the hearing ranges of many aquatic mammals and fishes (Slabbekoorn et al. 2010; Popper and Fay 2011) and can have an adverse effect on an animal's ability to communicate, feed, reproduce, and evade predators (Codarin et al. 2009; Simpson et al. 2016; Shannon et al. 2016). Intense noise can induce temporary and even permanent threshold shifts in both fishes and marine mammals (Amoser and Ladich 2003; Nachtigall et al. 2003; Finneran et al. 2005; Brietzler et al. 2020). Researchers have used several experimental methods to understand the negative effect of noise by measuring behavioral changes and hearing sensitivity. While these are necessary and valid measures for understanding the effects of noise on an animals' hearing sensitivity, these measures do not account for biochemical changes in the brain, which in turn modulate sensory, motor, and cognitive functions. More recently, research has focused on the role of neurochemical modulation of the inner ear and

central auditory areas that could be involved in filtering noise and attenuating acoustic damage.

All major classes of vertebrates have neurons in the hindbrain that contain the neurotransmitter, acetylcholine, and project to the inner ear (Köppl 2011). The proposed function of these efferents includes protection of the inner ear from overstimulation, increasing signal to noise ratio, and detection and attention to sounds (Tomchik and Lu 2006; Maison et al. 2013; Boero et al. 2018; Guinan 2018). Thus, one level where filtering noise occurs is in the inner ear via modulatory feedback from the brain (Tomchik and Lu 2006; Köppl 2011). In addition to cholinergic efferents, fishes and mammals are documented to have dopaminergic efferent neurons, which project to the inner ear and could therefore modulate acoustic signals at the level of the peripheral auditory system (Darrow et al. 2006; Forlano et al. 2014). In rodent models, dopamine neurons in the lateral olivocochlear (LOC) nucleus inhibit cochlear afferents. LOC neurons upregulate dopamine after sound conditioning, a low-level stimulus presented prior to a damaging stimulus, which is predicted to be involved with reducing damage at the level of the auditory nerve (Niu and Canlon 2002). Reducing dopamine (DA) receptors within the cochlea can increase vulnerability of hair cell damage (Maison et al. 2012) to acoustic trauma. Damaging noise triggers DA synthesis in the LOC, and it is predicted that DA protects the inner ear from overstimulation (Lendvai et al. 2011; Wu et al. 2020). Intense noise can induce irreparable damage to hair cells, which are not able to regenerate in mammals (Bermingham-McDonogh and Rubel 2003). Apart from recent studies in toadfishes (see below and Forlano and Sisneros 2016), virtually nothing is known about the role of dopamine in modulation of the inner ear under natural environmental conditions.

The inferior colliculus, or auditory midbrain in mammals, receives input from dopamine and other catecholaminergic (e.g., noradrenergic) neurons. In mammals, most of the dopamine terminals, or puncta, in the inferior colliculus come from the A11 population of dopaminergic cells located in the diencephalon (Takada et al. 1988; Nevue et al. 2016; Batton et al. 2019; see Wilson and Apawu 2022). A recent study using fast scan cyclic voltammetry and immunocytochemistry found a decrease in dopamine release and a decrease in the inhibitory D2 receptor distribution of the external cortex and central nucleus of the inferior colliculus after noise exposure (Wilson and Apawu 2022). The exact role of dopamine within the inferior colliculus is still unknown; however, disruptions and changes to dopamine within the central and peripheral nervous system can affect auditory processing (Matragrano et al. 2012; Hoyt et al. 2019).

Virtually all studies that have investigated the function of auditory neuromodulators during noise exposure have been conducted in terrestrial (rodent) models. Thus, there is a need to understand adaptations of the central auditory system of aquatic animals in the presence of environmental sounds, specifically in fishes that have an audiometric range within the frequency of anthropogenic noise. This is especially important for animals that require sound for communication and reproduction. Some fish species leave an area when noise is present (Slabbekoorn et al. 2010); however, animals that either cannot or will not leave their given

location, most likely have adapted to live within the noisy environment. Here it is proposed that central dopamine neurons and their influence over central and peripheral auditory processing may be a key adaptation in aquatic animals to survive in noisy environments.

## Toadfishes as a Model Species

*Opsanus tau*, the oyster toadfish, is a soniferous fish that relies on acoustic signals to communicate with one another and attract mates. These animals are known to reside along the US eastern seaboard, including populations that live along urban cities like New York City (Anderson et al. 2008) where commercial vessel traffic is particularly heavy (Fig. 1). Male toadfish establish nests and emit an advertisement call, a "boatwhistle," to attract female mates (Gray and Winn 1961; Fine 1978). Boatwhistles are detected via the lateral line, saccules, and other end organs of the inner ear (Radford and Mensinger 2014; Cardinal et al. 2018; Fay and Edds-Walton 1997; Maruska and Mensinger 2015). Males are responsible for egg care and maintain high nest fidelity (Maruska and Mensinger 2009; Mensinger 2014). This may make the toadfish more susceptible to the negative effects of noise since they may not evacuate the area when intense noise is present (Faulkner et al. 2018). It is

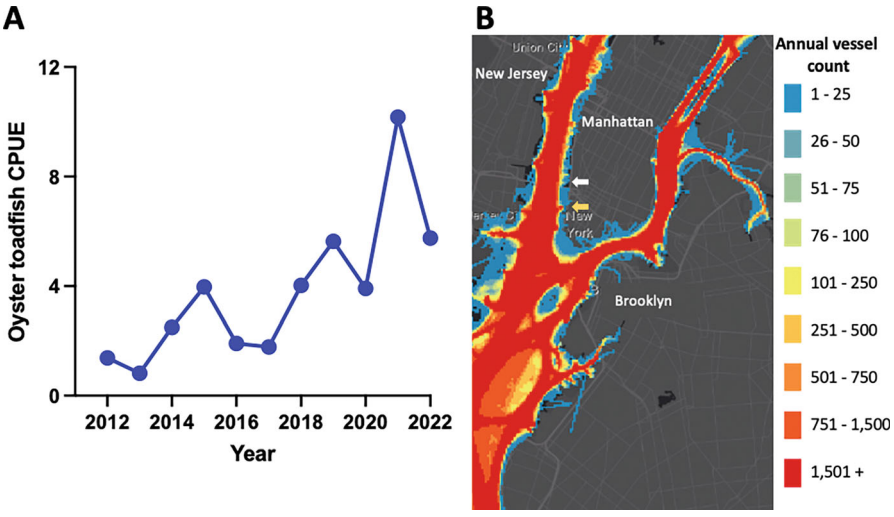

**Fig. 1** (**a**). Data from un-baited crab traps set at Hudson River Park (Pier 26/Pier 40, New York, NY; yellow and white arrow, respectively in B) and checked regularly to monitor population of fishes within the Hudson River system. Pier 26 and Pier 40 are where oyster toadfish are collected and counted by Hudson River Park's River Project, NY. The catch per unit effort (CPUE) was calculated for oyster toadfish populations (data courtesy of Hudson River Park, NY). (**b**). Automatic identification system (AIS) tracking information was collected from commercial vessels and large recreational boats. The map shows boat traffic within New York and New Jersey waters from 2021. (Image of map with boat traffic courtesy of MarineCadastre.gov and NOAA)

proposed that animals that stay in an area with increased noise may have increased stress levels and decreased reproduction (de Jong et al. 2020; Cartolano et al. 2020). However, there is evidence that oyster toadfish populations along some urban areas, like New York City, remain unchanged (see Fig. 1a), and perhaps diminished reproductive success does not occur in this species. For this reason, oyster toadfish may have adapted to these increasingly noisy environments (see Fig. 1b), in part, via modulation of their inner ears by auditory efferents in the brain.

Previous studies have used various toadfish species to examine the effects of noise on behavior and hearing sensitivity. Behavioral playback experiments conducted on the Lusitanian toadfish (*Halobatrachus didactylus*), within the same family as oyster toadfish (Batrachoididae), found that exposure to boat noise decreased the communication distance, interfered with male-to-male interactions, decreased calling rates of males (Alves et al. 2016; Alves et al. 2021; Amorim et al. 2022), and decreased reproductive success (Amorim et al. 2022). Researchers measured the effects of an outdoor musical festival on circulating cortisol in Gulf toadfish (*Opsanus beta*) and found significant increases in the stress hormone 7 h after the onset of music (Cartolano et al. 2020). Similar behavioral studies in oyster toadfish found that exposures to boat noise decreased calling behavior (Krahforst et al. 2016; Mackiewcz et al. 2021) and can potentially cause these animals to increase the amplitude of their calls, also referred to as the Lombard effect, in noisy environments (Luczkovich et al. 2016).

Auditory evoked potentials conducted on the Lusitanian toadfish found a decrease in auditory sensitivity during ship noise playbacks (Vasconcelos et al. 2007), most likely because the ship noise was within the hearing range of the toadfish. Additionally, ship noise can interfere with the detection of the boatwhistle due to masking (Alves et al. 2021). Oyster toadfish exposed to high intensity boat noise for at least 1 h experienced a temporary threshold shift (TTS) of a minimum of 8 dB SPL for at least 3 days measured by auditory evoked potentials (Rogers et al. 2020). Anthropogenic noises that cause significant threshold shifts could impact the females' ability to locate males, and therefore have a negative impact on reproductive success. Most of the literature examining the effects of noise on fishes, especially toadfishes, has focused on behavioral changes (calling patterns, amplitude) or TTS as measured by auditory evoked potentials. However, an understanding of responses at the circuit and neurochemical level to strong anthropogenic sounds may provide insight into neural adaptations that allow certain species to thrive despite increasing environmental noise.

## Recent Studies in Plainfin Midshipman Fish Support a Role for Dopamine in Peripheral Auditory Processing

The plainfin midshipman fish (*Porichthys notatus*), another toadfish in the family Batrachoididae, is found along the coast of the US Pacific Northwest and northern California and is a well-studied model system for understanding neural and hormonal mechanisms underlying vocal-acoustic behavior. Male midshipman fish

establish nests but produce an advertisement call, the "hum," lasting minutes to hours in comparison to the oyster toadfish (200–650 ms, Tavolga 1958; Mensinger 2014) to attract female mates (Brantley and Bass 1994). Females localize courting males by their hum, deposit their eggs in the nest, and return offshore, while males alone care for the eggs and developing fry (Forlano et al. 2015a). Female midshipman fish exhibit a seasonal increase in frequency sensitivity of the inner ear coincident with reproductive state (Rohmann and Bass 2011; Sisneros 2009; Sisneros and Bass 2003) that is driven by seasonal changes in hormones (Sisneros et al. 2004). In female midshipman, seasonal changes in saccular hair cell density (Coffin et al. 2012) and potassium channel expression (Rohmann et al. 2013) contribute to this plasticity. More recently, seasonal changes in dopamine innervation of the saccule (Forlano et al. 2015a; Perelmuter et al. 2019) is proposed as a major regulator of peripheral auditory sensitivity in the inner ear of this species. While seasonal changes in catecholamine fiber innervation was also demonstrated in auditory hindbrain and forebrain areas, its function is unclear (Forlano et al. 2015a).

## Projections in the Central and Peripheral Nervous System

### Cholinergic and Dopaminergic Efferent Projections to the Saccule

Cholinergic and dopaminergic neurons in the hindbrain and forebrain, respectively, send (efferent) projections to the inner ear. In teleost fishes, the octavolateralis efferent nucleus (OE) sends cholinergic projections to the saccule, the largest endorgan of hearing (SE, Fig. 2; Bass et al. 2000; Forlano et al. 2014), the other end organs of the inner ear, and lateral line (Köppl 2011; Tomchik and Lu 2006). Neurobiotin tract tracing studies demonstrate that most, if not all, OE neurons project to the saccule (Bass et al. 1994; Bass et al. 2000; Forlano et al. 2014) and these cholinergic projections to the fish saccule are inhibitory in nature (Furukawa 1981; Sugihara 2001).

Neural tract-tracing experiments have also demonstrated that dopaminergic neurons in the periventricular posterior tuberculum (TPp; diencephalon) project directly to the saccular epithelium and to cholinergic neurons in the OE (Forlano et al. 2014; Perelmuter and Forlano 2017). It is unknown whether the robust dopamine innervation onto OE somata and dendrites are inhibitory or excitatory in nature (Forlano et al. 2014); however, experiments in zebrafish (*Danio rerio*) have shown dopamine projections from TPp have an excitatory function on lateral line neuromasts (Toro et al. 2015). TPp is a conserved dopamine nucleus in the forebrain and is homologous to A11 cells in mammals (Tay et al. 2011), where these dopamine neurons project to the inferior colliculus and auditory brainstem (Nevue et al. 2016).

In midshipman fish, reproductive females show greater dopaminergic innervation on OE cholinergic somata and dendrites in comparison to winter females (as indicated by tyrosine hydroxylase immunoreactivity, a marker of dopamine synthesis (TH-ir; see Forlano et al. 2014; 2015a). Similarly, in the TPp, there is an

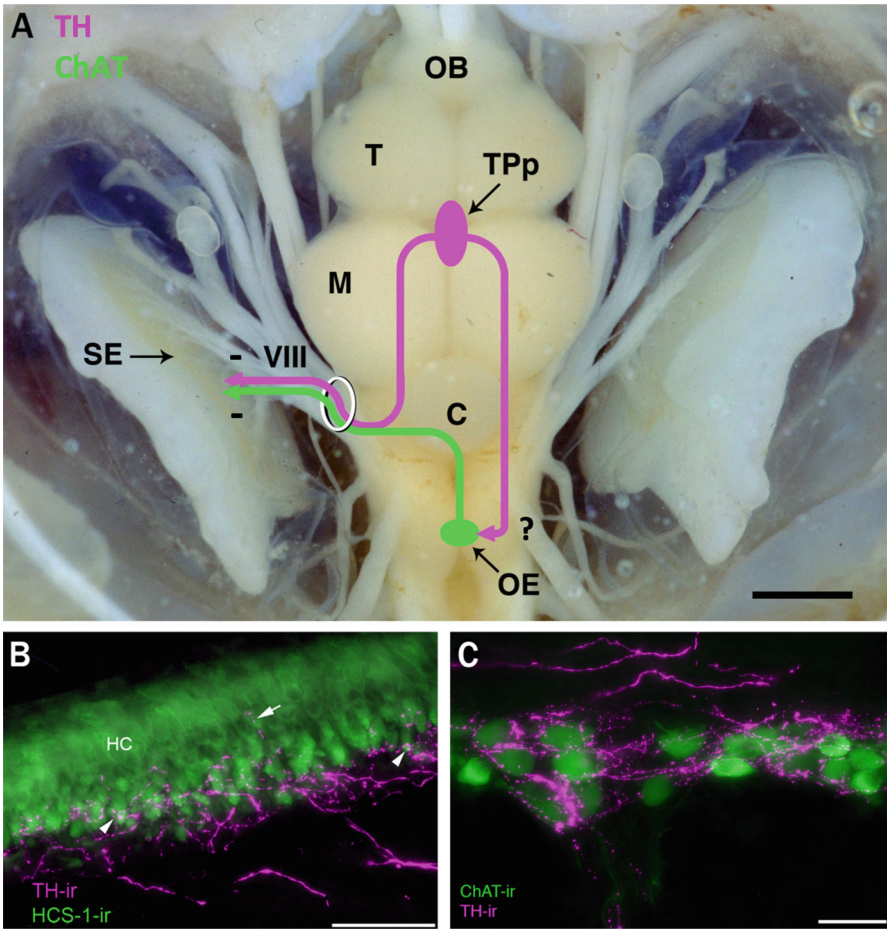

**Fig. 2** (**a**). dorsal view of the plainfin midshipman (*Porichthys notatus*) brain and inner ears. The saccule (SE) receives direct dopaminergic input (TH, magenta) from the periventricular posterior tuberculum (TPp) and receives cholinergic projections (ChAT, green) from the octavolateralis efferent nucleus (OE) via the eighth nerve (VIII) (Forlano et al. 2014; Perelmuter and Forlano 2017). Both of these inputs to the saccule are inhibitory(−) (Perelmuter et al. 2019; Furukawa 1981). The TPp also sends robust dopaminergic input to the OE but its action is unclear (indicated by "?"). (**b**). TH-ir fibers (magenta) enter the base of the SE and form punctate swellings (white arrowheads) around the base of hair cells (HC) (hair cell-specific marker, otoferlin-ir, green). (**c**). Beaded TH-ir fibers extensively wrap around OE neurons (ChAT-ir). Scale bar equals 1.5 mm in (a) and 50 μm in (b and c). Additional abbreviations in A: cerebellum (C), midbrain (M), telencephalon (T), olfactory bulbs (OB).

increase in TH-ir area of dopaminergic cells in summer females in comparison to winter females (Forlano et al. 2015a). In contrast, the saccular epithelium shows a decrease in TH-ir puncta (putative release sites of dopamine) in summer females in comparison to winter females (Forlano et al. 2015a). In the saccule, dopamine

produces a dose-dependent inhibitory effect on hair cell receptor potentials and thus decreases the sensitivity of the inner ear of midshipman fish (Perelmuter et al. 2019). Importantly, a seasonal decrease in dopamine innervation in the saccule coincides with an increase in frequency sensitivity and at the level of the hair cell in reproductive females (Perelmuter et al. 2019). Additionally, D2a receptors, known to be inhibitory in nature, are significantly decreased in the summer (Perelmuter et al. 2019). Therefore, a seasonal release of inhibitory input to the saccule will prime females for greater hearing sensitivity to locate mates in the summer (Perelmuter et al. 2019). However, more research is needed to elucidate the exact role of dopamine signaling and receptor expression in the inner ear during vocal communication in variable acoustic environments.

## Dopaminergic Cells in the TPp Are Responsive to Calls from Conspecifics

When TPp dopamine neurons are active during the summer reproductive season is an ongoing area of investigation. Importantly, sound playback studies coupled with using cFos immunohistochemistry (as a marker of neural activity) have shown that dopaminergic neurons in the TPp are responsive to conspecific vocalizations in type I (courting) males (Petersen et al. 2013), type II (sneaker) males (Ghahramani et al. 2018), and in females while attending the speaker emitting a synthesized hum (Forlano et al. 2017). Importantly, the TPp receives auditory input from the midbrain torus semicircularis via the periaquaductal gray (PAG, midbrain vocal-acoustic center) with which it shares bidirectional communication (Kittelberger and Bass 2013). In turn, the TPp projects to the nearby auditory thalamus (central posterior nucleus) and is widely connected to the basal forebrain, indicating the TPp is especially positioned to coordinate sensory-motor integration and behavior in response to acoustic stimuli (Petersen et al. 2013; Forlano et al. 2015b).

Taken together, changes in TPp dopaminergic innervation of the saccule and OE likely contribute to a seasonal increase in peripheral auditory hearing sensitivity; TPp may also function to modulate attention and motivation to salient acoustic social signals (Forlano et al. 2015a; Forlano et al. 2017; Perelmuter et al. 2019). In addition, cholinergic efferents (OE) are active in midshipman when they are calling, which is proposed to reduce stimulation of the saccule and lateral line by self-generated noise, thereby increasing sensitivity to external sounds during vocalization (Weeg et al. 2005). Cholinergic (OE) stimulation in another species, the *Dormitator latifrons,* supports its role increasing signal-to-noise ratio in auditory and lateral line systems (Tomchik and Lu 2006). Therefore, gaining a better understanding of the interplay between the dopaminergic and cholinergic efferent systems in contexts when relevant social signals need to be extracted from noisy soundscapes will be important to understanding their function in acoustic communication.

## Preliminary Studies Suggest Changes in Dopamine Synthesis Occur in the Auditory System of Toadfishes under Variable Acoustic Conditions

To better understand under what conditions there are changes in the synthesis and release of dopamine at their central and peripheral auditory targets, studies were conducted in midshipman and oyster toadfish measuring the phosphorylated version of TH (pTH), a proxy for dopamine synthesis and release (Xu et al. 1997), at the level of the saccule, OE, TS, and the source neurons (TPp) under various sound playback conditions.

Preliminary studies using female midshipman fish examined the effect of playback on catecholamine synthesis in the auditory system. Animals were exposed to 15 min of either the hum, brown noise control (within the frequency bandwidth and equivalent amplitude of the hum), or ambient control conditions. A significant decrease in enzyme activity measured by pTH-ir puncta intensity (terminals or putative dopamine release sites) was found in the hum conditions in comparison to noise and ambient controls in the OE and TPp (Hom et al. 2019). While no change in pTH-ir intensity was observed in the saccule, a decrease in pTH-ir puncta area was seen in hum condition compared to ambient control. It is hypothesized that a decrease in direct or indirect (via OE) action of inhibitory dopamine signaling to the saccule may increase peripheral auditory sensitivity when hearing conspecific vocalizations.

Another preliminary study by Hom et al. (unpublished observations) exposed oyster toadfish to either 30 min of ambient conditions or recorded boat noise used in a previous study that induced TTS after an hour-long exposure (Rogers et al. 2020). In the OE, there was a decrease in pTH-ir area ($\mu m^2$) in the noise condition in comparison to the control condition (Fig. 3). In contrast, TPp neurons showed an increase in pTH-ir area in the noise condition in comparison to controls. Similarly, in

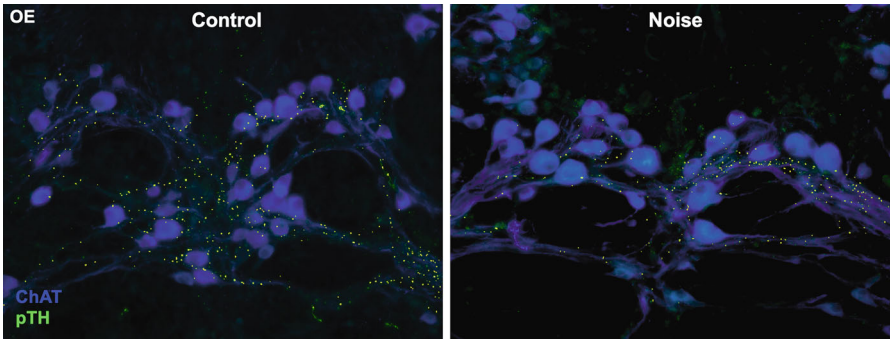

**Fig. 3** Micrographs of the OE depicts ChAT-ir somata (blue) and pTH-ir puncta (green) of both the control (ambient sound) and noise (continuous boat noise) conditions. There is significantly greater pTH-ir puncta area in the control versus the noise condition

the saccule, the noise condition showed a trend toward greater numbers of pTH-ir puncta. These results support a hypothesis that a downregulation in pTH puncta on the OE could increase inhibitory action of cholinergic projections to the saccule while an increase in pTH in the TPp in the presence of noise suggests an upregulation of dopamine synthesis in the neurons that may project to the saccule, similar to studies in rodents (Lendvai et al. 2011; Wu et al. 2020).

Overall, the release of dopaminergic inhibition of the saccule is proposed to enhance detection of salient signals in the reproductive season (Perelmuter et al. 2019). This work aligns with studies in rodents that show dopamine has an inhibitory effect on cochlear afferent neurons (d'Aldin et al. 1995, Lendvai et al. 2011, Ruel et al. 2001), and can result in preventing excitotoxicity in the cochlea (Ruel et al. 2001). Additionally, rodents exposed to intense noise exhibited an upregulation of TH-ir in the efferent auditory pathway and cochlea, confirming that dopamine is necessary for protecting against damaging noise (Wu et al. 2020; Niu and Canlon 2004). In the presence of noise, an increase of dopamine in the saccule could inhibit sensitivity to the inner ear, potentially protecting the saccule from damage. Furthermore, TPp dopamine neurons could exert additional control of saccular inhibition (and potentially other endorgans) via OE modulation, in the presence of intense noise. This type of multilayered regulation of the inner ear, could serve as an important adaptation for communication in complex underwater soundscapes.

## Ongoing and Future Studies

More research within the field of aquatic noise needs to be conducted on animals that have adapted to live in an increasingly noisy environment. While most of the research on the effects of anthropogenic noise on aquatic animals have focused on behavioral changes and potential hearing loss, it is important to also examine the neurochemical changes that might be occurring in these animals. Soniferous fish that use acoustic communication for reproduction, like the oyster toadfish, are a great model species to answer these types of research questions.

Future studies will examine neurochemical changes in both the central and peripheral nervous system of fishes, specifically measuring differences in catecholaminergic synthesis (Hom et al. unpublished observations) between fish in quiet versus noisy environments. Playback experiments testing animals in their natural environments or comparing populations from quiet and noisy soundscapes could illuminate how animals have adapted to their environment. This research would be pivotal in understanding how fish are evolving in louder soundscapes.

**Abstract**

The zebrafish, *Danio rerio*, has become an important model in hearing research to investigate the mechanisms underlying inner ear development, hair cell regeneration, and ototoxicity of environmental agents. However, limited information is known on its natural soundscape and acoustic conditions in captivity, as well as on the effects of noise exposure on the auditory system.

This chapter covers the present knowledge on (1) zebrafish natural soundscapes, (2) acoustic conditions in typical zebrafish housing systems, and (3) noise-induced hearing loss and inner ear damage in this model system. An overview is provided within a critical perspective considering the few existing studies and experimental limitations, while highlighting several open questions.

## Introduction

Understanding how changes in the environment affect organismal responses and their adaptive potential is paramount in the current scenario of global change (Kelley et al. 2018; Fox et al. 2019). Fish species are increasingly being challenged by changes in their sensory environments due to anthropogenic activities and climate change (van der Sluijs et al. 2011; Slabbekoorn et al. 2010). Human activities are causing a near-ubiquitous and unprecedented increase in environmental noise, which has become an important component of global change (Swaddle et al. 2015).

Anthropogenic noise often overlaps with hearing sensitivity ranges of fish species (Slabbekoorn et al. 2010), thus masking acoustic cues (Vasconcelos et al. 2007) and causing a multitude of other detrimental effects such as auditory impairment, inner ear damage, physiological stress, and behavioral disruption (Nedelec et al. 2015; Kunc et al. 2016; de Jong et al. 2018). The impact of these changes on fish sensory systems, and the ultimate consequences for fitness and evolution, are largely unknown (Kelley et al. 2018).

The zebrafish, *Danio rerio* (Cyprinidae), has become an important model organism to investigate hearing and deafness (Bever and Fekete 2002; Whitfield 2002; Wang et al. 2015). This species has a typical vertebrate inner ear at the cellular level, and its anatomy and development have been intensively described (Bever and Fekete 2002; Whitfield 2002). The rapid and accessible embryogenesis in zebrafish combined with the available genetic and genomic tools for systematic gene discovery made possible to create several mutant lines with impaired development and function of the inner ear, including models for human deafness and vestibular disorders (Whitfield 2002; Nicolson 2005; Varshney et al. 2016). Besides, this model organism has been widely used to investigate the molecular mechanisms of hair cell regeneration and for drug screening of ototoxic agents (Chiu et al. 2008; Ou et al. 2010; Varshney et al. 2016).

Zebrafish is an ostariophysan species with Weberian ossicles linking the swim bladder to the inner ear, enhancing hearing especially at higher frequencies (Bang et al. 2001). Even though this species has become a reference model in hearing research, limited information is available on its adaptation to the natural soundscape. Moreover, this species is typically raised in housing facilities with elevated noise levels generated by aerators, air and water pumps, water circulation, and feeding systems, which may compromise its well-being and breeding conditions.

This chapter focuses on zebrafish as a model in bioacoustics, covering the existing knowledge on (1) species adaptation to its natural soundscape, (2) acoustic conditions in typical zebrafish housing systems, and (3) noise-induced changes in the structure-function of the auditory system.

## Adaptation to Natural Soundscapes

By listening to the aquatic soundscape or acoustic scene, fish can extract relevant biotic information about the presence of conspecifics and potential predators and prey (Popper and Fay 1993; Ladich 2013). In addition, they can also gather

information on abiotic parameters such as wind, cavitation, and water currents going through different types of substrates (Popper and Fay 1993; Lagardère et al. 1994), which is important for orientation and selection of appropriate habitats. Indeed, the soundscape provides a wider three-dimensional perspective on the surrounding world than is possible using vision, olfaction, or electroreception. Since fish can detect and process both sound pressure and particle motion, localize sound sources, and perform auditory scene analysis, the underwater acoustic scene can be extremely rich in information compared to terrestrial habitats (Fay and Popper 2000; Fay 2009; Bretschneider et al. 2013; Popper and Hawkins 2018).

Zebrafish is a small cyprinid native to the Indian subcontinent, where it is typically found in shallow, slow-flowing, or stagnant waters in Northeastern and Southwestern India, Nepal, Bangladesh, South Pakistan, and Northern Myanmar (Engeszer et al. 2007; Arunachalam et al. 2013). This species tolerates a variable range of altitudes, temperatures, and water conditions, living in water bodies with widely different substrates and levels of vegetation, from natural wetlands to man-made ditches (Engeszer et al. 2007; Spence et al. 2008; Sundin et al. 2019).

The only study that evaluated the acoustic features of zebrafish natural habitats was conducted by Lara and Vasconcelos (2019). In this study, the environmental soundscape was recorded in five distinct habitats in Karnataka, Southwest India, from stagnant or low-flow water courses to the margins of a main river. The substrate found in these locations varied from sand, lime, silt, and/or bedrock, and zebrafish were either stationary swimming in compact shoals countering the water current or disperse in loose groups.

Lara and Vasconcelos (2019) reported a considerable variation in Sound Pressure Level (SPL) from 103 dB in a low-flow small stream, up to 126 dB re 1 μPa in a main river course (Tunga river). The spectral energy was overall concentrated bellow 3000 Hz, but energy peaks varied considerably between habitats mostly due to differences in abiotic sources (volume and speed of water flow, cavitation, and sediment composition and transportation). Similarly, other studies have reported comparable variability in ambient noise spectral profiles in freshwater ecosystems (Crawford et al. 1997; Lugli et al. 2003; Wysocki et al. 2007).

Moreover, Lara and Vasconcelos (2019) identified a quiet noise window (100–2000 Hz) within the noisiest habitat (Tunga river), which matched the species best hearing range between 600 and 1000 Hz (Higgs et al. 2003, Wang et al. 2015; Monroe et al. 2016) – see Fig. 1. A quiet window within the soundscape has been identified in other freshwater habitats (Crawford et al. 1997; Lugli et al. 2003; Lugli 2010), and it is most likely generated by propagation loss and absorption of sound waves in shallow environments (Erbe et al. 2022). Interestingly, the frequency range of such quiet window exhibited the highest variability across all acoustic environments (Lara and Vasconcelos 2019). Such findings strongly suggest that zebrafish may rely on environmental acoustic cues for orientation in the wild, which should be further investigated.

Indeed, the natural history of zebrafish may lend support to the sensory drive framework proposed by Endler (1992). According to this view, perception systems should evolve to be effective within local environmental constraints (e.g., Amorim et al. 2018). Although zebrafish are not known to produce sounds, contrary to other

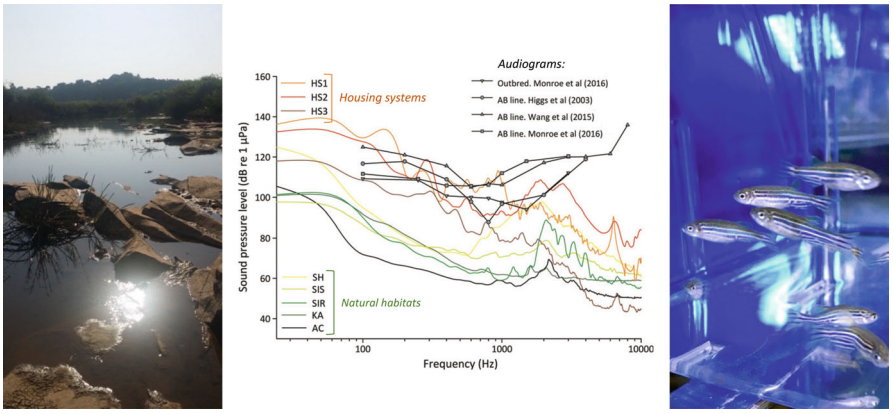

**Fig. 1** **Left**: Typical zebrafish habitat near Kaveri river, Southwest India (Karnataka state). **Middle**: sound spectra from both natural and captive noise conditions compared with zebrafish audiograms (gray bulleted lines). Mean auditory thresholds indicated are from AB wild-type line and wild-type line from Liles Tropical Fish, Inc. (Ruskin, FL). Natural habitats: SH–Shringeri, fast-flow Tunga River; SIS–Sidi Halla (sandy), low-flow stream; SIR–Sidi Halla (rocky), medium-flow stream; KA–Kallahalli, natural wells connected to Kaveri river; AC–Achacanni, shallow low-flow stream; and Zebrafish Housing Systems: HS1 and HS2 (stand-alone systems from Yakos 65, Taiwan) and HS3 (multilinking system with external pumping/filtering units from ZebTEC, Techniplast). Right: Zebrafish in typical laboratory tanks. (Adapted from Lara & Vasconcelos (2019))

cyprinids (Britz et al. 2021), they may rely on acoustic cues to learn about their surroundings (Popper and Fay 1997; Popper and Sisneros 2022). Future studies should consider playback experiments using sound recordings from different natural habitats to evaluate zebrafish preference for specific auditory cues.

Since Lara and Vasconcelos (2019) is the only study available on the zebrafish natural soundscapes, many questions remain open. For instance, particle motion is key for understanding how fish perceive their acoustic environment, including zebrafish (Popper and Sisneros 2022). Particle motion can be calculated indirectly from sound pressure measurements under certain conditions, but not in shallow waters where zebrafish and most fish species and invertebrates are typically found (Nedelec et al. 2016). Hence, future work should include direct measurements using a particle-motion sensor in the field and a comparison between pressure and particle motion across different zebrafish habitats, from low-flow courses and pools in mudflats to hilly watercourses.

Moreover, a comparison between wet and dry seasons would certainly be useful to obtain a more comprehensive characterization of the acoustic variation within a natural habitat since the information available is only based on the dry season – weak wind and no rain (Lara and Vasconcelos 2019). Both wind and rain are known to be important factors that alter underwater acoustics (Ma et al. 2005).

Finally, to investigate sensory adaptation to the natural soundscapes, upcoming research should measure auditory sensitivity of zebrafish caught in the natural

habitats. The audiometry studies available are based on animals that have been raised in captivity for multiple generations and are most likely different from the original wild strand (Harish et al. 2019, Milla et al. 2021). This is probably one of the reasons for the high variability in the auditory sensitivity curves reported in prior investigations – see Fig. 1. Fish-rearing systems imply phenotypic selection based on survivability and breeding rates under artificial environments, which leads to inevitable genetic and phenotypic changes (Fu and Yuna 2022). For instance, a recent study by Pantoja et al. (2020) showed that artificial selection of behavioral differences in acoustic startle habituation in larval zebrafish modifies whole-brain dopaminergic activity within just two generations, and that behavioral differences were carried on to adulthood with potential fitness implications.

Besides, the research on zebrafish hearing should consider not only the issue related to artificial selection in captivity that may have shaped auditory sensitivity, but also the chronic noise conditions that are typically found in housing facilities, which are discussed next.

## Coping with Noisy Housing Systems

Elevated background noise is a common problem in intensive fish farming systems, particularly recirculating systems, which are equipped with aerators, air and water pumps, blowers, filtration systems, harvesters, and feeding and maintenance machinery. Altogether, this equipment generates low-frequency noise mainly under 1000 Hz (Lagardère 1982; Bart et al. 2001; Wysocki et al. 2007) that typically falls within the best sensitivity ranges of most cultured species. However, only a few studies investigated the effects of aquaculture noise on animals, and results are not clear. Although some studies point to reduced egg viability, reproduction, and growth rates (e.g., killifish, Banner and Hyatt 1973; brown shrimp, Lagardère 1982, Regnault and Lagardère 1983; salmon, Terhune et al. 1990), others reported the absence of growth and physiological effects (rainbow trout, Wysocki et al. 2007, Davidson et al. 2009).

Zebrafish are commonly maintained in large-scale fish facilities before being used for research. Knowing that considerable number of studies focus on questions related to hearing, development, and ecotoxicology, a major concern becomes the potential noise effects of captive conditions on zebrafish well-being and underlying physiological implications (Lara and Vasconcelos 2021). Lara and Vasconcelos (2019) also characterized the acoustic properties of three distinct zebrafish housing systems, from two stand-alone systems with multiple tanks, pump, and filters integrated into a single rack to a multilinking system with multiple racks containing a water deposit connected to an external module enclosing all pumps and filters. The overall noise levels varied from 120 to 147 dB with most energy below 1000 Hz. The simpler systems with integrated filtering/pumps had higher SPL of 133–146 dB and spectral energy up to 22 dB above the species auditory thresholds. This is likely to induce significant masking effects and maybe even hearing loss, besides overall physiological stress and behavioral disruption. Contrastingly, the system with an

external water treatment module (containing filters/pump) presented lower noise levels of 120–126 dB re 1 μPa. Although the spectral energy was still well above the natural levels within the best hearing range of zebrafish (see Fig. 1), this housing system seems to be a considerable improvement to minimize noise transmission into tanks, following the recommendations by Lawrence and Mason (2012).

Building on the abovementioned, future research should test the potential implications of raising zebrafish under distinct noise environments. This may imply using playback setups to evaluate the exact contribution of the acoustic component for zebrafish well-being throughout the life cycle. This species undergoes auditory sensitivity changes with growth and aging (Zeng et al. 2021), and this might be a critical point when assessing sensitivity to noise exposure.

Furthermore, since particle motion is such a key component of fish auditory sensing, it becomes critical to consider this parameter in future research.

## Noise-Induced Hearing Loss

Building on this background, an obvious step to understand how zebrafish perceive sound and are affected by exposure to noise conditions was to rely on the Auditory Evoked Potential (AEP) recording technique to measure auditory sensitivity in this species under different acoustic conditions (Fig. 2). Breitzler et al. (2020) investigated for the first time Noise-Induced Hearing Loss (NIHL) at different amplitude levels and the underlying morphological damage of the inner ear saccular hair cells in zebrafish adults. After exposure to continuous white noise for 24 h, AEP recordings revealed noise level-dependent Temporary Threshold Shifts (TTS) up to 33 dB paralleled by hair cell loss at the highest level investigated (150 dB re 1 μPa). Recovery of the hearing function was dependent on the noise level, varying from 7 days (130–140 dB) up to 14 days (150 dB). At the loudest sound level, regeneration of the sensory tissue was observed within 7 days, which was prior to functional recovery. This study established zebrafish as an effective model to evaluate noise-related sensory loss and underlying cellular damage and recovery process.

Besides noise amplitude, temporal patterns in noise exposure are critical when assessing the impact of acoustic disturbances on organisms. Hence, a following study (Wong et al. 2022) evaluated the impact of different temporal patterns – continuous, fast and slow regular intermittent, and irregular intermittent noise on hearing loss (Fig. 2). The noise treatments consisted of short 1-s pulses interspersed with varying silent intervals similar to impulsive sounds generated in construction activities (such as pile driving) that require bottom-mounted structures (Sabet et al. 2015). Based on AEP recordings, Wong et al. (2022) identified highest threshold shifts in continuous and fast intermittent treatments, and no differences were found between regular and irregular regimes. Such sensory loss was accompanied by decreased presynaptic activity (Ribeye b protein). This study suggested that overall acoustic energy is more important than regularity when assessing the negative effects of noise on the auditory system.

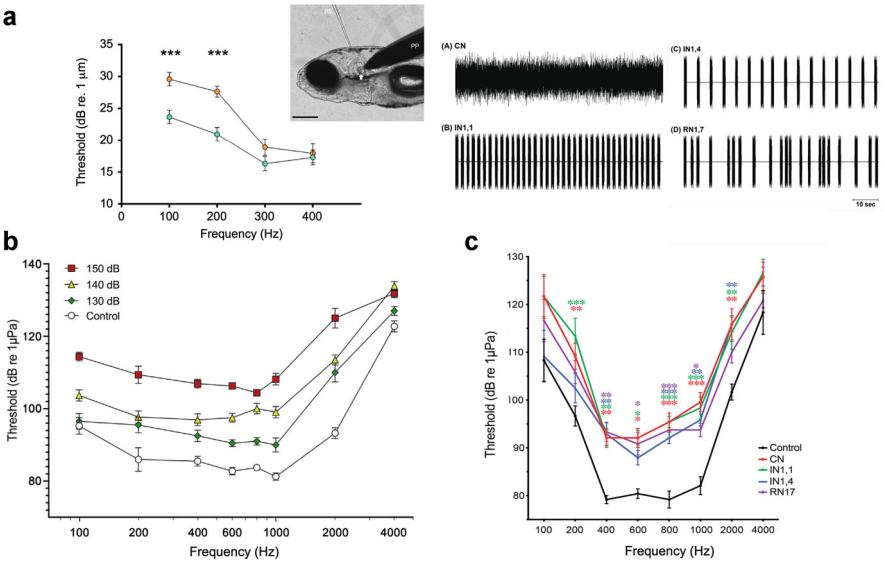

**Fig. 2** (**a**) **Top**: detail of a 5-day postfertilization zebrafish mounted in agarose for microphonic potential recordings, showing recording electrode (RE) and the stimulus probe (PP) touching the otolith. Scale bar: 200 µm. **Bottom**: microphonic thresholds from 5 dpf zebrafish from the control- and noise-treated group, showing significant differences at 100 Hz ($F1,22 = 17.60$, ***$P < 0.001$) and 200 Hz ($F1,27 = 23.84$, ***$P < 0.001$). Values are Means± Standard Error of the Mean (SEM). Based on Lara et al. (2022); (**b**) mean auditory thresholds ± SEM of zebrafish after 24 h of either lab silent conditions (control, c. 105 dB re. 1 mPa) or white noise exposure (at 130, 140, and 150 dB). Noise induced significant changes in the auditory thresholds ($F3, 27 = 73.91$, $p < 0.001$) (Adapted from Breitzler et al. (2020)); (**c**) **top:** acoustic treatments with variable temporal patterns of white noise: (**a**) continuous noise (CN); (**b**) intermittent noise with 1 s noise and 1 s silent interval (IN1,1); (**c**) intermittent noise with 1 s noise and 4 s silent interval (IN1,4); and (**d**) intermittent random noise with 1 s noise and 1–7 s silent (on average 4 s, RN1,7). **Bottom:** mean auditory thresholds ± SEM of zebrafish after 24 h of either silent lab conditions (control, c. 105 dB re 1 µPa) or white noise of different temporal patterns. *$P < 0.05$, **$P < 0.01$, and ***$P < 0.001$. (Adapted from Wong et al. (2022))

These studies were based on zebrafish adults, but auditory sensitivity is known to vary across the life cycle in this species (Zeng et al. 2021). Hence, an additional study evaluated the effects of noise exposure on larval zebrafish (Fig. 2). Lara et al. (2022) provided the first evidence that increased noise levels can impact auditory sensitivity and the amount of auditory hair cell receptors in a larval fish, and that such sensory loss is correlated with behavioral hypersensitization. The authors tested the effects of chronic exposure to white noise (150 dB dB re 1 µPa) on saccular sensitivity and morphology at 3 and 5 days postfertilization (dpf), as well as on auditory-evoked swimming responses using the Prepulse Inhibition (PPI) at 5 dpf. The method used to determine auditory sensitivity was based on field potential recordings (microphonics) from populations of saccular hair cells. Contrary to adult zebrafish that are difficult to measure saccular potentials due to the position

of the sensory epithelia, larval zebrafish are transparent, and their inner ear saccule is more accessible for electrophysiology recordings. Hence, Lara et al. (2022) relied on this advantage to measure saccular sensitivity from noise-treated larva and showed sensitivity loss at both 100 and 200 Hz compared to control, while the PPI tests revealed hypersensitization and a similar threshold shift at 200 Hz.

Bhandiwad et al. (2018) have previously tested the impact of noise on auditory sensitivity in larval zebrafish at 5–7 dpf but did not find significant changes in absolute PPI thresholds. Nevertheless, comparing results is challenging because these authors used lower stimulus frequencies of 30 and 90 Hz, yet the noise-treated group exhibited slightly higher auditory thresholds.

The findings from Lara et al. (2022) further showed that sensory loss in larval zebrafish was accompanied by circa 19–21% decrease in saccular hair cell number. This means that the acoustic environment affected inner ear development, when accessory hearing structures are not yet present and sound reception comes mostly from particle motion (Grande and Young 2004). Similarly, Uribe et al. (2018) also found saccular hair cell damage in 6 dpf zebrafish induced by acoustic trauma system using underwater cavitation that generates high-intensity broadband sounds. The noise treatment was about 186 dB re. 1 μPa RMS and applied for 120 min, which resulted in 14% decrease in saccular hair cells. This study, however, did not measure the actual changes in auditory sensitivity in larval zebrafish.

Only a few studies evaluated the effect of chronic noise in early ontogeny (Bureš et al. 2017; Dorado-Correa et al. 2018), which is a critical time for establishing phenotypic traits (Mueller 2018). Larval fish are known to rely on acoustic cues to detect suitable habitats for settlement, and the presence of elevated background noise may impair their hearing and habitat identification (Simpson et al. 2004; Leis and Lockett 2005; Montgomery et al. 2006; Parmentier et al. 2015). Further research should rely on the technical advantages of zebrafish, such as easy breeding and short life cycle, to investigate whether the acoustic environment in early ontogeny has carryover effects to subsequent life stages and transgenerational consequences.

## Final Remarks

The present chapter provides a review of the existing knowledge on the natural soundscape of zebrafish, establishing an important ground for future studies on the role of environmental noise shaping the hearing sense of wild zebrafish. It has also highlighted the importance of controlling noise conditions in laboratory housing facilities, as they have potential to mask hearing and induce hearing loss and physiological stress. Upcoming work needs to address important questions related to potential effects of chronic noise from housing systems on the zebrafish auditory system and physiological stress, among other questions that were abovementioned.

This review also focused on noise-induced hearing loss and inner ear damage in zebrafish based on different noise levels, temporal patterns, and developmental stage. The studies explained showed that the amount of acoustic energy is more important than regularity when predicting noise effects, and that auditory threshold

shifts and sensory-structural recovery are level dependent. Sensory loss was accompanied by reduced saccular hair cell number in both adult and larval zebrafish, and decreased presynaptic activity in adults.

Some measurements to improve acoustic conditions in housing systems were described, such as using a separate water treatment unit, but additional steps in experimental work with acoustic isolation periods before testing should be considered. The duration of the isolation period would then depend on the overall noise level registered in the housing system. Since continuous noise seems to cause higher impact on zebrafish hearing, a possible intermittent regime in operational protocols of aeration, pumping, and filtering systems should be evaluated.

Furthermore, there remains a scarcity of studies exploring how sensory systems respond to environmental pressures through genetic adaptation and sensory plasticity. The timescale over which such adaptations might take place remains largely unexplored (Kelley et al. 2018). Zebrafish should be considered as a promising platform for testing transgenerational effects and evolutionary consequences of altering soundscapes. By investigating their interaction with intrinsic factors such as aging (Vasconcelos et al. 2023), and key environmental parameters associated with climate change (e.g., temperature, acidification, and oxygen levels), zebrafish could yield valuable insights into the broader impact of these changes on aquatic organisms and ecosystems.

**Abstract**

Despite increasing evidence that underwater anthropogenic noise has negative consequences on baleen whale hearing and behavior, there are no direct data available on mysticete hearing in noise. Here, a behavioral response study design is used to quantify humpback whale hearing in natural ocean noise. A suite of tonal signals, at frequencies ranging from 62 Hz to 22 kHz, will be used as the stimuli. A change in humpback group behavior is assumed to indicate that the whales heard, and responded to, the signal. The intended sample size is between eight and ten independent humpback whale groups per frequency. Individual whale and group behavior will be quantified using both land-based data (where a team will track the group from a land-based station) and acoustic tag data (deployed on individual whales to record fine-scale 3D movement underwater).

The signal-to-noise ratio will be estimated at the response position of the whale, assuming that this will be consistent between groups for each frequency regardless of the level of background noise. Preliminary results confirm that humpback whales are likely to respond to signals at noise at levels comparable to other marine mammals and suggest these whales can hear the 16 kHz signals. Not only does this provide early data on hearing to high frequencies in a mysticete, but results indicate their ability to hear signals in noise is likely better than expected.

Audiogram · Impact · Baleen

## Introduction

Increasing anthropogenic underwater noise is of global concern given evidence of adverse physiological and behavioral effects on marine mammal populations (Cox et al. 2006; Erbe et al. 2016; Finneran 2015; Southall et al. 2016). Potential impacts on individual marine mammals include changes in their hearing threshold in high received levels, as well as disruptive behavioral changes, which can occur in a range of received levels. In some species, subtle but potentially more widespread behavioral disturbance likely depends only on the detection of anthropogenic signals in noise. Currently, we have no direct data on mysticete audiograms, yet this information is needed by a range of stakeholders (e.g., Navy, the oil and gas industry, industry regulators) who wish to predict how underwater anthropogenic sound might impact whales.

Baleen whale hearing can be assessed in several ways: (1) assessment of the frequency of their vocalizations, (2) functional models based upon auditory anatomy, (3) the performance of electrophysiological hearing tests, and (4) using behavioral responses to sound exposures. The first, and simplest, method assumes baleen whales can hear the frequencies at which they produce vocalizations. Since vocalizations are often associated with social and breeding activities, it is generally assumed that vocalization frequencies overlap with the range of hearing. However, empirically measured hearing ranges typically extend above and below the frequencies of vocalizations, indicating that the use of vocalization frequencies for predicting the frequency range of hearing is limited to a specific frequency band within the range of hearing. Additionally, no information about hearing sensitivity can be derived from the source level of vocalizations without additional information on signal detection capabilities of the intended receivers.

A second approach relies on anatomical studies of the ear, including finite element modeling (FEM). Here, some studies have focused on mysticetes. Houser et al. (2001) used cochlear membrane measurements of humpback whales (*Megaptera novaeangliae*) to develop a band-pass filter model of auditory sensitivity. The model suggested that peak sensitivity was between 2 and 6 kHz, with good sensitivity from 700 Hz to 10 kHz, although it did not consider external and middle ear

transfer functions. Recently, Tubelli et al. (2018) used FEM to develop transfer functions in humpback whales for different components of the peripheral auditory system. Their tympanic membrane (TM) model suggested best sensitivity at 1–3 kHz with good sensitivity (to −40 dB) from 15 Hz to 3 kHz. A second tympanic bone (TB) model suggested best sensitivity at 2–3 kHz, with good sensitivity from 200 Hz to 9 kHz. In fin whales (*Balaenoptera physalus*), FEM modeling of bone conduction predicts good hearing sensitivity from 20 Hz to 10 kHz (to −40 dB relative to peak) compared to 500 Hz to 10 kHz when not considering bone conduction (Cranford & Krysl 2015). Model results are therefore inconsistent, and audiometry data are required for validation.

The third approach uses audiometry (e.g., hearing tests), which have culminated in a reasonable understanding of hearing in toothed whales. Most audiometric studies focus on determining the minimum level of sound that can be "detected" by an animal for a particular frequency, often in the presence of natural or experimentally derived noise. There are two common audiometric approaches. The first is behavioral audiometry, which involves training an animal to respond if it hears a sound (e.g., Johnson 1967; Awbrey et al. 1988; Finneran et al. 2005; Kastelein et al. 2010; Houser et al. 2013a, b; Branstetter et al. 2017). The second is electrophysiological audiometry, which measures neural activity generated by the auditory system when it is stimulated by sound (Ruser et al. 2016; Houser & Finneran 2006; Szymanski et al. 1999). Electrophysiological studies are now regularly performed in small, toothed whales (dolphins and porpoises, e.g., Houser et al. 2007, 2008; Finneran et al. 2009; Castellote et al. 2014) since these species can be maintained or rehabilitated (if stranded) by humans.

While these techniques have been used successfully on odontocetes and pinnipeds, neither technique has been successfully applied to any species of baleen whale; none are kept in captivity, and their size largely precludes them from electrophysiological work. Only one electrophysiological experiment in a baleen whale, a gray whale calf (*Eschrichtius robustus*), has ever been undertaken (Ridgway & Carder 2001), and the results were reported as "equivocal."

The fourth and final method is the use of behavioral response studies. There have been a multitude of published behavioral response studies where the animals are subjected to various sources of noise (mainly anthropogenic) and their behavioral response (e.g., changes in dive, movement, and feeding behavior) is documented. The simple assumption here is that, in the absence of any other potential stimuli, if a whale responds to a noise source, then it must have heard it. Few studies, however, have used behavioral response data to make inferences about whale hearing sensitivity. This requires a more nuanced approach and many subjects to avoid pseudoreplication. In addition, the behavioral measurement of *absolute* hearing threshold requires an environment where the background noise is lower than the threshold by an amount that is more than the critical ratio (CR); otherwise, any sensitivity assessment must be assumed to be masked.

While it is possible to achieve low noise in studies with animals in tanks (e.g., Kastelein et al. 2009), background noise levels in the ocean will generally be high enough to potentially mask signals over much of the presumed frequency range of

hearing, even in what are generally considered quiet conditions. This is particularly the case at low frequencies (e.g., < 500 Hz) where traffic noise, the noise of distant shipping (Wenz 1962), contributes substantially to the prevailing background noise levels in many parts of the ocean. Mysticete hearing is expected to extend well below 500 Hz, where most of the energy in their vocalizations occurs.

Although a true audiogram (unmasked hearing threshold) will provide stakeholders with the sensitivity of hearing in mysticetes, this information is of limited use in a practical sense. Although estimates of absolute hearing thresholds can provide the basis for a weighting function (e.g., Finneran 2016; National Marine Fisheries Service 2016), which will more realistically estimate the whale's perception of loudness, these values would strictly apply for signals near the threshold of hearing where noise is unlikely to limit detection. However, at frequencies of good hearing, an audiogram will not be useful for determining threshold of detection of sounds in noise, as this will be limited by the noise in a band around that frequency and not by absolute sensitivity. It is only at the upper and lower ends of the audiogram, and in conditions of low background noise, that a measurement of absolute threshold would be achievable. In terms of determining the detection of sounds in the natural environment, and therefore predicting behavioral disturbance, frequency-dependent masked hearing thresholds, or measurements of the CR, are likely to be more useful to stakeholders that must address impacts and mitigation in potentially noisy, real-world environments. Ideally, both the absolute sensitivity and CR would be known.

The intent is to use behavioral response experiments to estimate hearing sensitivity in humpback whales under ambient noise conditions, like the behavioral observation audiometry (BOA) used in human infants. To do this, tones will be played to migrating humpback whales at frequencies across their expected hearing range. The received level of the tone at the whale when a statistically significant change in behavior occurs defines the minimum response level (MRL) for that frequency. Where the ambient noise level affects the threshold of detection, presumably in the region of best hearing sensitivity, the MRL will also be masked. At lower and higher frequencies, it is expected ambient noise will be sufficiently low relative to the threshold of hearing, and the behavioral response will occur at the MRL in the absence of masking.

## Methodology

Low-frequency ambient noise levels in the ocean are generally lower around Australia than in the Northern Hemisphere because of lower shipping densities. The proposed site at Peregian Beach, which is on the eastern coastline, is inshore and relatively sheltered from distant shipping, and low-frequency noise levels at low wind speeds (6–10 knots) are 10–15 dB quieter than would be predicted by Wenz' curves (Wenz 1962; Cato 2012).

Work will be conducted at Peregian Beach, 100 km north of Brisbane, Queensland, Australia, during September and October 2021–2023, when whales are migrating from breeding to feeding grounds (Fig. 1). The field site is unusual in that it is a

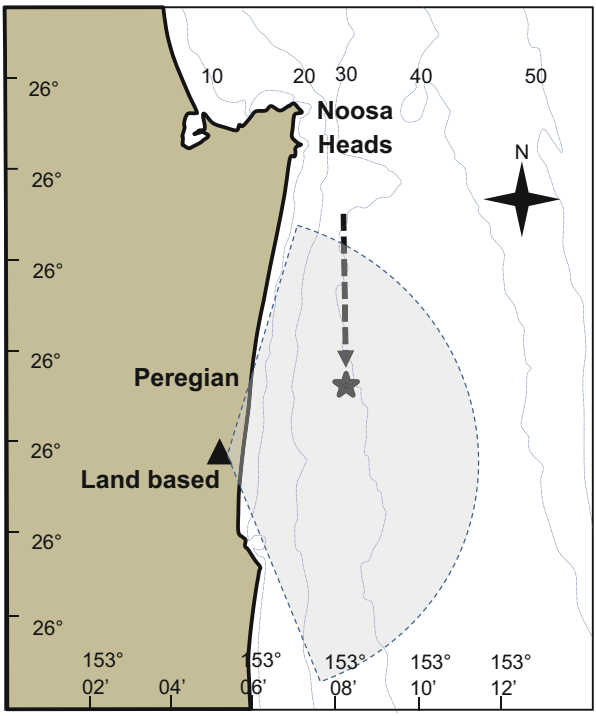

**Fig. 1** A representative drawing of the Peregian study area. An indicative pathway taken by migrating groups is shown by a dashed line, and an indicative position of the source vessel is shown as a star (but will vary based on the path of the group). The field of view of the land station is shown by the shaded area

near-shore migratory corridor for a large population of humpback whales (>30,000), at least half of which pass within 10 km of shore.

Major benefits of using this site are as follows: (1) much lower noise levels than in many ocean sites; (2) the predictable movement of the whales allows targeting and tagging whales relatively easily, as well as detecting responses reliably; (3) group responses can be measured from land leading to a robust sample size with minimal interference; (4) the social context of the target group (location and behaviors of whales within several kilometers of the focal group) can also be measured from land as social groupings have been demonstrated to affect behavior; (5) new groups will be available every day (low risk of resampling); (6) 11 previous field seasons at this site provide a wealth of background data on whale movements, behavior, and abundance; and (7) the study area has been extensively characterized acoustically leading to validated empirical models.

## Field Observational Setup

Land-based data will be collected by a visual team operating from a 73-m-high hill. A "focal follow" team will identify candidate groups as they move southward along the coast. Groups will be assessed for suitability for each experiment based on

having a relatively constant direction and travel velocity and therefore a predictable path. After selecting a candidate group, they will focally follow the group using a theodolite to capture every surface behavior and surface position of the group throughout the experiment.

*Tagging phase* – Attempts will be made to tag one of the whales in the group using a suction cup acoustic tag. During a tagging attempt, the vessel accelerates to within ~5 m of the group, and the tag is deployed from the end of a 6 m carbon-fiber pole.

*"Before" phase* – Even if tagging is unsuccessful, the experiment on the group will be continued using the land-based focal follow data. The group will be given ~20 min to "recover" to pre-tagging behavior before the beginning of the "before" phase. Target groups will then be tracked from land as well as from a small research vessel (which will maintain a distance of at least 300 m from the group) for at least 20 min before and then during the entire experimental treatment. The land-based observers will remain blind to the treatment (silent control or frequency upsweep transmission).

As the whales are migrating, their movement behavior is broadly predictable in that groups tend to travel at a reasonably consistent speed and course. The path of the experimental group can be predicted well enough during the post-tagging and "before" phase data from land-based tracking to position the source vessel so that the target group passes by. The experimental group will be approximately 4.5 km to the north of the source vessel at the start of the "during" phase.

*"During" phase* – Once the source vessel is anchored in a suitable position, it will deploy an acoustic transducer and await instructions on when to initiate the sound exposure. At least 20 min of "before" observations is required before exposure starts, and it is important that whales are not first exposed to the signal at a level where it will be detectable. Rather, we intend to start transmission of the exposure signal at a distance that is not detectable but will become detectable as the whales approach the source vessel.

Signal transmission will continue until the group has passed the source vessel and the distance between the group and source is increasing. Efficacy of the approach will be confirmed by control experiments in which no transmission occurs. Each experiment will target one group of whales and use one treatment to produce a balanced and independent sample of all treatments.

## Acoustic Measurement and Tag Recovery Phase

Once the group has cleared the area, there will be a series of boat-based hydrophone measurements of the frequency upsweep at the location at which the behavior of the group appeared to change (see collection of acoustic data below), as well as at points between the observed change and the source vessel. If tagging was successful, the tagging vessel will then follow the experimental group until the tag detaches from the whale, floats to the surface, and is retrieved. The tags will be fitted with VHF transponders so that they can be easily detected and found once at the surface.

### Tone Stimulus Characteristics

There will be seven different treatments: a silent control plus six frequency upsweep treatments. Frequency upsweeps will be one-third-octave upsweeps with starting frequencies of 62 Hz, 250 Hz, 1 kHz, 4 kHz, 16 kHz, and 22 kHz. These frequencies have been chosen to provide data for areas of likely best sensitivity (models suggest 1–6 kHz) as well as frequencies where significant sensitivity roll-off is expected (62 Hz; predicted by Houser et al.'s 2001 cochlear model and Tubelli et al.'s 2018 TB model). Targeting the lower end of the expected frequency range of humpback hearing will provide information on the slope (dB/decade) of the low-frequency roll-off, which is critically important to the development of LF weighting functions.

The upsweeps will be 2 s in duration and repeated every 4 s (hence a 50% duty cycle). Although the upsweep reduces the precision of the test in terms of it being a discreet frequency, the one-third-octave bandwidth is much less than the spacing between upsweeps. Upsweeps will be transmitted using a Lubell VC2C, Lubell LL916, or GeoSpectrum M18C-4, depending on the frequency of stimulation.

The source level used in each experiment will depend on the frequency of the tone used and the background noise (ambient noise in the absence of vessels – experiments will not be conducted in the presence of significant vessel noise). Using the results of test transmissions conducted during a pilot season (2020), source levels for each frequency will be tailored so that the SNR at 3–4 km from the source will be well below the anticipated masked hearing threshold based on measured critical ratios of odontocetes, pinnipeds, and sirenians (Erbe et al., 2016), as well as the responses of humpback whales to a 2 kHz tone in a previous experiment at this site (Dunlop et al. 2013). Note that many of the responses in the Dunlop et al. (2013) experiments occurred at stimulus onset and only a few samples likely captured the response threshold where the whale swam into the sound field. The source level for the proposed experiments has therefore been adjusted to capture the likely response threshold at approximately 3 km from the source vessel, based on results of Dunlop et al. (2013) and predictions from Erbe et al. (2016).

## Data Collection and Analysis

Land-based observers will conduct observations of groups of whales using a surveyor's theodolite linked to a purpose-designed tracking and behavioral recording program (S2SS; developed by Eric Kniest, University of Newcastle). The focal follow team will track and collect high-resolution data including every surface behavior and location of the experimental group during each experiment as the group moves southward through the study site (Dunlop et al., 2015, 2016a, b, 2017a, b). The position of the group relative to the source vessel, as well as the behavior of the group, is captured as a time series before and during transmission of the test tone.

Land-based focal follow data will be extracted and processed post-field. Here, five measurements will be extracted related to each group's movement and dive behavior:

- Group course
- Group speed
- Group dive distance
- Group dive time
- Group surface interval time

Group course and speed will be estimated using one position of the group each time it surfaces, usually the first or second position (if multiple positions are available during the surfacing event). Humpback whale dive behavior consists of a bout of "surfacing dives" (the short, shallow dives that occur during respiration bouts which are usually tens of seconds in duration) followed by a "deep dive" in which the group submerges for a longer period (usually a few minutes). A "deep dive" period is defined as the time from when the last group member disappears to when the first group member reappears, and the "surface interval" is defined as the time spent on or just under the surface between deep dives, incorporating all brief "surfacing dives." To separate deep dives from surface interval dives, for each group, the lag time between sightings will be calculated. This will give a time series of short (less than 1 min) lag times related to the group being on the surface and long lag times (greater than 1.5 min) related to the group being in a deep dive. Dive distance and dive time will then be estimated using the position and time of the group when last sighted before a deep dive and the position and time of the group when first sighted after the dive. Group surface interval will be estimated using the time the group first reappeared after a dive and the time the last member of the group disappeared before a deep dive.

Tags will provide data on high-resolution movement (3D pitch, roll, heading, and dive depth of the tagged animal), potential startle responses, and fluking patterns. The tag also records acoustics; it will potentially record the received frequency upsweeps, although it is very unlikely that the tone will be audible on the tags at the point of response due to flow noise on the tags. Resolution of the received level will be informed by the site-specific propagation model and additional acoustic recordings made by the tag vessel. Tag sensor data will be calibrated for its position on the whale. Dives, defined according to a minimum depth threshold and values such as bottom depth, points of ascent/descent, maximum depth, bottom time, etc., will then be extracted. Overall dynamic body acceleration will be calculated using the accelerometer data, with a rate of change in acceleration used to detect "quick" body movements such as a startle response. Fluke strokes will be identified as a cyclic variation in pitch. Absolute heading will be included as sine and cosine components, as well as heading variability (variance in heading over a 1 min window) and speed (vertical velocity divided by the sine of the body pitch angle) for ascents and descents correlated to flow noise.

Integration of the data streams will increase the power of statistical approaches to detecting behavioral changes. Potential behavioral responses will be quantified from the two datasets by extracting the following variables:

1. Fine-scale dive responses: Dive variables including descent rate and duration, ascent rate and duration, total dive duration, maximum depth, surface interval, fluke rate, body acceleration, and heading variance will be extracted for each dive on the tag.
2. Group-level dive and movement responses: Group travel speed, travel direction, dive time, dive distance, and surface interval time will be quantified for successive dive cycles throughout the "before" and "during" phases (i.e., starting from approximately 20 min after tagging attempts had ceased).

The analysis will follow an analytical procedure published by De Ruiter et al. (2013). Each group's dataset will be considered as a multivariate time series of dive, respiration, and movement parameters. These multivariate parameters will then be collapsed into four univariate time series, one related to group-level movement behavior (using course, speed, and dive distance), the second related to group-level dive behavior (using dive time, surface interval), the third related to individual (tagged) dive responses (dive time, number of respirations per surfacing, ascent and descent rate), and the fourth related to individual (tagged) movement responses (speed, overall dynamic body acceleration, roll, fluke rate).

First, using only (pre-exposure) baseline data, the mean, variance, and covariance of all measured variables will be estimated. These will then be used to calculate a Mahalanobis distance for each time (tag data) and dive (focal follow data) window during transmission. A plot of time along the x-axis and Mahalanobis distance on the y-axis will be created for each group, representing a time series of univariate data points per experiment. The change point, where the calculated Mahalanobis distance significantly deviates from baseline, will then be determined. The threshold for a change-point detection will be set at the 95th percentile of the baseline Mahalanobis distance, following previous studies using this technique (e.g., Stimpert et al. 2014). This would be, for example, a dive which was substantially shorter than baseline dives, an extended surface interval, a significant deviation in course, and/or a significant change in travel speed. The dive number or time window at which this point occurred is assumed to be the point at which the group first responded to the tone signal. For the control dataset, there should be no substantial deviation from baseline for any dive or within any time window and therefore no change point detected. If a change point is not detected after groups and whales were exposed to the tone, it will be assumed the individual or group did not respond.

The distance between the experimental group and the source corresponding to the "change point" will then be determined using the theodolite focal follow data. This will allow for the received level and signal-to-noise ratio at the change point to be estimated from recordings made at the time of the experiment (using bottom-mounted loggers as well as boat-based hydrophone recordings); see acoustics section below.

Acoustic data will be collected using a combination of deployed autonomous recorders, boat-based hydrophone recordings, and tag recordings. All experiments will occur within a well-defined study area, and an autonomous acoustic logger (Wildlife Acoustics SM2M) will be deployed for the duration of the field season to provide a continuous record of noise for context.

Recordings will also be collected during each experiment. After anchoring, the source vessel will record continuously using HTI-96-MIN hydrophone (High Tech, Inc., MS) into a H4n Pro digital recorder (Zoom Corporation, Tokyo) to provide a record of the signal, to provide a measure of noise, and to assess the presence of various undesirable noise sources such as nearby singing whales (which could also change the behavior of the focal group) and nearby vessels. During the transmission period, the tag vessel will continue to follow the whale group slowly at a distance of more than 300 m. When a change of behavior is observed by the focal group, the tag vessel will deploy a SoundTrap 300 STD recorder (Ocean Instruments, Auckland) on a light mooring at the location of the change in behavior to capture the signal and noise as soon as possible after the putative response. After the end of the experiment, the tag vessel will make a series of 2 min recordings (High Tech HTI-96-MIN hydrophone, H4 Zoom digital recorder) approximately 200, 500, 1000, and 2000 m from the source vessel on a line between the source vessel and the location of the putative response. During these recordings, the tag vessel will shut down and, if necessary, deploy one or more sea anchors to limit drift and reduce unwanted flow noise. Acoustic tag recordings will also be obtained from the subset of tagged animals.

The recorder deployed at the site of the putative behavior change and the tag boat recordings will accurately measure relevant noise levels and allow the development of a specific and accurate empirical model of received level as a function of distance from the source for each experimental group. Although the deployed SoundTrap may capture the transmitted signal, this modeling is necessary as signal received levels are expected to be very low and may not be detectable or measurable as they will be very close to noise floor of recorder. Additionally, subsequent analysis of the behavioral data may demonstrate that behavior changed at a different distance from the source than where the SoundTrap was deployed and the ability to accurately estimate received level and noise at those locations will be required.

The tag boat recordings will be processed in several steps. First, they will be assessed for the presence of the signal by spectrographic examination. The highest-level examples of the signal in each recording will be saved as clips. Analysis will measure the raw signal level as well as noise in the same third-octave band and then provide a noise-corrected estimate of the true received level of the signal. These will then be fit to a frequency-specific propagation model to predict the received level at the behavioral change point.

Noise in the relevant one-third octave will also be measured over the entire ~2 min recording of the tag boat recordings as well as over a few minutes at the start of the deployed SoundTrap recording. The SoundTrap recording will provide the best estimate of true noise at the change point, while the tag boat recordings will provide useful additional measures. Noise in all recordings may fluctuate temporally

over a few seconds (especially due to singing whales), and it is important that our measure of noise represents the quieter parts of the recording where the signal may have been most detectable. Lowest reasonable third-octave noise will be used to also calculate the spectral noise level by making the appropriate bandwidth correction for the relevant one-third octave. Together these estimates of received level and noise at the change point will be used to provide a conservative (highest likely) estimate of third-octave SNR as well as a conservative estimate of spectral SNR, effectively a measure of the critical ratio of responsiveness (CRR), for each experiment.

Tag recordings will also be used, but it is unlikely that the tones will be audible on the tags at the point of response due to the relatively high flow noise recorded on the tags and the low received levels expected. In this study, tags are most useful for detecting cryptic changes in behavior rather than recordings of the sound exposure.

Planned sample sizes are eight to ten focal groups per treatment (depending on the response variance), of which, based on previous experience with tagging, three are likely to include tagged animals. This sample size is based on a power analysis for the detection of a significant behavioral change in response to tones at a population level (Dunlop et al. 2013). The analysis outlined below involves estimating behavioral changes at an individual level and then using these results to determine the "most sensitive" group – in effect, defining the MRL. A sample size of eight to ten provides an adequate distribution of responses with which to do this. The three tagged animals per treatment will inform these results, meaning a much more robust sample size can be achieved within the time frame.

The analyses above will produce a series of SNRs at the change point and response level for each frequency upsweep from both tag dive data and group-level movement data. Each group will have either one measure of the response level (from focal follow movement data) or two (where one individual will be tagged). The $SNR_0$ per frequency will be used as the MRL for that frequency.

## Results and Discussion

The following presents preliminary results from the first field season (2021) to demonstrate proof of concept. A total of 15 experiments were successfully completed. Due to tag failures, data analysis relied only on land-based focal follow data.

Preliminary results for four experiments are presented: a control, a 1 kHz tone, a 4 kHz tone, and a 16 kHz tone experiment. The Mahalanobis distance was calculated using the land-based data as described above. Two Mahalanobis distance measures were calculated from the group-based data: one that encompassed three movement variables (group travel speed, course, and the distance traveled underwater in between surfacing events) and one that encompassed two dive variables (group long dive time and group surface interval).

Figure 2 presents the results for each experiment. The control experiment was carried out on a mother-calf-escort group. As this group was logging and only two dive cycles and three sightings were available in the pre-exposure period, the dive Mahalanobis distance was not calculated. The start of the transmission phase

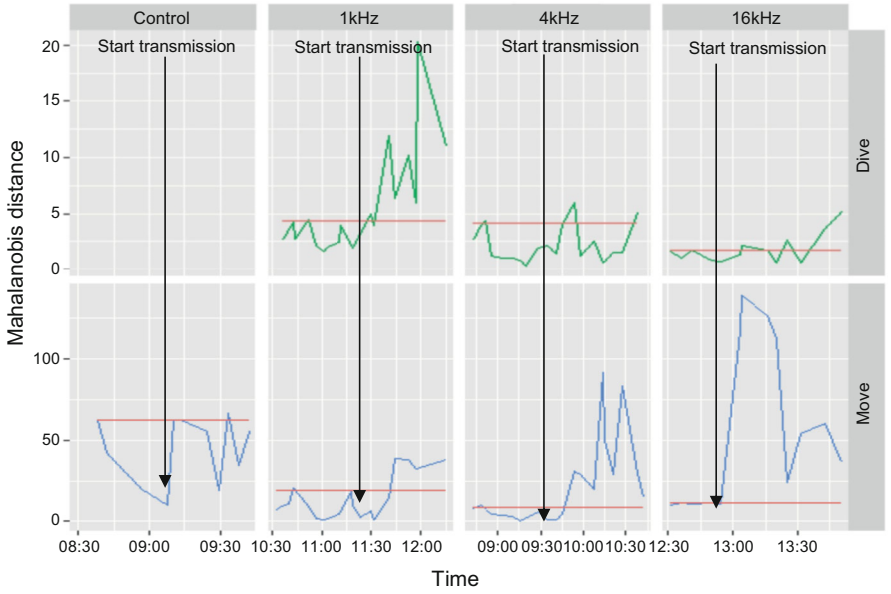

**Fig. 2** Results of a control and 1 kHz, 4 kHz, and 16 kHz experiment with the Mahalanobis distance for dive behavior in green and movement behavior in blue. The red line is the 95th percentile for the baseline period. The start of transmission is indicated by the black arrow

(equipment deployed, no signal) was taken as when the group was within 3 km of the source vessel as per the other trials. The calculated Mahalanobis distance estimated during the simulated transmission phase did not fall outside of the 95th percentile distances estimated during the baseline period.

For the 1 kHz experiment, transmission started when the mother-calf-escort group was approximately 3.7 km from the source vessel. The timepoint at which a movement response occurred was the surfacing event at which the calculated Mahalanobis distance for movement was greater than the 95th percentile calculated during the baseline period. Parameters were measured from the previous surfacing event to this surfacing event, meaning the change in behavior likely occurred at some point during the dive cycle. This change in movement was due to the group changing course to a westerly (inshore) direction, an increase in their dive distance between surfacing events, and an increase in their travel speed. A dive response also occurred at the same surfacing event (and distance from the source vessel) due to an increase in dive time. The group was 2.9 km from the source vessel when surfacing after the change in dive occurred and 2.7 km from the source vessel when surfacing after the change in movement occurred. At 2.9 km, the received level of the signal at the group was estimated to be 86 dB re 1 μPa, and the spectral SNR (or CRR) was estimated to be 20 dB.

The mother and calf groups used for the 4 kHz and 16 kHz experiments both responded by changing their movement (changing to an inshore, westerly,

direction, slowing their travel speed, and decreasing their dive distance). For both experiments, this change in behavior occurred at signal onset which was approximately 2.9 km from the source vessel for the 4 kHz experiment and approximately 3.4 km from the source vessel for the 16 kHz experiment. The received level at signal onset (and behavior change) was estimated to be 85 dB re 1 μPa for the 4 kHz experiment and 83 dB re 1 μPa for the 16 kHz experiment with spectral SNRs (CRRs) estimated to be 26 and 38 dB, respectively. Like the 1 kHz experiment, changes in behavior likely occurred at some point during the dive cycle; however, measurements could only be taken after the group had surfaced. Future experiments will therefore attempt to capture the response threshold by extending the distance at which the during phase begins and/or lowering the source vessel and using tags.

In summary, these preliminary experiments demonstrate proof of concept in that targeted playback experiments can be used to inform the hearing range and sensitivity of humpback whales. Out of the 15 experiments completed, a significant change in movement and/or dive behavior (as estimated using the Mahalanobis distance) occurred in all groups apart from the control group. The changes in behavior occurred at SNRs that are consistent with CRs from other marine mammal studies and studies of mammalian hearing more broadly. However, for approximately half of these experiments, the response occurred at signal onset, meaning the experiment likely did not capture the response threshold. In addition, due to tag failure, the response distance had to be estimated using the position of the group on the surfacing after detection had occurred. Future experiments will therefore extend the distance of the during phase to at least 4.5 km from the source vessel and/or lower the source level of the signal to ensure that the group swims into the sound field. Tags will also be deployed to enable the point at which the group changes behavior, even if it occurs during a dive cycle, to be more accurately captured.

Although in its early stages, the current study demonstrates that behavioral response studies can be useful for more than determining responses to anthropogenic sound. Behavioral response studies on hearing in free-swimming, wild cetaceans are possible under certain conditions and are similar in principle to the methods used in BOA. Already, this work has confirmed that humpback whales are likely to have CRs comparable to other marine mammals and suggests that humpbacks can hear 16 kHz signals. The whales routinely appeared to detect signals that were not evident using single hydrophone recordings (audibly or spectrographically) and in conditions of high conspecific noise (song chorusing) showing, for the first time, that mysticetes likely have considerable processing gains in hearing as demonstrated in some other marine mammals (Branstetter et al. 2010). Not only does this provide early data on hearing to high frequencies in a mysticete but also shows that their ability to hear signals in noise is potentially superior to our own ability to detect underwater signals, at least using single-sensor systems. In both frequency range of hearing and hearing sensitivity, we are therefore likely to be underestimating the acoustic information available to humpback whales under natural conditions.

**Abstract**

Dugongs (*Dugong dugon*) are listed globally as "Vulnerable to Extinction," raising substantial concerns for their welfare. Underwater sounds are potentially critical survival cues for dugongs, but there are few data on dugong hearing, much less on how ambient sounds, natural or anthropogenic, may affect dugongs.

A project was undertaken in 2022 to obtain auditory evoked potential (AEP) responses in wild Australian dugongs during health assessments. In support of that study, a parallel effort investigated cranial and auditory system anatomy of

dugongs to determine optimal placements of hydrophones for delivering sound stimuli and of the recording electrodes for AEP response measurements. Relevant anatomical measurements were obtained from computerized tomography (CT) imaging and dissection of three dugong specimens collected in a previous study of stranded dugongs from northern Australia in collaboration with Dr. Helene Marsh and Dr. Donna Kwan of James Cook University.

The study demonstrated three external landmarks that allow triangulation of surface points closest to the middle ear, inner ear, auditory nerve, and brainstem of dugongs. These anatomical landmarks are proportionately spaced across animals, allowing placement calculations for animals tested in field studies regardless of body mass, age, and sex.

## Introduction

Sirenians (manatees and dugongs) are found throughout the tropical and subtropical waters of the world, inhabiting fresh water, estuarine, and marine coastal regions. These relatively docile herbivores are air-breathing obligate aquatic mammals. Although they are part of the general group called marine mammals, their closest taxonomic, evolutionary group is the Proboscidea, which includes elephants (Domning et al. 1982). This somewhat surprising lineage raises several interesting questions regarding their sensory adaptations; e.g., are their sparse body hairs a dominant, tactile sensory system overshadowing hearing and/or vision; how acute is their vision and hearing; are their auditory abilities driven primarily by adaptation to water-borne sounds; do they share the exceptional low frequency hearing of elephants; and do they have any echolocation ability similar to those of odontocetes? Further, how do any of these sensory abilities vary across extant sirenian species living in different habitats? Some sirenians, such as the Amazonian manatee (*Trichechus inunguis*), live exclusively in shallow fresh water environments with essentially no predators (except humans). By contrast, dugongs live in marine coastal waters, with substantial risks from multiple predators.

Dugongs are found in the Indian and Pacific Oceans in warm shallow seas in areas of abundant seagrasses. In Australia, dugongs occur in the coastal waters of northern Australia with a substantial population in the Torres Straits. Dugongs are listed worldwide as "Vulnerable to Extinction" (IUCN 2021) and under Australian legislative acts are listed also as "Endangered, Vulnerable, and Other Protected Fauna." Despite these protections, there are multiple threats to dugong survival, particularly loss of seagrasses on which they depend. Because seagrasses are primarily found in shallow nearshore waters, dugongs may be subject to ship strikes, net entanglements, and behavioral disturbances from commercial and private vessel traffic and coastal construction, particularly near urban centers (Hodgson and Marsh 2007; Marsh et al. 2018). This again raises the question of what dugongs can hear and whether sounds from vessels and other human activities may impact dugong hearing and impair

sound-dependent activities such as intraspecific communication, detection of predators, and navigation.

Behavioral, auditory evoked potential (AEP), and anatomical studies have been conducted to investigate hearing in manatees, another group of sirenians (Bullock et al. 1980; Supin et al. 2001; Klishin et al. 1990; Gerstein et al. 1999; Ketten et al. 1993). These studies demonstrated the advantage of combining physiological and anatomical approaches and provide data for comparison of results across sirenian species. However, it is premature to assume it is possible to extrapolate dugong hearing capabilities from manatee data. It is important to keep in mind that despite their taxonomic ties, manatees evolved in environments with different adaptive pressures including a different sound profile from that of their marine relatives. Dugong ears may consequently have different hearing ranges and sensitivities and localization abilities than those of manatees.

Currently, there is a serious lack of auditory data in any form for dugongs. Frequencies of underwater calls range from 0.15 to 18 kHz for dugongs, implying a hearing range of at least seven octaves (Southall et al. 2019). One pilot AEP study was conducted on a single older captive male (Ketten et al. 2000). The test frequencies ranged between 2 kHz and 40 kHz. Best sensitivity was found at 10 kHz; however, there was a noticeable a region of diminished sensitivity in the hearing response beginning at 4 kHz and peaking at 8 kHz with a return to a typical hearing curve form at 10 kHz. This phenomenon is commonly referred to as "notch," which is characteristic of frequency loss in older individuals and typically occurs near the point of peak sensitivity. The observed notch in the study animal suggests the individual had diminished hearing at least at 4-8 kHz and may potentially have had diminished hearing at other frequencies, particularly at higher frequencies of his hearing range, and therefore does not represent average, normal hearing abilities for this species. A second consideration for the Ketten et al. (2000) study is that, in the absence of any related anatomical data, electrode placement was arbitrarily based on a line drawn between the external opening of the auditory canal (meatus) and the rear margin of the eye. This may have affected the absolute levels of the responses but is unlikely to have affected the shape of the total response curve (Fig. 1).

AEP measurements are based on playing sound stimuli at different frequencies and recording neural responses evoked by each stimulus. The precise placement of stimulus sources (loudspeakers, suction cup hydrophone, freestanding hydrophones, etc.) and response detectors (surface or needle electrodes) may differ by species based on anatomical differences in the location of auditory structures and sources employed. The results noted above underscore the need for AEP data from individuals of both genders and multiple age group in order to have a clear understanding of hearing in any species.

## Dugong Auditory System Anatomical Project

To determine the feasibility of measuring hearing in wild dugongs, a pilot project was conducted of AEP measures of hearing in wild dugongs in Australia in 2022. The AEP data were to be collected from multiple wild dugongs undergoing routine health assessments (Lanyon et al. 2010). Prior to the AEP studies, a preliminary project was

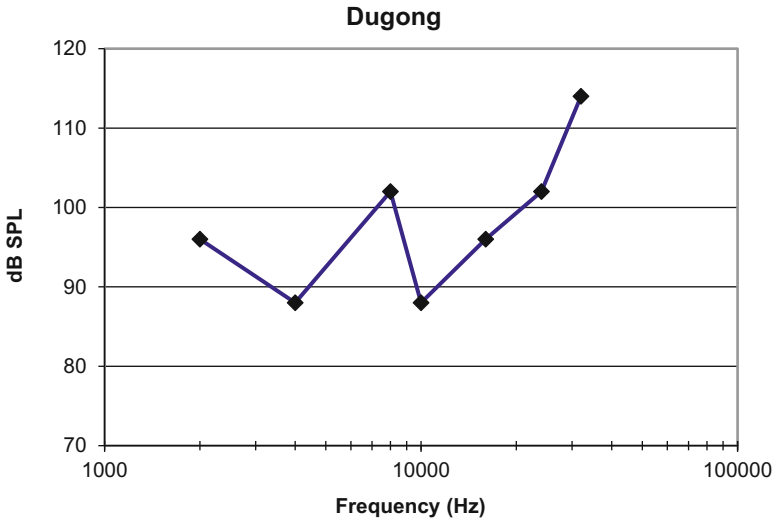

**Fig. 1** AEP-derived audiogram from a captive male dugong obtained in a single session at Sea World, Queensland. Note the marked decrease in sensitivity between 4 and 8 kHz. undertaken to characterize the cranial and auditory anatomy of dugongs to determine locations for placement of surface hydrophones to deliver sound stimuli to the test subjects and to assess multiple sites for placement of recording electrodes that would optimize AEP responses based on proximity to auditory neurologic structures and would be accessible in a live, prone dugong undergoing examination and testing for AEP measurements.

To accomplish this, dugong skull architecture, bone thicknesses, head musculature, and the proximity of multiple surface locations were analyzed to determine the lowest impedance path and shortest distances from head surface to the middle ear, inner ear (cochlea), auditory nerve fibers, and auditory brainstem. In addition to determining optimal locations, it was necessary to formulate a means of establishing the electrode location on any individual based on its relationship to consistent, readily identifiable surface landmarks. Therefore, the main objective was to find surface features from which it was possible to triangulate the best locations to optimize the sound input and electrode placement to detect the AEP neural response signal.

## Methods

### Specimens

Dugong heads were obtained postmortem from male and female stranded animals under permits for collection and export of specimens issued to Dr. Helene Marsh (James Cook University, Queensland, Australia) letters of authorization and

importation and permits for importation of specimens from endangered species issued to D. R. Ketten. Three specimens were selected to span the potential range of body size/age and sex of animals that may be tested in the AEP project: an adult male (ID D-dug 02), an adult female (ID D-dug 08), and a young calf male (ID D-dug 04). Postmortem condition varied, but all specimens had intact brain and auditory system tissues. The specimens were held chilled at 4 °C until received and prepared for gross examination and imaging.

Each specimen was first examined directly to assess external tissue integrity and to document and measure positions of multiple external landmarks and to explore what internal, underlying features could be identified by palpation, such as the external opening of the external meatus (ear canal), the mandible (lower jaw), and the zygomatic bone (cheekbone) (see Figs. 2 and 3).

**Fig. 2** Adult female dugong head, left lateral view, showing surface distances from snout edge (at 99 cm mark on tape) to eye (below 109 cm mark on tape) to meatus (dark spot inside white circle located at 116.5 cm). (Used with permission, copyright D. R. Ketten. All rights reserved)

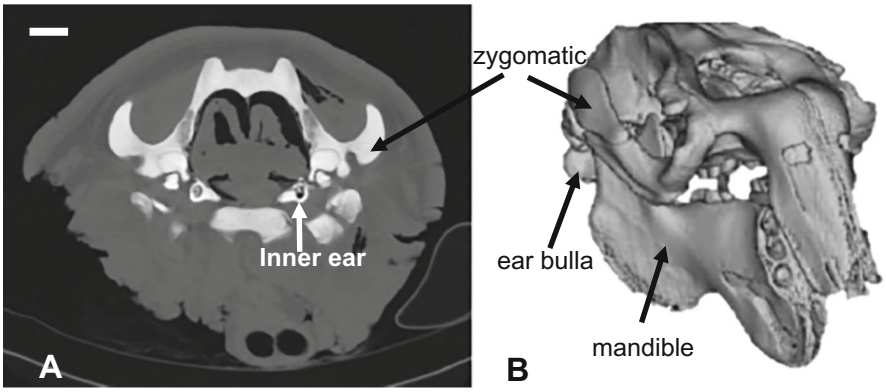

**Fig. 3** (**a**) CT scan 3 mm slice cross-section at the level of the middle and inner ear in an adult male dugong. The arrow points to the periotic bone, which is the part of the ear bulla that contains the cochlea, which is the dark spiral in each periotic bone. The scale bar = 7 mm. (**b**) Three-dimensional CT reconstruction of the skull of the same specimen demonstrating the position of the zygomatic flange and the mandible to the ear bulla which contains the middle and inner ear

## Imaging

The intact dugong heads were examined using a Siemens Volume Zoom helical computed tomography (CT) scanner at the Woods Hole Oceanographic Institution Computerized Scanning and Imaging Facility (http://csi.whoi.edu). The specimens were scanned using an imaging protocol of 0.5 mm and 3 mm acquisitions, 0.5 to 3 mm table speed; KV and effective mAS varied according to the mass of tissue being imaged. Data were acquired and reconstructed in soft tissue (U40) and bone kernels (U70), 200 FOV for whole heads. Bone and soft tissue windows at standard and extended scales were used in image reconstructions because of the extreme densities of some bony tissues and the need to differentiate small gradations in soft tissues of the auditory system. All data were archived as both raw acquisition data and DICOM formatted image files. Primary images were formatted at 0.1, 1.0, and 3.0 mm slice thickness in the transaxial plane. Raw acquisition data were employed for imaging at smaller fields of view and for multiplanar reconstructions in sagittal and coronal planes and to digitally realign the slice plane to match a mid-modiolar cochlear axis.

All image data were further processed and reconstructed into 3D and video images using Siemens VRT software, Amira 5.4, RadiAnt version 2020.1.1, and Osirix 12.0 software programs.

# Results

## Measurements

Three-dimensional reconstructions of the CT scans provided visualizations of the relationship and digital measures of distances for anatomical landmarks to critical ear features in each of the three dugong heads. Distances were obtained from specimens by direct surface measures and on CT scans to determine nearest distances to the inner ear from each of three external landmarks: anterior dorsal bridge of the snout/facial disk, midpoint of the eye, and the external meatus of the ear canal, which is a small dark opening, approximately 3 mm in diameter in adults (Fig. 2).

Scans and dissections were used also to determine distances in additional internal structures palpable on the surface. Internal structures that could be detected readily by palpation included the posterior edge of the mandible and the zygomatic bone, a prominent elongated ovoid bony flange beneath the eye that forms part of the eye socket in sirenians (Fig. 3). These two structures are located just dorsal and anterior to the ear bullae, which are the bones that contain the middle ear cavity and ossicles (tympanic bulla) and cochlea (periotic bulla).

For the two adult dugongs (Fig. 3), measurements were as follows:

| Measurements | Female | Male(cm) |
|---|---|---|
| Snout tip/facial disk to mid-eye | 10.4 | 12 |
| Mid-eye to meatus | 6.8 | 7.6 |
| Meatus to middle ear bulla | 4.5 | 5.2 |
| Rear edge of mandible to middle ear | 2.5 | 3.0 |

Because mammalian ears are fully functional *in utero* in late stages of pregnancy, and because it was uncertain what age animals may be tested in future studies, it was decided to determine whether there were significant differences in the landmark and ear locations and proportionalities according to age. Therefore, similar measures were obtained from the one young specimen available, a very young male calf.

On the juvenile (Fig. 4), the measures are the following:

| Measurements (cm) | Juvenile male |
|---|---|
| Snout tip/facial disk to mid-eye | 6.5 |
| Mid-eye to meatus | 4.4 |
| Meatus to middle ear bulla | 2.07 |
| Rear edge of mandible to middle ear | 1.2 |

## Placement Determinations

Based on these measurements, two options were proposed for determining where to place electrodes on each individual subject during the AEP experiments. One option is to palpate the jaw and locate the rear edge of the mandible, then locate the midpoint of the zygomatic bone. The point at which lines drawn posterior from the mandible and ventral from the zygomatic cross is the approximate location of the entry to the middle ear and also the closest lateral point to the auditory nerve

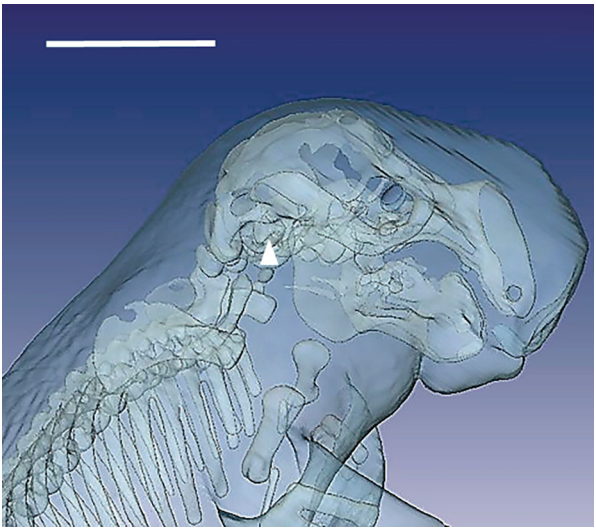

**Fig. 4** Three-dimensional reconstruction of scans of young male dugong calf. The skin has been rendered translucent to show the underlying structures of the head. The white arrow is pointing to the tympanic bone/bulla housing the middle ear. The inner ear is located in the periotic bone/bulla located medial to the tympanic bone. Based on the described triangulation, the tip of the arrow is approximately the surface location proposed for the AEP sensory signal receiving electrode location. Scale bar = 5 cm. (Used with permission, copyright D. R. Ketten. All rights reserved)

and brain stem. A second option proposed was to employ four strings or strips. By calculating the proportionalities for the measures listed, the same may be expected for the subject being tested. Therefore, triangulating the intersection of the described projections from the surface landmarks provides a location closest to the position of the cochlea.

It was recommended also to place the hydrophone as the input source over the meatus. This was based on observations during a dissection on one of the heads in which the meatus was injected with a blue dye in order to trace the path of the external auditory canal. Although the canal was quite narrow, it appeared patent and the dye was seen to end near the surface of the tympanic bulla, close to the eardrum.

## Discussion

Based on the research described in this chapter, it was decided the meatus should be the default location for the sound source input. However, the optimal path for sound to the ear remains uncertain. The dugong has a defined external meatus and a narrow canal that is patent for at least part of its length. It was not possible to establish a definitive connection in the one dissected specimen for the external canal onto the tympanic membrane (eardrum) because of tissue degradation. Therefore, it is uncertain if dugong sound reception is primarily via the meatus and external canal or via an alternative route. One intriguing possibility is the unique sirenian feature of a hypertrophied lipid filled zygomatic bone which lies adjacent to the ear bones and has been proposed in manatees as a possible underwater reception path. This is a feature that may be explored in future studies by measuring differences in receptivity for sound source placement at each of these possible paths.

For the location of the receiving electrode it was determined that the optimal position would be a point that is as close as possible to the middle and inner ear bulla. The scans showed this position can be found by locating the intersection of a line drawn approximately 5 cm ventrally from the meatus with a point 2–3 cm posterior to the rear edge of the lower jaw. That location should also coincide with the bottom ridge of the zygomatic bone which, if palpable, is an equally reliable landmark. As is shown in the reconstructions, this point lies directly over the bulla just below the long arm of the malleus, which is one of the three well-developed middle ear bones and is the closest accessible minimally invasive point to the neural bundle for a lateral probe (Fig. 4).

The head measurements showed that the critical ear features lie at positions that are predictable and proportional in juvenile and adult dugongs. Additional specimens will show us whether there is a general ratio electrode placement template that can be employed for each animal based on a few external measures. The main difference observed is in the interaural separation of the inner ear structures which is significantly larger in the adult. That may be relevant for localization abilities for younger versus adult animals, but this was not a critical element for the study described here.

The anatomical work in this combined project focused on measures of surface features related to sound reception and CT-scans of adult and juvenile heads to locate the shortest paths surface to inner ear and auditory nerve locations. Surface measures were taken of visible and palpable structures to guide electrode placement on live animals. Scans of three heads were uploaded to create 3D reconstructions that visualize and measure distances between surface features and relevant skull, ears, blubber, and musculature within each dugong head.

## Conclusions

The AEP study employing the anatomical study proposed approaches to locating electrode and stimulus source obtained good results with an appreciable signal-to-noise ratio. This suggests that analyses of the fundamental skull, musculature, and auditory anatomy of dugong juvenile and adult heads provided useful guidance for optimal hydrophone placement for transmitting acoustic stimuli transmission to the ear and, even more important, determining locations for placement of electrodes for detection of auditory nerve response signals.

This was accomplished primarily by examining CT images of three existing dugong specimens using surface measures, CT scanning of the intact specimens, and dissection of the auditory regions. Head measurements showed critical ear features lie at predictable and proportional positions in juvenile and adult dugongs. These measurements lay the foundation for developing a "bespoke" template for electrode placement for each animal based on a few external measures.

The value of CT imaging in this study parallels the diagnostic and anatomical value of scan data in for human and veterinary medicine. Clearly, this is an approach to that can provide undisturbed anatomical geometry *in situ* for many larger and rare marine species.

Preliminary additional observations suggest there are significant differences in interaural distances of dugong versus manatee ears; that the dugong eardrum and middle ear structures are stiffer; and that the auditory nerve fiber number is greater in dugongs. The preliminary conclusion is that the dugong ear is fundamentally sirenian but may have a higher frequency of peak sensitivity and potentially better underwater localization than that of the manatee. These are speculations on limited data but they do demonstrate that there remains a wealth of questions to investigate about the sensory capabilities of dugongs.

**Acknowledgments** Funding for this research was provided by the Department of Agriculture, Water and the Environment, Canberra, Australia. The research was a collaborative effort by the University of Queensland Dugong Team, Sea World Australia, Woods Hole Oceanographic Institution, and JASCO Applied Sciences. Access to the dugong specimens and the effort for the anatomical research were made possible by the invaluable assistance of Dr. Helene Marsh, Dr. Wendy Blanshard, Dr. Donna Kwan, and, most important, with the permission, assistance, and hospitality of the Torres Strait Islanders of Mabuaig Island.

**Abstract**

Noise from vessel activity is a major contributor to underwater soundscapes throughout many parts of the world. Vessel noise often induces physiological and behavioral changes in marine animals and can mask ecologically important signals, i.e., limit animals' abilities to detect these signals. Quantitative study of in situ masking in marine environments is often challenged by limited understanding of noise characteristics, sound propagation, and hearing physiology of animals. As a result, studies often make assumptions about model parameters based on limited data. Masking studies in marine environments traditionally use sound pressure, which is detected by mammals and some fishes, to describe in situ acoustic data and animals' hearing thresholds. Few masking assessments have incorporated particle motion, the back-and-forth vibratory part of sound which is the primary stimulus for fish and invertebrate hearing, limiting application of models to these abundant taxa. In this chapter, models previously employed to estimate masking effects of noise on communication and listening space in aquatic environments are summarized, followed by an example and discussion

## Introduction

Vessel noise is frequently present in marine environments and often greatly exceeds natural ambient levels of underwater soundscapes. Historical estimates in several regions report increases in the contribution of noise from shipping traffic to marine soundscapes between 1950 and 2012 (Frisk 2012; Miksis-Olds et al. 2013). Vessel noise has a multitude of adverse physiological and behavioral impacts on marine taxa. Studies of these impacts are numerous for marine mammals, fewer for fishes, and even fewer for aquatic invertebrates (Hawkins et al. 2015). Behaviorally, species across these broad taxa may exhibit startle responses; spend less time foraging; alter swimming, schooling, or social behaviors; and alter the rate and other characteristics of their calls (Magnhagen et al. 2017). Vessel noise may also lead to reduced reproductive success (de Jong et al. 2018). Further, noise from shipping (and other anthropogenic activities) can mask, i.e., inhibit, animal's ability to detect ecologically important signals in their environment (Slabbekoorn et al. 2010; Erbe et al. 2016). These natural signals may include mating or other social calls from conspecifics, sounds revealing the presence of predators or prey, navigation cues, and other signals within animals' ambient soundscapes. Accordingly, it is critical to monitor and model vessel noise to understand how it may inhibit marine animals' abilities to communicate and detect sounds in their habitats and to assess the effectiveness of noise mitigation practices.

Models estimating masking in marine environments typically predict reductions, due to noise, in the range over which animals can communicate with conspecifics or more generally the range over which they can detect (or "listen in" on) natural sound signals. Communication range estimates are applicable to species known to call for specific ecological functions, such as to attract mates. Models for reductions in listening range can be applied to any species that detects sound and whose hearing thresholds (minimum amplitudes the animal can detect pure tones at given frequencies) have been measured. Several excellent papers have applied models of communication and listening space reduction to estimate masking effects of vessel and seismic survey noise on a variety of marine mammal species and a few fish species (e.g., Clark et al. 2009; Stanley et al. 2017; Putland et al. 2018).

Few masking studies have included acoustic particle motion, which is the primary stimulus for hearing in fishes and aquatic invertebrates (Popper and Hawkins 2018; Rogers et al. 2020). A recent lab study reported raised hearing thresholds due to

masking noise for both sound pressure and particle motion in oyster toadfish, *Opsanus tau* (Rogers et al. 2020). However, to the authors' knowledge, no published studies modelling communication or listening space changes due to masking have incorporated particle motion data. "Particle motion" refers to the back-and-forth oscillatory motion of particles in a sound field, whose collective motion (compression and rarefaction) leads to net propagation of sound pressure waves. This chapter summarizes recent methods applied to estimate changes in communication and listening space for marine taxa during anthropogenic noise, followed by an example and discussion of how particle motion data can be, and why it ought to be, incorporated into masking studies focusing on fish and invertebrate taxa.

## Methods Assessing Masking Potential of Anthropogenic Noise

Table 1 summarizes metrics used by recent studies to estimate masking effects of sound pressure level associated with underwater anthropogenic noise on communication and listening by marine animals. Most of these studies focused on vessel noise, though some addressed masking by air gun noise from seismic surveys. These studies have estimated sound pressure level masking effects on communication in multiple fish and mammal species including New Zealand bigeye (*Pempheris adspersa*), Atlantic cod (*Gadus morhua*), haddock (*Melanogrammus aeglefinus*), harbor seals (*Phoca vitulina richardii*), bottlenose dolphins (*Tursiops truncatus*), Bryde's whales (*Balaenoptera edeni*), fin whales (*Balaenoptera physalus*), humpback whales (*Megaptera novaeangliae*), and right whales (*Eubalaena glacialis*). Studies on masking of listening have focused on Atlantic cod, bowhead whales (*Balaena mysticetus*), belugas (*Delphinapterus leucas*), bearded seals (*Erignathus barbatus*), ringed seals (*Pusa hispida*), and, more generally, categorical low-, mid-, and high-frequency cetaceans. The reader is referred to Erbe et al. (2016) for a thorough review of communication masking studies on marine mammals and related terminology and definitions that may be extended to other animal taxa.

Beyond the parameters listed in Table 1, frequency bands and time windows of analysis for signal (e.g., conspecific call) levels, ambient noise levels, and masking noise levels must be carefully chosen to represent the sound perception abilities (and sound production characteristics, if assessing communication) of species of interest. The frequency window chosen should be equal to an animal's critical bandwidth, which is defined based on critical ratios (Fletcher 1940; Erbe et al. 2016). A critical ratio is the difference between a sound level (usually sound pressure level) of a pure tone that is just audible during white noise and the sound level of the white noise. Notably, this definition has been expanded to include other continuous broadband noise in place of artificial white noise (Erbe et al. 2016). The critical bandwidth is the bandwidth of white noise at which the detection threshold of a tone at the center of the noise band stops increasing with increasing width of the noise band; this bandwidth is considered to estimate the bandwidth of an animals' auditory filter at the same center frequency (Fletcher 1940). Critical bandwidths have been directly measured for some marine mammals, including California sea lions (*Zalophus*

**Table 1** Metrics used to model absolute (e.g., in meters) or relative (e.g., as percent difference) spatial extents of masking for communication or listening, from recent studies focusing on marine animals and underwater noise sources. All of these studies focused on sound pressure levels

| Metric name | Definition | Equation | References |
|---|---|---|---|
| Signal excess (SE) | 50% probability of detection of signal if the signal's presence is random in space and time | $SE = SL - PL - NL - DT$,<br>where:<br>SL = source level<br>PL = propagation loss[a]<br>NL = noise level<br>DT = detection threshold | Clark et al. (2009), Hatch et al. (2012), Matthews et al. (2015)[b], Pine et al. (2016, 2020, 2021), Stanley et al. (2017), Cholewiak et al. (2018), Putland et al. (2018) |
| Communication range (CR)[c] | Range or radius from the caller over which call can be detected by a conspecific. (Absolute quantity) | SE is set to zero to solve for range $r$ in the PL term. The exact equation for CR depends on how PL is specified. For example,<br>if: $PL = N\mathrm{Log}_{10}(r)$,<br>then: $CR = 10^{(SL - NL - DT)/N}$ | Clark et al. (2009), Matthews et al. (2015), Pine et al. (2016, 2020, 2021), Stanley et al. (2017), Cholewiak et al. (2018), Putland et al. (2018) |
| Communication space (CS) | Area, centered at the caller, over which call can be detected by a conspecific. (Absolute quantity) | If assuming equivalent propagation conditions at all azimuths:<br>$CS = \pi * CR^2$ | Clark et al. (2009), Cholewiak et al. (2018), Gabriele et al. (2018) |
| Communication range reduction (CRR) | Percent difference in the communication range during noise and the maximum communication range under quiet conditions. (Relative quantity) | $CRR(\%) = 100\left(\frac{r_1 - r_2}{r_1}\right)$,<br>where:<br>$r_1 = 10^{(SL - NL_1 - DT)/N}$<br>$r_2 = 10^{(SL - NL_2 - DT)/N}$<br>$NL_1$ = mean or percentile of sound level of the environment without masking noise in the animal's critical bandwidth (CB) or of the animal's audiogram in the CB, whichever is higher<br>$NL_2$ = mean or percentile of sound level during masking noise, in CB<br>N = spreading coefficient | Hatch et al. (2012), Pine et al. (2020) |
| Listening range reduction (LRR) | Percent difference in linear range over which a receiver can detect a sound during noise and maximum range under quiet conditions. (Relative quantity) | $LRR(\%) = 100(1 - 10^{-\Delta/N})$,<br>where:<br>$\Delta = NL_2 - NL_1$ | Pine et al. (2020) |

(continued)

**Table 1** (continued)

| Metric name | Definition | Equation | References |
|---|---|---|---|
| Listening space reduction (LSR) | Percent difference in area over which a receiver (centered in area) can detect a sound during noise and maximum range under quiet conditions. (Relative quantity) | $LSR(\%) = 100(1 - 10^{-2(\Delta/N)})$ | Matthews et al. (2015), Pine et al. (2018, 2020) |

[a]Propagation loss can include multiple terms depending on the level of complexity and accuracy deemed appropriate for an environment. Simpler models often include a single term, $N\text{Log}_{10}(r)$, where $N$ is a spreading coefficient and r is the range from the sound source

[b]Matthews et al. (2015) used two additional terms, + DI and + SG, where DI is the directivity index, representing an animal's ability to discriminate sounds coming from a particular direction (spatial release from masking), and SG is the signal gain, representing an animal's ability to use knowledge of the time-frequency structure of a call to differentiate it from background noise

[c]Some studies use the terms "communication space" and "communication range" interchangeably, but these are separated here to distinguish between explicitly reported area (e.g., $km^2$) and linear range (e.g., km)

*californianus*), harbor seals, and northern elephant seals (*Mirounga angustirostris*), and indirect methods to estimate auditory filters through critical ratios have been used for many marine mammal species including whales, seals, and dolphins (Erbe et al. 2016). Decidecade (approximately one-third octave) bands are often used as a conservative approximation of marine mammal critical bandwidths (Erbe et al. 2016). Critical bandwidth estimates are only available for a few fish species, including Atlantic cod (Hawkins and Chapman 1975) and goldfish (*Carassius auratus*; Fay 1992). To the author's knowledge, no published data exist on auditory filter bandwidths of aquatic invertebrates. One-octave bands have been used to approximate the critical bandwidth for fishes, based on estimated critical bandwidths measured for Atlantic cod (Hawkins and Chapman 1975; Stanley et al. 2017; Pine et al. 2021). Call characteristics, including source level which is a key input parameter for communication space models, are undescribed for most fish and invertebrate species as well. Because data on call characteristics, critical bandwidths, and detection thresholds are limited for fishes and invertebrates, studies on these taxa often assume these values based on taxonomically related species.

There are multiple mechanisms by which animals can compensate for or obtain "release" from masking effects to improve signal detection during noise. "Spatial release from masking" (SRM) can occur when the noise and signal are received from different directions. "Comodulation masking release" (CMR) can occur when the noise has amplitude modulation in a wider frequency range than the auditory filter bandwidth around a signal, i.e., it is coherently modulated (Hall et al. 1984). Animals can also exhibit "vocal plasticity," altering call characteristics to increase detectability of calls by conspecifics during noise. Call alterations may include increasing the amplitude of calls (also known as the "Lombard effect"), increasing

call rate, or changing frequencies of calls. These three types of "anti-masking" strategies have been widely studied in terrestrial mammals (including humans), and evidence for them exists in multiple marine mammal species (Hall et al. 1984; Brumm and Zollinger 2011; Erbe et al. 2016). Terms accounting for SRM and CMR have been included in equations for signal excess in some marine mammal communication space models (Clark et al. 2009; Matthews et al. 2015).

Published data on anti-masking mechanisms are currently available for only a few species of fishes and are lacking for aquatic invertebrates (Hawkins et al. 2015). The CRM strategy has been quantified in goldfish (Fay 2011). Fishes have been shown to have different sensitivities to sound along different axes (Hawkins and Popper 2018). How fishes might incorporate directional cues to attain spatial release from masking is not well understood (Popper and Hawkins 2018), though some evidence exists for this ability in Atlantic cod (Hawkins and Popper 2018). Vocal plasticity in amplitude, call rate, or frequency has been observed in several fish species including damselfish (Pomacentridae), Lusitanian toadfish (*Halobatrachus didactylus*), and freshwater blacktail shiner (*Cyprinella venusta*; Holt and Johnston 2014; Radford et al. 2014). Plainfin midshipman have also been observed increasing the amplitude of their mating calls when played artificial tones (Brown et al. 2021). To the authors' knowledge, reduced signal-to-noise ratios (SNR) of signal detection by the listener or increased SNR of a caller's vocalizations via these mechanisms have only been quantified for sound pressure and not particle motion. Owing to limited data on anti-masking strategies of aquatic animals, including mammals, such strategies are often excluded from listening and communication space models (but see Clark et al. 2009; Matthews et al. 2015), likely leading to over-estimation of masking for species that employ these strategies (Erbe et al. 2016).

## Incorporating Particle Motion in Modelling Masking Effects of Vessel Noise

To apply sound pressure level methods reviewed in the previous section to particle motion data, particle acceleration, velocity, or displacement levels can be used in place of sound pressure levels. Of these, particle acceleration is typically considered the most relevant to fish and invertebrate hearing (Popper and Hawkins 2018). However, there are some additional considerations to be made. Unlike sound pressure which has a single magnitude in all directions at a given point in space, particle motion is a vector quantity with a magnitude and a direction. Particle motion can be reported for individual axes or for vector sums of two or three orthogonally spaced axes to give a 2D or 3D direction and magnitude. Thus, masking in terms of particle motion could be described for multiple directions with respect to an animal. Although there is much to be discovered about how mechanistically fishes and invertebrates utilize particle motion cues to distinguish signals during noise, given the known importance of particle motion to their sound detection, it is prudent to incorporate it into assessments of masking effects of noise on these taxa (Popper and Hawkins 2018; Nedelec et al. 2021).

Potential masking of vessel noise was investigated for one fish species, red drum (*Sciaenops ocellatus*). Red drum produce courtship calls that are tied to reproductive success (Montie et al. 2016) and inhabit continental shelf waters in the US Mid- and South Atlantic and Gulf of Mexico (Lowerre-Barbieri et al. 2008). Audiograms for red drum have been published for pressure and particle motion (Horodysky et al. 2008). Because source levels of red drum calls were not available in peer-reviewed literature, this analysis focused on listening range reduction (LRR). LRR is the percent difference in linear range over which a receiver can detect a sound during noise and the maximum range under quiet conditions. It is calculated as follows:

$$\mathrm{LRR}(\%) = 100\left(1 - 10^{-\Delta/\mathrm{N}}\right), \tag{1}$$

where $\Delta = \mathrm{NL}_2 - \mathrm{NL}_1$ and N is a geometric spreading coefficient. $\mathrm{NL}_1$ is defined here as the median root-mean-square (RMS) sound level of the environment without masking noise in the animal's critical bandwidth or level of the animal's audiogram at the center of the critical bandwidth, whichever is greater (i.e., the "baseline" level). $\mathrm{NL}_2$ is the median sound level during masking noise, in the critical bandwidth. One-octave bands were chosen to represent critical bandwidths of red drum, based on estimated critical bandwidths measured for Atlantic cod, and following recent communication space studies on fishes (Hawkins and Chapman 1975; Stanley et al. 2017; Pine et al. 2021).

To explore the use of in situ particle motion data in masking models, passive acoustic data were leveraged from five sites of the Atlantic Deepwater Ecosystem Observatory Network (ADEON) located throughout the US Mid- and South Atlantic Outer Continental Shelf (Tripathy et al. 2021; Kowarski et al. 2022). Passive acoustic data were collected at ADEON sites from compact four-channel hydrophone arrays (0.5 m, orthogonal spacing) on bottom landers during November 2017 to December 2020; the data from November 2017 to June 2018 were considered here. RMS pressure and particle acceleration values were calculated in 60 s time windows. The average RMS pressure value between the four hydrophones for each 60 s window was taken to report sound pressure level. The finite-difference approximation (Gray et al. 2016) was used to calculate particle acceleration for three orthogonal axes, and for simplicity, the vector norm (square root of the sum of squares of linear acceleration of each axis) was calculated to give scalar magnitudes (as in Jones et al. 2022). Times of vessel closest points of approach (CPAs) were identified with an automated detector (Martin 2013) and manually checked to remove time points with confounding hydrodynamic flow signal and broadband transient signals (of unknown origin). Ambient (baseline) soundscape pressure and particle acceleration levels were defined for time points outside of when vessels were detected. Site locations, depths, total number of vessel CPAs, and counts of vessel CPAs with RMS sound pressure level and particle acceleration values above red drum's hearing thresholds (in terms of sound pressure and particle acceleration, respectively) are summarized in Table 2.

**Table 2** Study site locations, depths, and counts of vessel closest points of approach (CPAs) including totals detected per site; numbers of CPAs with 60 s RMS levels ($NL_2$), calculated in one-octave bands centered at 128 Hz, above red drum's audiogram at 128 Hz in terms of sound pressure; and those in terms of particle acceleration

| Site name | Site abbreviation | Latitude; longitude | Depth (m) | Total num. CPAs | Num. CPAs with $NL_2$ > hearing threshold (pressure) | Num. CPAs with $NL_2$ > hearing threshold (particle acceleration) |
|---|---|---|---|---|---|---|
| Hatteras South | HAT | 35.200° N; 75.020° W | 296 | 255 | 97 | 118 |
| Wilmington | WIL | 33.585° N; 76.451° W | 461 | 272 | 48 | 55 |
| Savannah Deep | SAV | 32.042° N; 77.348° W | 790 | 101 | 34 | 47 |
| Jacksonville | JAX | 30.493° N; 80.003° W | 317 | 93 | 34 | 45 |
| Blake Escarpment | BLE | 29.251° N; 78.351° W | 872 | 200 | 40 | 54 |

Soundscape and vessel noise data were limited to a one-octave band centered at 128 Hz, a frequency at which red drum's hearing thresholds are relatively low (more sensitive) compared to other frequencies. The vessel noise values ($NL_2$) and $NL_1$ values were calculated with sound pressure levels and particle acceleration levels, to obtain separate sound pressure- and particle acceleration-derived LRR values. The coefficient of propagation loss was chosen to be N = 15 (for both sound pressure and particle acceleration), which is intermediate between cylindrical and spherical spreading. For both sound pressure and particle acceleration, red drum's hearing thresholds were higher than median ambient soundscape RMS levels at each site; thus, the fish's hearing threshold (at 128 Hz, linearly interpolated from measured thresholds at 100 and 200 Hz) was used as $NL_1$.

A greater number of CPAs were above hearing thresholds in terms of particle acceleration than in sound pressure at each site, though these differences were not significant ($p > 0.05$, Mann-Whitney U test, $n = 5$ sites). RMS pressure and particle acceleration of vessel noise were strongly linearly correlated (HAT, $R^2 = 0.81$; WIL, $R^2 = 0.85$; SAV, $R^2 = 0.92$; JAX, $R^2 = 0.83$; BLE, $R^2 = 0.84$), suggesting that vessel noise was being received (by the hydrophone array) in the far field (Nedelec et al. 2021).

Taking the differences between particle acceleration-derived LRR and sound pressure-derived LRR for each individual vessel CPA revealed that particle acceleration LRRs were greater than sound pressure LRRs for most vessel passes (Fig. 1a).

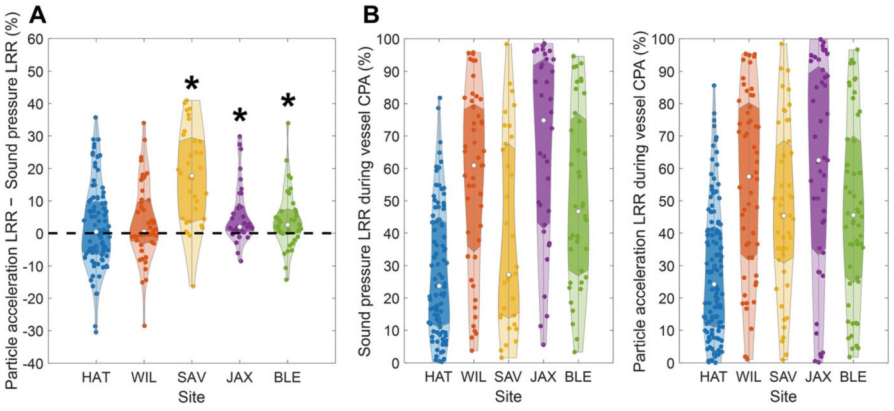

**Fig. 1** (**a**) Differences between percent listening range reduction (LRR) in terms of particle acceleration and that in terms of sound pressure, for each vessel's closest point of approach (CPA). Asterisks indicate sites with significantly different medians from zero ($p < 0.01$, Wilcoxon rank sum tests). Sample sizes for each site in this figure differ from those for CPA counts in Table 2, as the RMS sound pressure level and RMS particle acceleration level of the vessel had to both be above hearing thresholds to be included here: HAT, $n = 89$; WIL, $n = 48$; SAV, $n = 34$; JAX, $n = 34$; and BLE, $n = 39$. (**b**) Distributions of sound pressure-derived LRR (left) and particle acceleration-derived LRR (right) values for all vessel passes with sound levels above hearing thresholds in terms of sound pressure and particle acceleration, respectively. Sample sizes are the number of CPAs above hearing thresholds in Table 2 for pressure and particle acceleration. Filled circles are individual data points, open (white) circles are medians, and darker shaded regions are inter-quartile ranges (25th percentile to 75th percentile)

For three sites, SAV, JAX, and BLE, median differences (particle acceleration LRR minus sound pressure LLR) were significantly greater than zero ($p < 0.01$, two-tailed Wilcoxon rank sum tests). Conversely, considering all CPAs above thresholds, the distributions of sound pressure-derived LRR values and particle acceleration-derived LRR values were statistically similar to each other for each site ($p > 0.05$, Mann-Whitney U tests), ranging from near 0% to between 82% and 100% (Fig. 1b).

In this scenario, when taking the ratios of vessel noise RMS levels to hearing thresholds, median predicted LRRs were greater for particle acceleration than for sound pressure (Fig. 1a). However, combining vessel CPAs over the study period for each site, the distributions of LRR values for each site were similar in terms of sound pressure and particle acceleration (Fig. 1b), and octave band levels in each metric correlated well with each other, suggesting vessel noise approximated plane waves received in the far field (Nedelec et al. 2021). This meant that the variability in LRR among vessel passes was greater than the variability in the difference of sound pressure-derived LRR and particle acceleration-derived LRR for individual vessels. Thus, sound pressure and particle acceleration appeared to give redundant results (for this species, noise source, and region) over the long term, but for most sites, the median LRR values were systematically different between the metrics for individual vessel passes. Audiogram curves may have different shapes in terms of pressure and particle motion for given species, i.e., they may differ in relative sensitivities for each metric across frequencies (Radford et al. 2012), which could lead to different LRRs for each metric.

Masking assessments for fishes and invertebrates would be more accurate and useful and could be applied to more species, with audiogram data on more species in terms of both pressure and particle motion, and ideally using widely agreed-upon methodological standards. Masking models are sensitive to uncertainties in animals' audiograms (Pine et al. 2020). There are a lack of audiogram data in terms of particle motion and lack of standardized, consistent methodology for obtaining audiograms for non-mammal taxa. Among the fish species with available audiogram data, most were only obtained in terms of pressure. Further, for given fish species, wide ranges (over 40 dB for goldfish) in thresholds have been published, due to different data collection and threshold analysis methods, environmental variables (e.g., differences in temperature), and equipment used across studies (Halvorsen and Ainslie 2018). Fishes' and invertebrates' audiograms are often higher than the median ambient soundscape levels of their habitats (Tricas and Webb 2016; Jones et al. 2022); thus, listening range estimates for these taxa often will be directly weighted by their audiograms rather than by ambient soundscape levels.

Though not investigated in detail here, particle motion should also be considered in communication range and CRR estimates for fishes and invertebrates. Modelling communication range is more complex than modelling listening range because it requires more *a priori* knowledge including source levels of biological signals and anthropogenic noise sources (Pine et al. 2020). Source level estimates for known sound signals produced by fishes and invertebrates are limited, and those in terms of particle motion are even more scant. Many of these taxa communicate with

conspecifics in the near field, where particle motion and pressure will not predictably scale with one another and must both be measured directly (Nedelec et al. 2016). Additionally, particle motion will drop off with distance more rapidly than sound pressure in the near field (Kalmijn 1988). Thus, even if the masking noise is received in the far field, communication ranges of ecologically relevant signals in terms of particle acceleration may often be more limited than those in terms of sound pressure.

## Conclusions

Measuring and reporting both sound pressure and particle acceleration is recommended for models of changes in listening and communication space during noise for fishes and aquatic invertebrates. These models also require accurately collected (ideally in a standardized manner) data on sound levels and propagation of anthropogenic noise, natural soundscapes, and hearing thresholds of study animals. More co-located measurements of pressure and particle motion of soundscapes and noise sources are needed because (1) pressure and particle motion will not scale predictably with one another in all environments and (2) incorporation of particle motion data allows analyses in terms of the primary sound-detection stimulus for these taxa. Even when sound pressure and particle motion correlate well, as for vessel noise in the present example study, ratios of noise levels to hearing thresholds for individual noise events may differ for sound pressure and particle motion, and one cannot assume equivalent audiogram curves (e.g., same shape) for each metric. Further, even when studies focus on species that likely do not sense sound pressure at all (e.g., elasmobranch fishes and many aquatic invertebrates), including sound pressure data is still useful to improve understanding of the relationships between sound pressure and particle motion in different environments and for different types of noise and to allow applicability of datasets to sound pressure-sensitive taxa. Although the present example was in relatively deep water (300–900 m), in shallower, nearshore environments such as harbors and bays, particle motion is less likely to scale predictably with pressure (Nedelec et al. 2016). Thus, its measurement and inclusion in masking studies of particle motion-sensitive taxa are of heightened importance in shallower environments.

Higher ratios of received vessel noise to hearing thresholds led to higher particle motion-derived LRR values in the present example using red drum as the study species, compared to pressure-derived LRR values. In this scenario, estimating LRRs just in terms of sound pressure would have under-predicted LRR values for red drum. Again, LRR estimates can be strongly influenced by audiograms, and this is especially true for many fish and invertebrate species whose thresholds are below median (and often higher percentiles) of ambient soundscape levels. Development of standards in hearing measurements and particle motion measurements for such taxa will increase precision and confidence of LRR models. Potential differences in estimated CRR should be explored in future studies as well.

With limited masking studies using particle motion at present, it is difficult to predict how sound pressure- and particle motion-derived LRR values will differ from each other for other species, regions, and noise sources. Where individual vessel passes were concerned in the present example, particle motion-derived LRRs tended to be higher for red drum than pressure-derived ones, indicating a potential for LRRs to differ for each metric. However, in this deepwater environment where vessel noise was likely received in the far field, variability in source levels across multiple vessel passes led to similar LRR distributions. The extent that LRR values will differ for pressure and particle motion will likely depend on depth, bathymetry, and other factors affecting sound propagation, species, and characteristics of the noise source (e.g., vessel type) specific to each study scenario. It would be interesting in future studies to assess whether specific mitigation methods recently applied, such as vessel slowdowns and engineering solutions that quiet sound emitted by engines and propellers, equivalently lead to reductions in sound levels and LRR estimates for both particle motion and sound pressure. One cannot expect them at present to be identical for any given scenario. The authors hope this discussion will encourage more researchers to incorporate particle motion data in masking models for fishes and invertebrates. To facilitate these analyses, more particle motion measurements should be made in underwater soundscape and noise monitoring projects.

**Acknowledgments** The Atlantic Deepwater Ecosystem Observatory Network (ADEON) study was funded by the US Department of the Interior, Bureau of Ocean Energy Management, Environmental Studies Program, Washington, DC, under contract number M16PC00003. Funding for ADEON ship time and additional funding for ITJ were provided by the Office of Naval Research, Code 32. We are grateful to the organizers of the 2022 Effects of Noise on Aquatic Life conference for providing travel funding for ITJ.

**Abstract**

A pilot study to measure hearing capabilities in wild dugongs (*Dugong dugon*) was conducted in Moreton Bay, Australia. To successfully obtain hearing measurements, an approach for measuring auditory responses in wild dugongs using neurophysiological measures was developed. Preparatory to the measurements, basic head anatomy of dugongs was investigated to optimize placements of the acoustic transmitting and receiving neuronal sensors. Three dugongs were selected as suitable candidates for the auditory measurements based on the results of a preliminary health assessment. Following the absence of observable responses by the first animal, click and sinusoidally amplitude modulated signals were used as acoustic stimuli for the second and third animals, eventually

resulting in reproduceable and scalable neuronal responses. The recorded neuronal signals represent a proof of concept for the first auditory measurement in wild dugongs. Valuable insights were gathered during the pilot study allowing optimization of the procedure for a planned follow-up study which will test a larger number of wild dugongs.

## Introduction

Increasing levels of human-made noise in the world's oceans have prompted concerns about physiological impacts on the hearing apparatus and functioning of marine wildlife species and their disruption to behaviors including alterations in habitat use (NRC 2003, 2005). Despite these concerns, there are comparatively few measures of hearing ranges and sensitivities of wild marine mammals. Thus, it is difficult to determine the potential effects of noise on these animals in natural habitats.

In Australia, dugongs (*Dugong dugon*) occur in the coastal waters of northern Australia from Moreton Bay in the east to Shark Bay on the Western Australian coast. Dugongs are listed as *Vulnerable to Extinction* at a global scale (IUCN 2021) and listed and protected under the EPBC Act in Australia. Major environmental threats to dugongs vary with location but the most important threat globally is considered to be degradation and loss of their seagrass habitat. Furthermore, as a consequence of their habit of grazing in shallow nearshore areas, boat strike and incidental entanglement in fishing nets and in swimmer protection nets present mortal risks for dugongs (Hodgson et al. 2007).

As fully aquatic animals, underwater sound is considered a critical survival cue for dugongs, potentially important for detection of predators, awareness of underwater features such as reefs and shoal areas, and intraspecific communication (Ichikawa et al. 2012). How dugongs perceive and respond to underwater sound may also affect their potential to avoid collisions with vessels (Hodgson and Marsh 2007), evade underwater construction zones, and detect nets equipped with acoustic alarms. Understanding the auditory capabilities of dugongs has important consequences for threat mitigation and conservation planning. At present, there is a lack of auditory response data for dugongs.

Dugongs are members of the Sirenia, a mammalian order of herbivorous aquatic mammals that includes manatees. Studies on the phylogenetically related manatees (West Indian *Trichechus manatus*, Amazonian *T. inunguis*, and West African *T. senegalensis*) suggest that there are substantial differences among sirenians in terms of their hearing abilities. One study on a captive West Indian manatee found responses to acoustic stimuli ranging from 400 Hz to approximately 45 kHz with best sensitivity near 25 kHz, but also indicated some responses at signals as low as 15 Hz (Gerstein et al. 1999). It has been suggested that the perception of some

signals, especially around 20 Hz, were likely vibrotactile rather than auditory (Gaspard et al. 2013).

Auditory evoked potential (AEP) studies have also been conducted on all three manatee species (Bullock et al. 1980; Klishin et al. 1990; Supin et al. 2001). The use of AEPs in marine mammal audiometry is a recognized means of determining animal hearing quickly and safely in a variety of taxa (Supin et al. 2001; Reichmuth et al. 2013; Finneran 2015). The AEP method for auditory threshold determination compares well to traditional behavioral methods (Yuen et al. 2005) and has advantages in allowing rapid threshold measurements from untrained subjects (Nachtigall et al. 2005, 2007).

A comparison of the AEP data across these studies suggested that each of the three manatee species has narrower hearing ranges than the behavioral work reported, with best sensitivity typically in the 10–15 kHz range. These studies also demonstrated that the AEP approach is feasible on sirenians of most sizes and has the advantage of being able to test multiple individuals from each species, across sexes and all age cohorts.

One brief study conducted on a single captive male dugong indicated a probable low frequency cutoff near 300 Hz and high frequency cutoff near 40 kHz (Ketten et al. 2000). However, there was also a noticeable "notch" in the hearing response at 8–10 kHz suggesting that this individual had diminished hearing in at least that range and possibly overall (▶ Chap. 44, "Anatomical Measurements of Dugong Auditory Systems for Evoked Potential Studies").

Vocalizations may also be used to provide some (limited) indications on the potential range of "best" hearing, because in most mammals sounds are produced near but not at the frequency of peak sensitivity of hearing (Wartzok and Ketten 1999). However, thus far, studies on the acoustic repertoire of sirenians are few and often insufficiently controlled to yield information on a full functional range. Sound production data are available for three of four sirenian species: frequencies of underwater calls range from 0.4–22 kHz for West Indian manatees compared to 0.15–18 kHz for dugongs (Southall et al. 2019). However, the extent of their hearing range and auditory sensitivity remains unclear.

This chapter describes a pilot study to measure hearing capabilities of wild dugongs through the auditory evoked potential (AEP) approach. An initial study examined the morphology of the dugong head and hearing apparatus to determine appropriate placement of each of the acoustic transmitting and neuronal receiving sensors (see ▶ Chap. 44, "Anatomical Measurements of Dugong Auditory Systems for Evoked Potential Studies"). The hearing tests conducted in the field were the first to measure auditory capacity of wild dugongs.

## Methods

A pilot study to test hearing sensitivity was successfully conducted on three wild dugongs in Moreton Bay, Southern Queensland, Australia, in May 2022, as part of an annual health assessment program (Lanyon et al. 2010). This study was conducted under The University of Queensland Animal Ethics Approval Certificate

2021/AE000821, Scientific Research Permit WA0019236, and Moreton Bay Marine Park Permit MPP18-001119-1.

The technical approach for the proposed measurements mainly follows the relevant ANSI/ASA standard (S3/SC1.6-2018) for obtaining audiograms from toothed whales but is partially modified to account for the aim of achieving basic auditory responses from a dugong. In the absence of direct measurements, the first measurements were intended to establish baseline neuronal responses.

AEP measurements are based on playing sound stimuli at different frequencies and recording neural responses evoked by each stimulus. The precise placement of stimulus sources (loudspeakers, suction cup hydrophone, jawphones, free standing hydrophones, etc.) and response detectors (surface or needle electrodes) may differ by species based on the anatomical differences in the location of auditory structures and sources employed.

## Dugong Head Morphology

Optimizing jawphone and electrode placement was accomplished by analyses of the fundamental skull, musculature, and auditory morphology of the dugong head (see ► Chap. 44, "Anatomical Measurements of Dugong Auditory Systems for Evoked Potential Studies"). These data provided the necessary guidance for optimal placement for transmitting acoustic stimuli to the ear and, equally or more important, determining locations for placement of electrodes for best detection of neural response signals.

## Subjects

The study was conducted over the Eastern Banks of Moreton Bay, Queensland, in May 2022. Several dugongs were captured using the open water method (Lanyon et al. 2006) and craned onto the back deck of a research vessel for medical examination as part of an annual health assessment program (Lanyon et al. 2010).

Each dugong was held unrestrained and in a recumbent prone position on a closed-cell foam mattress under shade on the rear deck of the research vessel. Vital signs were monitored throughout the restraint period including during health assessment prior to the hearing tests. Vital signs included body temperature measured through use of an oral temperature probe, heart rate measured at 5 min intervals using a Doppler ultrasound unit, and respiratory rate measured continually in real time. Vital signs for each dugong remained within the normal ranges for apparently healthy dugongs (Lanyon et al. 2010).

Three dugongs were selected as suitable candidates for the pilot study to measure hearing sensitivity through auditory evoked potentials (AEP), based on their apparently healthy state, excellent body condition, normal vital signs, docile demeanor, and the clinical sampling having proceeded in a timely manner so that the dugong could be released within the 60-min period for handling the animals as stipulated by the permit.

The first dugong sampled was a pubertal male (MB22207), 250 cm straight body length (BL) with unerupted tusks (previously captured for health assessment as an immature in June 2015, BL 225 cm). The second dugong (MB22211) was an immature female (210.5 cm BL), while the third (MB22212) was a mature female (286 cm BL).

## Hearing Tests

Stimulus generation and data acquisition were conducted using the evoked response study tool (EVREST) electrophysiological monitoring system (Finneran 2009). To control the position of the sound source and stimulus level received by the animal, the sound projector (a 2.5 cm diameter spherical hydrophone, ITC 1042) was embedded in a silicon suction cup which was placed over the left external auditory meatus (blue arrow in Fig. 1).

Three 28-gauge needle electrodes (inverting, noninverting, and ground), which were long enough to penetrate the hypodermal blubber layer, were used to acquire the AEPs (red arrows in Fig. 1). The noninverting electrode was placed along the dorsal midline and over the assumed location of the brainstem, i.e., at the animal's neck. The inverting electrode was positioned over the ipsilateral meatus and the ground electrode was located on the back of the animal.

Test stimuli consisted of sinusoidally amplitude modulated (SAM) sounds of 32 ms duration and a modulation rate of 600 Hz. The stimuli were presented at a rate of 24.8 presentations per second (following the results for manatees, Mann et al. 2005). The signals were presented at low to moderate sound pressure levels (SPLs) relative to the published hearing sensitivity of the manatees tested in previous studies and gradually varied to obtain responses. Sounds were generated via a laptop computer and SPLs were controlled by a digital attenuator.

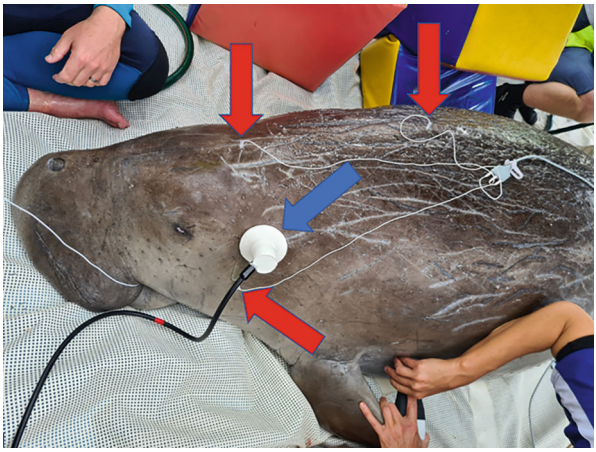

**Fig. 1** Dugong lying on a mattress showing the placement of the sound transmitter (blue arrow) and the three receiving AEP electrodes (red arrows) during hearing tests. (Copyright: Janet Lanyon)

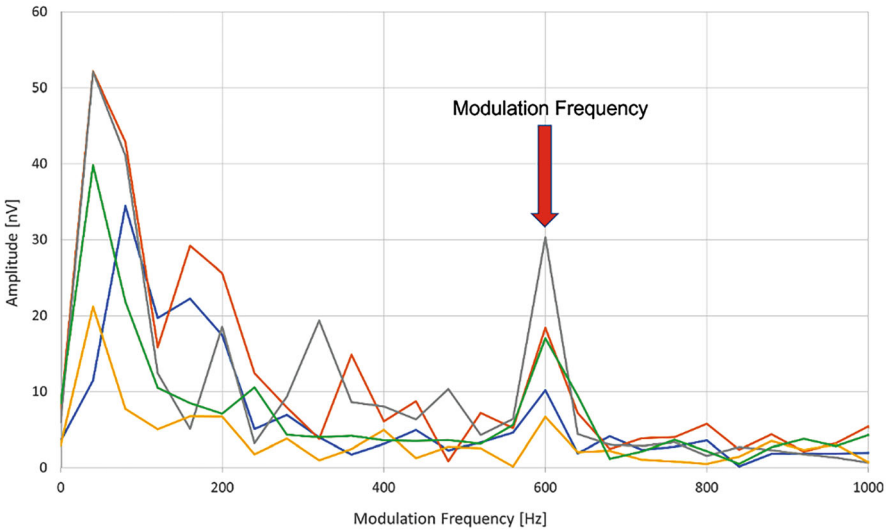

**Fig. 2** Spectral analysis of the AEP responses to acoustic stimulation at 10 kHz which was amplitude modulated at 600 Hz; red arrow indicating a neuronal response at the modulation frequency. (Copyright: Klaus Lucke)

Evoked potentials were collected in response to up to 1024 presentations of the stimulus at each sound level. Evoked potential magnitudes were calculated by performing a Fast Fourier Transformation (FFT) to identify and quantify the neuronal response at the modulation frequency (indicated by the red arrow in Fig. 2). The potential difference between the inverting and noninverting electrodes was amplified (94 dB) and bandpass filtered (30 Hz to 3 kHz) with a biopotential amplifier (ICP511; Grass Technologies) before being digitized using a multifunction data acquisition card (NI PCI-6251, National Instruments, USA) and stored on a laptop computer. Evoked responses were digitized at a rate of 40 kHz with 16-bit resolution over a 40.3-ms sweep duration. The differential electrode signal was synchronously averaged using a weighted averaging method (Elberling and Wahlgreen 1985). During the measurements, the boat's engine and all accessory electrical devices had to be switched off to reduce the ambient noise onboard and to eliminate electrical artifacts in the AEP measurements.

## Results

Two dugongs tested in this study showed detectable neuronal responses to presentation of sound stimuli. Neuronal responses at the modulation frequency were found at repeated measurements of 10 and 16 kHz at varying received stimulus levels; a clearly identifiable neuronal response was also identified at a single measurement conducted at 32 kHz.

Emitted sound levels were varied during successive measurements at 10 and 16 kHz over a range of up to 12 dB. These revealed that the neuronal responses increased proportionately with increases in signal level. Absolute received levels were not calculated as the sound source had not been recently calibrated.

## Discussion

This study is the first attempt to investigate hearing in wild dugongs. The results of the AEP measurements conducted during the pilot study provide a proof of concept for using this approach for systematic auditory studies on wild dugongs that are temporarily captured and restrained. The analysis of the recorded data revealed that neuronal responses scale with the received level, thereby providing a first approximation for determining frequency range of hearing, frequency of best hearing, and, potentially, hearing thresholds in these animals. While these auditory parameters for this species were not established in this pilot study, valuable insights and experience were gained which will be invaluable for planning and conducting a more comprehensive and definitive auditory study.

The animals were sufficiently docile to successfully conduct AEP measurements and, what is more important, showed no signs of discomfort nor increased stress due to the procedures involved in the hearing test.

The anatomical results provided invaluable guidance for the best placement of the sound source and AEP electrodes. The precise locations will be optimized during the follow-on study but results already show a good signal strength (i.e., a good signal-to-noise ratio).

The conclusion of the pilot study, apart from a proof of concept, is that under appropriate environmental conditions it will be possible to sample a larger number of dugongs including testing at least two frequencies per animal within the limited time frame currently permitted for holding wild dugongs out of water. By testing three basic frequencies per animal (e.g., a low, high, and a random frequency), it should be possible to create a composite audiogram representing the hearing range and frequencies of best sensitivity for Moreton Bay dugongs. A detailed investigation of the dugong hearing system and anatomical comparison with manatees will be essential to assess the robustness of the auditory results.

**Acknowledgments** Funding for this pilot study was provided by the Department of Agriculture, Water, and the Environment, Canberra. This pilot project was a collaborative effort by The University of Queensland Dugong Team, Sea World Australia, Woods Hole Oceanographic Institution, and JASCO Applied Sciences.

**Abstract**

Knowledge of an animal's hearing sensitivity is critical to understanding how species perceive their auditory world and their susceptibility to hearing loss when exposed to anthropogenic noise. Auditory evoked potentials (AEPs) are commonly used to measure auditory responses, but it can be challenging to compare thresholds across studies. A tractable source of inter-study variation is the effect of the threshold determination method. Using control data collected for a study investigating underwater hearing loss in the freshwater turtle *Trachemys scripta elegans* (red-eared slider; n = 3), a subset of 400 Hz underwater thresholds was

analyzed using three methods: regression, visual, and F-statistic. The regression method consistently calculated lower thresholds compared to the visual and F-statistic methods, with a mean difference of 6.2 and 7.3 dB re 1 μPa, respectively. The mean difference between the visual and F-statistic methods was 1.1 dB, with the F-statistic method producing the highest thresholds. Regression-determined thresholds were also lower than visual at 175, 600, 800, and 1000 Hz by a mean of 4.3–8.2 dB; relative sensitivity across frequencies was consistent between the two methods. Elucidating how thresholds may vary depending on analytical approach improves our ability to compare data across Testudine species, a highly threatened taxon.

## Introduction

Noise pollution is a prevalent anthropogenic component of the sensory world of many marine and freshwater animals (Gedamke et al. 2016; Rountree et al. 2020). There are numerous potential impacts of this noise on both vertebrates and invertebrates (Duarte et al. 2021), including a temporary or permanent reduction in hearing abilities (Smith et al. 2004; Popper et al. 2014; Finneran 2015). Knowledge of an animal's hearing sensitivity, which varies by species, individual, and age, is critical to understanding the susceptibility of a species to this noise-induced hearing loss (Saunders and Dooling 2018). Auditory sensitivity is described using hearing thresholds, which are the minimum amplitudes of a sound that are detectable to an animal. Hearing abilities can be evaluated using either behavioral (e.g., psychophysical) or electrophysiological methods, although it should be noted that these two approaches are not equivalent, as the former also incorporates perception (Popper and Hawkins 2021). In both cases, an auditory stimulus is presented, and either the animal's electrophysiological or behavioral response is observed. Behavioral techniques require an animal to produce a trained, conditioned, or natural response upon detection (Chapman and Hawkins 1973; Bhandiwad et al. 2013; Lavender et al. 2014). Electrophysiological methods acquire responses using electrodes on (often sedated) animals to measure the neurological voltages produced in response to the auditory stimulus (Corwin et al. 1982). In general, psychophysical methods are considered to produce lower thresholds (i.e., greater sensitivity) than electrophysiological methods (Yuen et al. 2005; Finneran and Houser 2006; Lavender et al. 2014; Sisneros et al. 2016), as behavioral responses reflect integration and perception throughout the auditory system. However, for many species and life stages (e.g., cephalopods, crustaceans, larval fishes) or when working with wild animals, training is not feasible. In these cases, electrophysiological methods are needed to measure auditory sensitivity at the level of neural responses by the ear.

Auditory thresholds are obtained using auditory evoked potentials (AEPs), a minimally invasive and relatively efficient method of measuring sensitivity to sound (Burkard et al. 2007). One consideration is that the experimental setup (e.g., study methodology, equipment, background sound conditions) can affect the calculated thresholds, thus influencing the comparison of thresholds measured in different studies (Ladich and Fay 2013; Sisneros et al. 2016). While the effects of some sources of inter-study variation can be difficult to quantify (e.g., electrode depth), we can improve our understanding of methods that are more tractable to enable a better interpretation of thresholds measured across studies.

Here, three different analytical methods of interpreting AEP data to generate auditory thresholds were compared: a regression-based method, visual discrimination of the responses, and an F-statistic method. This comparison was made using AEP measurements collected from the freshwater turtle, *Trachemys scripta elegans* (red-eared slider). Despite the prevalence of anthropogenic noise and the threatened status of many Testudine species (Rhodin et al. 2018; Stanford et al. 2020), there are no data informing the occurrence or magnitude of noise-induced temporary threshold shifts (TTS) in turtles in either air or water. To address this data gap, underwater auditory thresholds were collected from three *T. scripta elegans* individuals after control conditions and after exposure to continuous white noise (50–1000 Hz) that varied in amplitude and duration. Applying different analytical methods to these control data provided an opportunity to understand how thresholds may vary depending on the method chosen. While this comparison is useful to consider hearing studies across taxa, it is especially helpful for Testudine species, a threatened group for which there are limited auditory data. An improved ability to compare data between studies increases our predictive power to understand the susceptibility of both freshwater and sea turtles to underwater noise pollution.

## Methods

As part of a study investigating TTS in Testudines, auditory thresholds were measured repeatedly at 400 Hz in *T. scripta elegans*. The study was approved by the Massachusetts Division of Fisheries and Wildlife (Permit #: 075.20LP) and the Institutional Animal Care and Use Committee (WHOI ID#s: 25252.01 and 25999). Three adult females (referred to as RES01, RES04, and RES05) were used to remove the confounding variables of age and sex (Wang et al. 2019; Wang et al. 2021). Turtles ranged from 18.5 to 18.8 cm in carapace length, 17.7 to 18.5 cm in carapace width, and 865 to 1100 g in weight. Control measurements were used to define each animal's baseline auditory abilities to enable the determination of the occurrence and magnitude of TTS. Hearing at 400 Hz was studied because this frequency is in the range of their highest auditory sensitivity (Fig. 1). Over the course of the study, 76 thresholds for RES01 and 94 thresholds for both RES04 and RES05 were measured.

A combination of sedation and physical restraint was used to enable the collection of underwater AEP measurements (Harms et al. 2014; Piniak et al. 2016). Turtles were sedated with intramuscular midazolam (1 mg/kg) and dexmedetomidine (3–90 μg/kg), administered by a veterinarian. RES01 required the addition of ketamine (2–3 mg/kg).

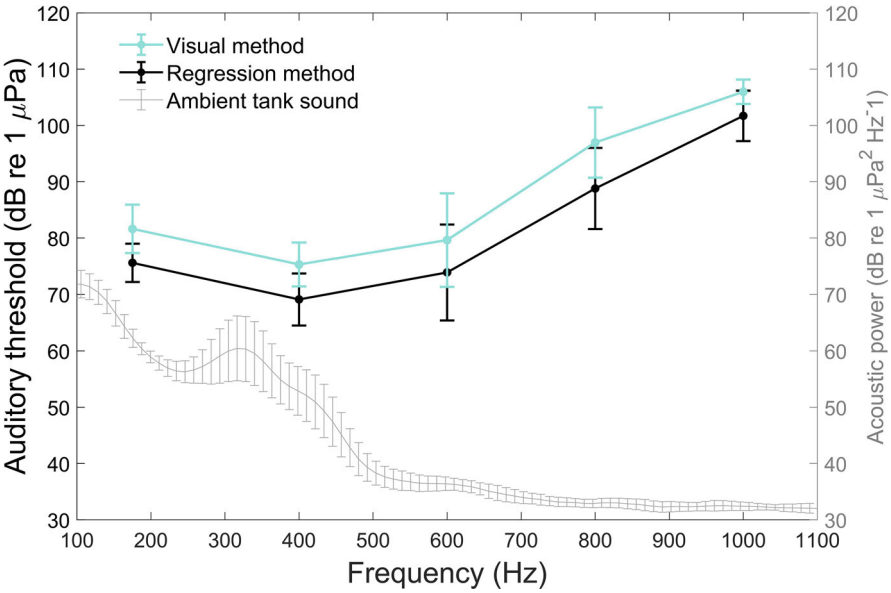

**Fig. 1** Comparing *Trachemys scripta elegans* underwater auditory thresholds calculated using the visual and regression methods. Audiograms represent the mean (1 SD error bars) of thresholds collected for three individuals for the test frequencies of 175, 400, 600, 800, and 1000 Hz. The 400 Hz threshold determined using the regression method represents the mean of the 75 thresholds selected to compare to the visual method; the mean of all 400 Hz thresholds collected across the study for the three individuals is 70.3 dB re 1 μPa (n = 264). Ambient tank sound (mean ± 1 SD) was calculated using recordings from 10 randomly selected experimental days during the testing period, with hydrophone at the position of the turtle's head without the animal present

After the desired plane of sedation had been reached, turtles were wrapped with an elastic bandage to both limit movement and for securing to a plastic platform, which could slide vertically along a PVC frame to raise the turtle to breathe. This platform and frame also maintained a consistent placement of the turtle's head underwater. Testing took place in a PVC tank (0.84 L × 0.38 H × 0.53 W), and the turtle's ear was approximately 13 cm below the waterline and 45 cm away from an underwater speaker (UW-30; Lubell Labs Inc., OH, USA), which transduced the auditory test tones. A recording electrode (Rochester Electromedical Inc., FL, USA) was inserted 2–3 mm dorsal to the right tympanic membrane, in an anterior-to-caudal direction. The reference electrode was inserted into the subcutaneous tissue to the left or right of the tail and the ground electrode hung in the water. The generation of the stimulus tones and collection of the electrophysiological responses of the turtles to these tones were controlled through custom LabVIEW software (National Instruments, TX, USA). The equipment and general setup for the AEP measurements were similar to that used in previous auditory studies [e.g., Stanley et al. 2020].

Five sequential 400 Hz thresholds were collected during each session for each turtle. Test tone stimulus amplitudes were measured at the beginning and end of each experimental day, and the average of the two measurements was used to determine the

thresholds measured that day. All three individuals were tested on the same day. Each threshold trial started at the same sound level (no attenuation). The stimulus amplitude was then attenuated in 5 dB steps until no response was observed in the response waveform or its fast Fourier transform (FFT) spectrum. The greater the attenuation, the lower the received level by the turtle. An average of 250–500 responses were collected for each attenuation level, depending on how quickly the FFT stabilized. These averaged waveforms were exported from LabVIEW for subsequent threshold determination in MATLAB (v R2019a, MathWorks, MA, USA).

An FFT (1024 points) was calculated of the averaged AEP waveform collected for each attenuation level (e.g., Fig. 2). The FFT has a peak at approximately twice the test frequency (Piniak et al. 2016), and the specific frequency used for the response was dependent on the individual and the parameters of the FFT; in the example in Fig. 2, the peak occurred at 781 Hz. As in other taxa (Pacini et al. 2010; Mooney et al. 2020a; b; Dinh and Radford 2021), this peak decreased with decreasing amplitude of the auditory test stimulus (Fig. 2). These FFTs were used in each of the three threshold analysis methods investigated.

Initially, thresholds were determined using the regression method, as in Mooney et al. (2010). This method regresses the FFT peak by the amplitude of the stimulus that elicited each response (Fig. 3). Points were removed from this regression analysis for three reasons. First, points that represented suprathreshold responses were removed, as these responses often had a wider frequency bandwidth and a more variable amplitude at twice the test frequency. Second, while the first attenuation level that produced no AEP response was included in the regression, any additional

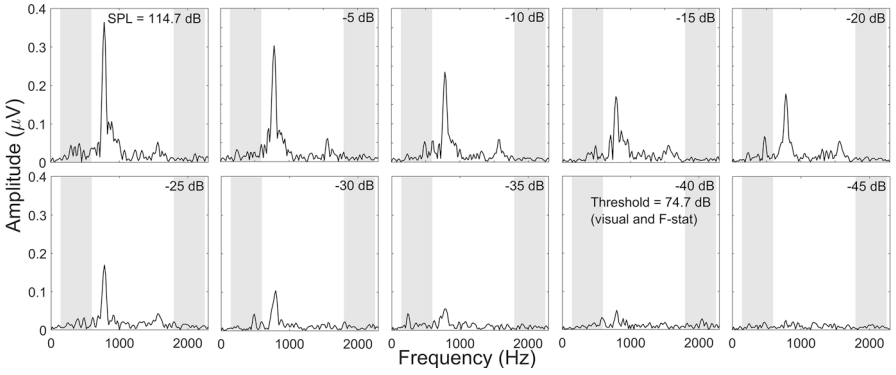

**Fig. 2** Example fast Fourier transforms (FFTs) of auditory evoked potentials (AEPs) collected from *Trachemys scripta elegans* underwater in response to a series of 400 Hz tone pips. The AEPs were measured from RES05 in response to decreasing sound levels. The stimulus was first presented with no attenuation (root-mean-square sound pressure level = 114.7 dB re 1 μPa). The peak of the turtle's auditory response was at 781 Hz, and this response was determined to be indistinguishable at the attenuation level of −40 dB (using visual, regression, and F-statistic methods). The corresponding auditory threshold for these data using the visual and F-statistic method was 74.7 dB re 1 μPa. The frequencies shaded in gray represent those selected to calculate the average background noise for the F-statistic method

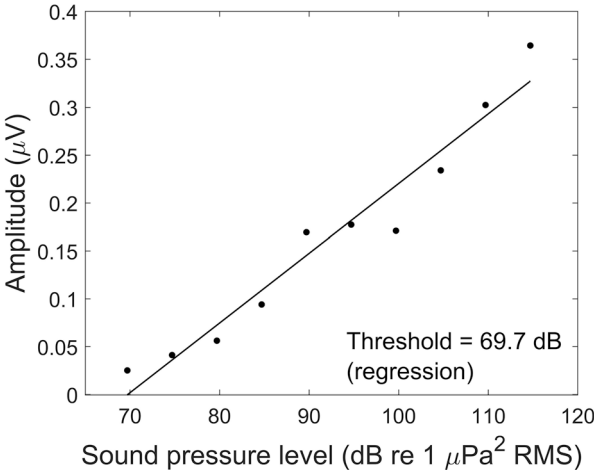

**Fig. 3** Auditory threshold determined using the regression method. Here, the auditory response peaks of RES05 in Fig. 2 are regressed against the sound pressure levels of the test tone stimulus that produced those responses. The auditory threshold using the regression method was 69.7 dB re 1 μPa, which is where the regression line crosses the y-axis at $y = 0$ (theoretical no response)

points representing no response were excluded as these would otherwise artificially lower the threshold estimation. No response was determined if there was no distinguishable peak at twice the test frequency; if there was a small peak at this frequency, it was required to be greater than approximately 0.02 μV, the typical noise floor at surrounding frequencies. This cutoff threshold for distinguishing a peak from electrophysiological and/or environmental noise varied slightly across trials. In the example in Fig. 2, the last response was determined at −40 dB re 1 μPa attenuation. Third, while response amplitudes typically decreased relatively monotonically with stimulus amplitude (as in Fig. 2), there were cases when points deviated significantly from this line (often due to variation in peak frequency) and were excluded. The r-square goal of these regression lines was typically >0.9, with variation by trial and turtle. This regression line was used to determine the auditory threshold: the stimulus amplitude on the x-axis at which the regression line crossed $y = 0$ was considered the theoretical no response and the threshold (Supin et al. 2001). In the example demonstrated in Figs. 2 and 3, the threshold was 69.7 dB re 1 μPa (Fig. 3).

To compare this regression method to alternate threshold determination methods, five control trials were randomly selected for each of the three turtles to reanalyze using visual and F-statistic methods, for a total of 25 thresholds at 400 Hz per individual. The visual method, often used to analyze evoked potential recordings in fishes (Kenyon et al. 1998; Wright et al. 2010; Stanley et al. 2020), involves visually inspecting the waveform and/or FFT peak and determining the minimal sound level at which there is no detectable response. This sound level is taken as the threshold. It is unlike the regression method because it does not directly use a sound level with no detectable response and does not extrapolate below the background physiological and environmental noise level. Thus, in the example in Fig. 2, no response was first seen at −40 dB, and the threshold using the visual method was determined by subtracting 40 dB from the test tone amplitude of 114.7 dB re 1 μPa, resulting in a threshold of 74.7 dB re 1 μPa. In this study, one person analyzed all data for consistency.

The F-statistic method, often applied in odontocetes and humans (Dobie and Wilson 1993; Finneran et al. 2007), is considered to reduce the subjectivity in determining when no responses occur in the FFTs of the AEP waveforms. This method compares the amplitude at the frequency selected in the FFT to represent the response to an average of the electrophysiological noise at frequencies both less and greater than the response frequencies. For example, in Fig. 2, the frequencies used to determine the mean background noise level are shaded in gray. These frequencies were selected because they are outside the widest response bandwidth and could be used consistently across all three individuals. These frequencies also excluded the first harmonic of the response (at approximately 1600 Hz) seen at the higher stimulus sound levels (0 through −25 dB attenuation; Fig. 2). These windows were selected to be equivalent on both sides of the response (30 frequency points) to achieve 60 total points, resulting in degrees of freedom of F(2, 120) (Finneran et al. 2007). These degrees of freedom were used to identify the appropriate critical value using an F-table with alpha = 0.05. The F-statistic was computed by dividing the amplitude of the FFT response by the average noise over the selected bandwidths. An AEP response was determined to be present if this F-statistic was greater than the critical value. In the example in Fig. 2, the F-statistic method was in agreement with the visual and regression methods, as the F-statistic fell below the critical value after the −40 dB attenuation level. Like the visual method, the F-statistic method also determines the threshold by subtracting that first no-response attenuation level from the non-attenuated amplitude of the test tone. Thus, here the visual and F-statistic methods both produced a threshold of 74.7 dB re 1 μPa.

To compare the three threshold determination methods, the mean and range were calculated of the 25 thresholds determined using each method for each individual, in addition to the 75 thresholds combined across individuals. For each threshold, the difference in threshold value between each method combination was also calculated.

The visual method has been commonly used in turtle auditory studies (Bartol et al. 1999; Dow Piniak et al. 2012; Martin et al. 2012; Piniak et al. 2016; Wang et al. 2019). Therefore, the regression-determined *T. scripta elegans* audiogram collected in preparation for the TTS study was also reanalyzed using the visual method. Mean auditory thresholds at 175, 600, 800, and 1000 Hz were determined, in addition to the 400 Hz control data (as above). Two to eight thresholds were collected per frequency (other than 400 Hz) for each turtle. As for the 400 Hz thresholds, the stimulus amplitude was decreased in 5 dB steps to determine thresholds at 175 and 600 Hz, substituting as needed smaller step sizes at 800 and 1000 Hz due to lower sensitivity at these higher frequencies. The presence of a response was also more variable at 1000 Hz.

## Results

Auditory thresholds of the three *T. scripta elegans* individuals depended on the method chosen to analyze the AEP data. At both the individual and species level, data analyzed using the regression method led to lower thresholds compared to the visual and F-statistic methods (Fig. 4, Tables 1 and 2). The F-statistic method

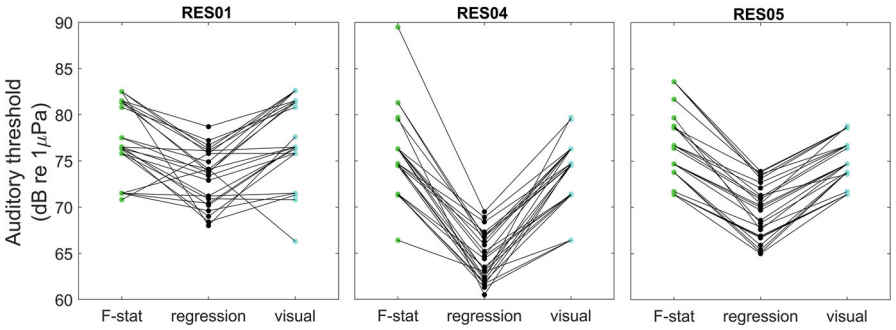

**Fig. 4** Comparison of 400 Hz auditory thresholds calculated using the F-statistic, regression, and visual methods. Seventy-five thresholds measured from three *Trachemys scripta elegans* individuals were calculated using the three different methods; lines connect thresholds determined using the same auditory evoked potential data to show how threshold values change depending on method

**Table 1** Mean (± SD) and range of 400 Hz auditory thresholds analyzed using regression, visual, and F-statistic methods (in dB re 1 μPa)

| Threshold determination method | RES01 (n = 25) | RES04 (n = 25) | RES05 (n = 25) | Individuals combined (n = 75) |
|---|---|---|---|---|

**Table 2** Mean (± SD) and range of differences in 400 Hz auditory thresholds analyzed using regression, visual, and F-statistic methods (in dB re 1 μPa)

| Methods compared | RES01 (n = 25) | RES04 (n = 25) | RES05 (n = 25) | Individuals combined (n = 75) |
|---|---|---|---|---|
| Regression minus visual | −4.0 (3.7)<br>−9.5–7.8 | −9.1 (3.3)<br>−17.4–−3.4 | −5.4 (1.6)<br>−8.7–−2.3 | −6.2 (3.7)<br>−17.4–7.8 |
| Regression minus F-stat | −4.0 (3.8)<br>−14.5–5.0 | −11.1 (3.8)<br>−20–−3.4 | −6.8 (2.5)<br>−12.1–−3.8 | −7.3 (4.5)<br>−20.0–5.0 |
| Visual minus F-stat | 0 (3.5)<br>−10.0–5.0 | −2.0 (3.2)<br>−10.0–5.0 | −1.4 (2.3)<br>−5.0–0 | −1.1 (3.1)<br>−10–5.0 |

produced the highest mean 400 Hz thresholds for RES04, RES05, and across the 3 individuals and was equal to the visual threshold mean for RES01 (Table 1). When directly comparing the methods, the visual and F-statistic thresholds were the most similar, with a mean difference of only 1.1 dB across the 3 turtles (Table 2). There were greater differences when comparing the regression thresholds to visual and F-statistic thresholds, with a mean difference of −6.2 and −7.3 dB re 1 μPa,

respectively. The regression method led to thresholds up to 15–20 dB lower than the same data analyzed using the visual or F-statistic methods (Table 2). Overall, RES04 showed the greatest differences in threshold value when comparing the three analytical methods; RES01 showed the smallest differences (Table 2, Fig. 4). RES01 was the only turtle with thresholds that decreased when using the visual or F-statistic methods when compared to the regression method. Two (of 25) visual thresholds were lower than the regression thresholds (by −0.1 and −7.8 dB re 1 μPa; Fig. 4), and the value of one threshold was equivalent between methods. Two F-statistic thresholds were lower compared to the regression method(−2.6 and −5.0 dB; Fig. 4).

In general, the range and variation were similar between the three analytical methods (Table 1). However, the number of unique values varied depending on the method chosen, considering thresholds rounded to the nearest tenth for all three methods. The regression method provided 20, 23, and 25 unique values (out of 25 per animal) for RES01, RES04, and RES05, respectively. Visual thresholds provided 12, 8, and 9 unique values for RES01, RES04, and RES05, respectively. The F-statistic method generated 10, 10, and 11 unique values for RES01, RES04, and RES05, respectively. The thresholds determined using the visual and F-statistic methods showed a more clustered distribution compared to the more continuous range of regression-determined thresholds (Fig. 4).

Using the regression method, there was also greater individual variation in mean 400 Hz threshold among the three turtles. RES04 was the most sensitive turtle (lowest threshold) and RES01 the least sensitive (highest threshold), regardless of which of the three methods used. Using the regression method, the difference in mean threshold between RES04 and RES05 was 5.1 dB re 1 μPa and the difference between RES05 and RES01 was 3.7 dB. Using the visual method, this difference was 1.4 dB (RES04 and RES05) and 2.3 dB (RES05 and RES01), and using the F-statistic method, this difference was 0.8 dB (RES04 and RES05) and 0.9 dB (RES05 and RES01).

The regression method also produced lower thresholds at the other four frequencies investigated, compared to those calculated using the visual method (Fig. 1, Table 3). Combining individuals, the mean of the 75-threshold subset for 400 Hz is shown in Fig. 1 and Table 3 to compare to these same data analyzed using the visual method; the 400 Hz threshold using the mean of all data collected (n = 264) was 70.3 dB re 1 μPa (SD = 5.6). The mean difference between the visual and regression methods across the five frequencies was 6.1 (SD = 1.4) dB re 1 μPa.

**Table 3** Mean (± SD) auditory thresholds analyzed using regression and visual methods, individuals combined (in dB re 1 μPa)

| Frequency (Hz) | Regression | Visual |
|---|---|---|
| 175 | 75.6 (3.4) | 81.6 (4.3) |
| 400 | 69.1 (4.6) | 75.3 (3.9) |
| 600 | 73.9 (8.5) | 79.6 (8.3) |
| 800 | 88.8 (7.2) | 97.0 (6.2) |
| 1000 | 101.7 (4.5) | 106.0 (2.2) |

## Discussion

This study shows that the determination of auditory thresholds collected from *T. scripta elegans* can be dependent on the method chosen to analyze the AEP data. In reality, all threshold determination methods require some degree of data interpolation and assumptions. However, considering how the predicted thresholds vary among the three methods can enable a better comparison between studies that use different analytical approaches. The potential advantages and disadvantages of these methods are also considered.

Auditory evoked potential data collected from three turtles was first analyzed using the regression method, and the visual and F-statistic methods were selected to compare to the original thresholds. These three methods each start with an FFT (itself dependent on selected parameters) of the animal's response waveform and consider at which received sound level this response is no longer distinguishable from the background electrophysiological and environmental noise (e.g., electromagnetic interference or EMI). The F-statistic method addresses this question by dividing the average amplitude at frequencies surrounding the response frequencies to the response amplitude and compares the quotient to a critical value (Finneran et al. 2007). The visual method instead makes this determination by eye and by using a cutoff threshold to help determine when a response peak is indistinguishable from the noise. For example, Piniak et al. (2016) used a 6 dB cutoff. Here, a similar approach to determine no responses for the regression method was employed by using a 0.02 μV response threshold, which varied slightly by session depending on the noise floor. The regression method uses the regression model to quantitatively assess how the response amplitude changes with received level and estimates the threshold from that model, which naturally falls below the measurement noise floor. A better model fit can instill higher confidence in the threshold estimate. An advantage of the F-statistic method is that it inherently integrates electrophysiological noise level and can be the most automated of the three methods; however, by the same turn, it also sacrifices the opportunity for the human eye to distinguish an auditory response in an FFT. Human pattern recognition can be excellent and is often used in other bioacoustic methods such as whistle discrimination [e.g., Silva et al. 2016]. Elevated background noise, contributed across the selected noise bandwidths or from isolated peaks (e.g., from EMI), does not always negate a real auditory signal, especially if that response peak matches, in frequency and shape, the responses observed at higher received levels. Indeed, there were instances when the F-statistic fell below the critical value despite the presence of what was considered a response peak using the regression and visual methods. This may have contributed to higher 400 Hz thresholds when using the F-statistic method (considering the mean and individual results for RES04 and RES05; Table 1).

The regression and F-statistic methods require selecting a response frequency to regress the amplitude at that frequency by sound level or to calculate the F-statistic, respectively. While this peak was often consistent through attenuation levels [at approximately twice the test frequency (Piniak et al. 2016)], there were cases where this peak varied, such as in suprathreshold or bimodal responses. When using

the F-statistic, one might predict the greatest quotient to occur at the highest stimulus sound levels, but this did not always occur. Suprathreshold responses resulted in energy distributed across a greater response bandwidth and a lower amplitude at the chosen response frequency, compared to response amplitudes at lower received sound levels. In these cases, determining a response using only the criterion of an F-statistic greater than the critical value could lead to falsely determining no response at the highest stimulus sound levels. This issue could be addressed by visually confirming the response measurements, as was done here. In the regression method, these suprathreshold responses were typically removed from the regression.

The frequency that provided the most consistent peak throughout the attenuation levels was selected for the regression method, and this was straightforward in most cases. However, in the case of RES01, the response peak was often bifurcated between two frequencies, and the best frequency for the regression (as determined by the $r^2$ value and maximizing number of points used) was not always the frequency where the last distinguishable response was seen. In contrast, the F-statistic and visual methods allow more flexibility in the frequency selected to determine a response, and this led to the only four instances, all using data collected from RES01, where the regression method produced a higher threshold compared to the other two methods (Fig. 4 and Table 2). This also likely contributed to the smallest threshold differences occurring in RES01 when comparing thresholds calculated using the regression method to the F-statistic and visual methods (Table 2).

The visual and F-statistic methods produced very similar 400 Hz thresholds (Fig. 4 and Table 2), similar to that observed in grey seals [*Halichoerus grypus* (Ruser et al. 2014)], while the regression method produced the lowest thresholds (Table 1). In studies comparing regression to F-statistic [*Delphinapterus leucas* (Mooney et al. 2020a)] and visual methods [*Loligo pealeii* (Mooney et al. 2010)] across several frequencies, there was overall a high correspondence between the methods compared, but this outcome varied by frequency. These comparisons (regression and F-statistic, regression and visual) showed nearly identical thresholds at some frequencies, but thresholds at other frequencies showed differences similar to those observed here (6–7 dB). Counter to Mooney et al. (2010), visual thresholds were observed to be consistently higher than regression thresholds across all frequencies tested (Fig. 1).

Visual thresholds are often determined using the sound level of the last detectable response (Kenyon et al. 1998). F-statistic methods may involve a certain number of reversals, essentially averaging sound levels producing last detectable responses and no responses [e.g., Finneran et al. 2007], which are also used in some behavioral threshold studies (Kastelein et al. 2009; Finneran and Schlundt 2010). However, given that detection methods may be somewhat masked by noise, it is likely that the threshold is lower than the predictions of the visual and F-statistic methods. The regression method assumes neuronal responses that may be below the noise floor and are not observable given the methodology employed. This method addresses this uncertainty by interpolating a theoretical no response by using in the regression the first attenuation level (i.e., highest received level) at which no response was detected. This explains why the regression method predicted lower thresholds than the other

two methods, which may allow this electrophysiological method to more closely reflect findings of lower thresholds in behavioral studies where both detection and perception are integrated (Popper and Hawkins 2021).

Interestingly, greater individual variation was observed in the mean 400 Hz thresholds using the regression method compared to the visual or F-statistic methods. This finding may be partially driven by the limited number of values a threshold can take when using the visual and F-statistic methods. Test tone levels were attenuated in 5 dB increments, which define the potential threshold values, whereas the regression method interpolates between these increments. Non-biological variation across methods is introduced by the dB increments of attenuation and calibration precision, yet the regression method may allow for more biological variation to be observed. If the final detectable response is fairly strong or marginal, the visual and F-statistic methods calculate the same threshold. The regression method, however, would interpolate the theoretical no response of the points in those two cases differently, leading to different thresholds. Further, since the regression method determines thresholds using response data from several received levels versus just the lowest level that produced a response, this method may allow for a better understanding of auditory responses. However, the regression method requires a sufficient number of points for the model. This inherently requires testing a series of received levels, and potentially more than may be necessary to obtain a threshold using the visual method. This additional testing may be prohibitive under some conditions (e.g., limited sedation time, testing in the field) if it requires more time to determine a threshold.

Compared to the visual method, the regression method produced lower thresholds and a more sensitive audiogram across all tested frequencies (Fig. 1, Table 3). The mean visual thresholds were within the 1 SD error bars for the 600 and 1000 Hz regression thresholds. Further, the error bars for both methods overlapped for all test frequencies reflecting a general correspondence. Importantly, the shape of the audiogram (relative sensitivity across frequencies) was consistent using either method. Despite this general similarity, the visual method consistently produced thresholds 4–8 dB re 1 μPa greater than the regression method across these five test frequencies for *T. scripta elegans*. This knowledge may be valuable as we seek to understand thresholds measured across turtle species, particularly endangered or threatened species. Such information would help managers better compare the auditory sensitivity and TTS results in these freshwater turtles to other species for which visually determined thresholds are available.

**Abstract**

Human divers can be exposed to high-energy underwater noise sources as part of their jobs. Establishing safety guidance for noise exposure is critical to protect divers from injury. However, in-air guidance cannot be used because humans detect sound underwater using a different pathway (bone conduction) than the traditional air-conducted pathway. To date, the body of literature on what humans can hear and how we respond to noise exposure underwater is limited, although interest in the topic is growing. This chapter will provide a thorough review of the existing underwater hearing experiments and evaluate which studies have collected quality hearing threshold data that can be used to establish what humans

## Introduction

Underwater noise has long been a concern for aquatic animals (Popper and Hawkins 2016). For over a century, researchers have studied the effect of sound on the behavior and physiology of marine animals, primarily mammals and fishes. Much less emphasis has been placed on the potential impact of underwater noise on humans, specifically human divers (Casper and Babina 2022). Recreational divers are not usually at risk of being exposed to high-energy noise sources, but military and commercial divers often operate in noisy environments as part of their regular duties. Examples of high-energy noise sources include underwater construction tools, large vessel traffic, sonar, and explosives. This population of divers is at risk of potential hearing damage, as well as other non-auditory injuries. Establishing safe exposure guidance for divers operating around active acoustic sources is critical to protect them from harm while also allowing them to complete their jobs.

A major challenge to developing effective underwater noise guidance is that, when submerged, evidence indicates that humans do not hear through the traditional air-conducted pathway. Instead, humans hear through the mechanism of bone conduction. For a detailed description of this alternate underwater sound pathway, please refer to Casper and Babina (2022). In short, there is experimental evidence that humans detect sound underwater that is delivered directly to the inner ear through bone conduction via the skull, bypassing the outer and middle ear. The research that supports this phenomenon will be discussed in further detail in the "Underwater Hearing Threshold Studies" section of this chapter. The challenge, however, is that most of what we know about noise safety guidance comes from in-air sound studies, and this in-air safety guidance cannot be used for underwater noise exposure. Therefore, researchers must determine what humans can hear underwater and what sound pressure levels will lead to injury, whether in the form of a hearing threshold shift or other non-auditory injury.

The goal of this chapter is to review the existing literature to illustrate the wide variations in results of hearing thresholds measured in humans. Additionally, the scant information available on human response to underwater noise exposure, including behavioral and physiological responses, will be discussed to emphasize the challenges associated with developing safety guidance to underwater noise exposure.

## Literature Review Approach

A review of the literature was conducted using PubMed, Google Scholar, and Defense Technical Information Center (DTIC) to identify articles related to underwater human hearing and noise exposure studies published between 1900 and 2022. Articles, conference proceedings, book chapters, and technical reports were only used if they were either publicly available through a journal website or, in the case of technical reports, downloadable through DTIC. Search terms included "human underwater hearing," "underwater noise," "diving noise," "underwater tool noise," "noise exposure," "human hearing thresholds," "hearing threshold shift," "diver hearing," and "diver noise exposure." Conference abstracts were not included. It should be noted that the author is aware of several additional international reports that exist but are not available for public distribution and were therefore not included in this chapter.

This underwater hearing literature review is organized in chronological order by decade, to show the reader how the exploratory research in this field has been inconsistent, with the bulk of efforts occurring between the late 1960s and mid-1980s.

## Underwater Hearing Threshold Studies

### Pre-1960s Experiments

The first documented experiment of underwater hearing in humans was the seminal work performed by Stetter (1929). The goal of the study was to compare hearing sensitivity at a single frequency between humans and minnows (*Phoxinus laevis* L.). A research subject was placed in a transparent water-filled box. The experimenter would walk up and down a hallway blowing a whistle at 662 Hz. The subject would signal to another experimenter if they could hear the stimulus while submerged. There was no calibration of the signal level, so Stetter was only able to conclude that minnows were more sensitive to the 662 Hz signal than humans. Even this basic conclusion should be made with caution as the small, enclosed testing environment would have been subjected to numerous surface reflections. Regardless of the limitations, this study established that humans are capable of hearing tones underwater.

Ide (1944) of the US Naval Research Laboratory performed underwater threshold measurements on several divers. This document was not available for this review, so any assessment made is based on critiques from Smith (1969). Smith's assessment (p. 4) was "Ide failed to report many important methodological details." No information is given on how the sound pressure level (SPL) at the diver's head was estimated and controlled or on the specifics of the test procedure. Underwater ambient noise levels were not reported. Air-conducted hearing levels of subjects were also not reported. Smith reported that the tests were conducted at depths of 0.9 to 1.8 m in water that was 10.7 to 12.2 m deep. Furthermore, Smith reported

"audiometer-type tests" were used, and the subjects were three men listening underwater with "the unaided ear." Measurements were collected from 100 to 6000 Hz. Overall, threshold results (using "audiometer-type tests") below 1000 Hz were higher than any other study reported in this chapter, raising questions about ambient noise levels during testing. With so many unknowns, the author agrees with Smith (1969) that it is not appropriate to include this data in the "Analysis" section of this chapter.

Sivian (1947) reported on an earlier study in which subjects were tested in a swimming pool. Initially, their ears were just above the water to collect in-air hearing thresholds at 1000 and 3000 Hz. The method of obtaining thresholds was not reported in this study. The subjects were then submerged either 22.8 or 38.1 cm, and thresholds were collected from the same airborne source. The subjects were found to have a 44–55 dB decrement in sensitivity from underwater to in air. No measurements of the sound levels were made. The measurements in air are suspect due to the uncontrolled environment and suspected high levels of ambient noise (Smith 1969). Sivian, however, was the first to suggest that human underwater sound detection could be through bone conduction.

Reysenbach de Haan (1956) was the first to attempt to measure signal level underwater. In an 18-m-deep pool, subjects (number not reported) were positioned 25 m away from the sound source with their heads "just below" the surface. Thresholds were measured between 1000 and 16,000 Hz. The signal level was lowered until the subjects reported that they could no longer detect the sound. Sound pressure level was not measured at the subjects' heads; rather, it was calculated based on measurements from a different location in the test pool. Additionally, ambient noise was not measured (or reported). The depth of the subjects could also have affected the results. With their heads just below the surface, sound transmission due to reflections could interfere with the results. An interesting variable that was explored was the difference in thresholds obtained if the diver had air trapped in the ear canal. How the air was removed was not documented, but thresholds were found to be lower at most frequencies. It should be noted that this finding was not observed in more recent studies. Reysenbach de Haan also promoted the theory of bone-conducted hearing underwater.

Hamilton (1957) was the first scientist to measure sound pressure levels at the location of the divers' heads as well as the ambient noise of the environment. Two subjects using scuba would sit on either end of a support beam with a hydrophone placed between them at the level of their heads. The divers were submerged 4 m below the surface of a 9.1-m-deep lake. During signal transmission, divers would hold their breath to reduce breathing and bubble noise. This was also the first study to test in-air and underwater hearing using the same subjects, a trend that would continue moving forward with most studies. Tones between 250 and 4000 Hz were tested in both environments. To establish thresholds, the sound levels were decreased by 1 dB steps until the subjects could not hear a signal and then increased until the subjects could reliably hear again. This was repeated 20 times at each frequency resulting in a thorough, rigorous data set.

To further test the bone conduction theory, Hamilton (1957) had the divers plug their ears with their fingers, with subjects reporting that they did not perceive a difference in loudness of the signal. In addition, the underwater hearing thresholds compared to air-conducted thresholds were offset by about 40 dB, which matched the difference between air-conducted and bone-conducted thresholds reported in the literature at that time.

The only concerns raised by this study were the potential influence of the second diver in proximity to the first. It was possible that the presence of another diver could disrupt the sound field. However, Hamilton (1957) reported seeing no difference in signals from the hydrophone whether there were one, two, or no divers. The other concern is that one diver could be influenced by the behavioral responses of the other diver. Regardless of these concerns, this study was well designed and controlled, providing confidence in the results.

Wainwright (1958) obtained underwater hearing thresholds in two subjects using the method of limits at a depth of 3 m in a 15.2-m-deep lake. Thresholds were obtained between 125 and 4000 Hz. The transducer was calibrated prior to testing, but there was no mention of measuring the received level at the divers' heads or measurements of ambient noise (though this facility is known for its quiet environment, as the author has also used it for testing). Additionally, Wainwright measured in-air thresholds in both subjects. Results from this study suggest higher hearing thresholds than many other studies conducted around this time period (e.g., 15–30 dB higher than Hamilton (1957)). Smith (1969) suggested these subjects may have had some hearing impairments, and therefore these results would not be generalizable to the overall human population.

One method that Wainwright (1958) employed was to have the subjects plug their ears with their fingers. The subjects reported no change in perceived loudness, consistent with Hamilton's (1957) testing. The subjects used a closed-system (rebreather) scuba system to minimize the noise from air bubbles released during breathing. Wainwright made claims that the sound made from the rebreather system is below the threshold of human hearing, but it is unclear if the measurement of these sounds was done in air or underwater or how they were conducted.

A summary of the above pre-1960s studies reveals numerous approaches to measuring underwater hearing in humans. These studies established that humans are able to hear sounds underwater, with the likely pathway occurring via bone conduction rather than the traditional air-conducted pathway through the outer and middle ears. In general, most studies had unreliable methods, whether it was a lack of underwater measurements or subjects with questionable in-air hearing thresholds. With so many discrepancies, it appears that Hamilton's (1957) underwater threshold study is the only reliable study that can be carried forward for additional analysis.

## 1960s Experiments

Montague and Strickland (1961) tested seven subjects using similar methodologies to Hamilton (1957) and Wainwright (1958), except for using the von Békésy

procedure for measuring hearing thresholds. Divers were equipped with open-stage scuba gear. The thresholds were established between 250 and 6000 Hz. Four of the divers had normal in-air hearing, and three divers showed signs of high-frequency hearing loss. Overall, the underwater thresholds showed high variability between the subjects at most frequencies. The sound transducer was calibrated prior to testing, but no measurements were made at the divers' head or of the ambient noise. With these variables missing, it leaves many questions about the validity of the data.

Of interest, the researchers also had the divers wear neoprene hoods of differing thickness. All divers wore a 3/16″ hood, and some tried other thicknesses. In general, it appeared that the hood resulted in a 20 dB attenuation of frequencies at 1000 Hz and greater. There was no difference in thresholds at frequencies below 1000 Hz. When divers were asked to pull the hood back from their foreheads and ears, the hearing was restored.

Brandt and Hollien (1967) presented the first of a series of underwater hearing tests that were conducted by the University of Florida Communication Sciences Laboratory. Most of the studies were conducted at the Bugg Spring Test Facility in Florida in a 53.3-m-deep spring that was known for its quiet environment. The experimenters built an elaborate setup such that the divers would always be at a known location from the transducers and the signals received by the subjects could be easily measured and calibrated. Eight subjects (male and female) had their thresholds measured between 125 and 8000 Hz using the von Békésy procedure. The divers used open-circuit scuba equipment and held their breaths during acoustic signal transmission to reduce the bubble noise. Testing was done at two depths (3.7 m and 10.7 m) with minimal differences in thresholds between the two depths or between males and females at most frequencies.

Given the care taken with data collection, the underwater thresholds from this study are considered to be accurate and representative of human underwater hearing. There was a trend of reduced hearing at higher frequencies based on air-conducted thresholds; however, it is unclear if this is due to hearing loss or the noise levels in the environment where the air-conducted thresholds were obtained.

Two additional studies were conducted by the team during this decade. One examined the effects of air trapped in the outer auditory canal on underwater hearing thresholds (Hollien and Brandt 1969), and the other explored the effect of depth on thresholds (Brandt and Hollien 1969). In the first study (Hollien and Brandt 1969), subjects wore specialized ear plugs as they descended to the test depth. Once pressure was equalized, they would remove the ear plugs, and the test was administered. This method resulted in testing with the air trapped in the ear canals. These subjects were also tested with their ears irrigated with water to remove any trapped air bubbles. In both cases, the divers had similar hearing thresholds, further implying that the traditional air-conducted pathway of hearing is not the primary path of underwater hearing detection.

In the second study (Brandt and Hollien 1969), divers were tested at 21.3 and 32 m to further explore if depth had any effect on underwater hearing thresholds. There were minimal observed differences in hearing at these depths and with those previously tested (Brandt and Hollien 1967).

Smith (1969) measured underwater hearing thresholds in 16 male divers in a 22.9-m-deep quarry with the subjects 4.6 m below the surface. A reference hydrophone was used to measure the sound field at the divers' heads. Unique to this study, air conduction and bone conduction thresholds were measured (using standard audiometric methods) to compare to the underwater thresholds from 1000 to 8000 Hz. Smith provided the most compelling evidence for underwater hearing via bone conduction by finding that divers with suppressed air-conducted thresholds did not show suppressed underwater hearing thresholds. Only divers with suppressed bone-conducted thresholds had suppressed underwater thresholds.

In this same study, eight of the subjects had hearing thresholds measured with and without neoprene hoods. Results showed reduced sensitivity when wearing the hoods, consistent with Montague and Strickland (1961). Smith followed this study with another in a deeper environment, looking at the protective effects of hoods with depths. There was no observed difference in attenuation between hoods at 10.1 and 30.2 m, suggesting that the hoods provide equal protection at least to 30.2 m. There is an expectation that at some "crush" depth, the air trapped in neoprene will be reduced enough to minimize the sound reduction capabilities.

Smith (1969) conducted one further study to look at underwater threshold variability within subjects. He ran eight subjects three to four times, with at least 24 h separating each test. He concluded that intra-subject variability was within the range that is normally observed in air-conducted hearing testing, though his results did show higher variability with increasing frequency.

Underwater hearing testing in the 1960s provided a wealth of data that were collected in quiet, controlled testing environments with proper characterization of the sound fields. Specifically, the tests conducted by Brandt and Hollien (1967) and Smith (1969) qualify as data sets that can be carried forward for further analysis. Brandt and Hollien (1967) recognized the importance of testing in a low ambient noise environment, specifically choosing their location based on this variable. They also constructed an apparatus that would give them precise knowledge of the divers' heads and the ability to calibrate their sound measurements. Smith (1969) followed this same path while also recognizing the value of measuring subjects' bone-conducted thresholds to provide additional evidence that underwater hearing is via bone conduction.

## 1970s Experiments

Norman (1971) measured underwater hearing in three divers at three different frequencies, 250, 1000, and 2000 Hz, using the up-down parameter estimation by sequential testing method. Thresholds were measured using four different conditions: bareheaded, fully hooded, bareheaded with neoprene patches covering the ears, and hooded with holes cut so that the ears were fully exposed. As in previous studies, Norman found that hearing thresholds at 1000 and 2000 Hz were increased in all cases where the skull was covered (hood) or mostly covered (hood with ear

holes). The hood provided minimal attenuation at 250 Hz. The neoprene patches that only covered the ears had no impact on hearing thresholds.

Unfortunately, Norman (1971) did not report any of the thresholds measured; rather, he described changes in thresholds relative to the bareheaded condition. In addition, the study was conducted in a 2.6-m-deep swimming pool with sounds produced by an in-air speaker that was floating in a plexiglass box. There was no mention of how sound levels were calibrated.

Hollien and Feinstein (1975) conducted a study similar to Norman (1971), except that they used a hood that had ear tubes that extended into the outer ear canal. The study was conducted at the same Bugg Spring Test Facility as their previous work (Brandt and Hollien 1967). Seven subjects were tested from 250 Hz to 8000 Hz in the bareheaded, hooded, and ear-tube conditions at a depth of 9.1 m. They observed no difference in thresholds between hooded and hood with tubes, suggesting that the air-conducted pathway does not play a role in underwater hearing. However, at frequencies above 500 Hz, there were significantly lower hearing thresholds in the bareheaded condition when compared with either hooded condition, indicating that neoprene hoods attenuate sound only at higher frequencies. When comparing measured thresholds between this study and the previous one (Brandt and Hollien 1967), the latter study yielded lower average thresholds and will be used as the representative data from this research team.

The 1970s were largely devoid of underwater hearing threshold studies, although these two experiments are worthy of mention (Norman et al. 1971; Hollien and Feinstein 1975). Both continue to further the notion that underwater hearing is accomplished through bone conduction. The data from these studies will not be carried over for final analysis.

## 1990s Experiments

There were no hearing threshold studies conducted during the 1980s. Al-Masri et al. (1993) initiated a series of UK studies that would set new standards in terms of the number of subjects tested and optimal testing environments. Al-Masri et al. (1993) measured the underwater free field of hearing (also known as minimum audible field [MAF]) in 54 normal-hearing sport divers. The testing was conducted in an acoustically isolated steel box resulting in an ambient noise average of 44 dB re 1 μPA across most frequencies. While the depth of the tank was only 1.5 m, the sound field around the subjects was calibrated. Subjects held their breath during testing. The sounds tested were 1/3 band octave noise frequencies between 250 Hz and 8000 Hz, resulting in lower underwater hearing thresholds (20–35 dB) at most frequencies compared to any other human studies up to this point. Only the average thresholds were reported, however, and the authors do not provide error bars or raw data. In-air hearing thresholds were also collected.

Parvin and Nedwell (1995) conducted a similar test with 21 subjects. They used a slightly larger acoustically isolated steel box that was 2 m deep, but still had significantly reduced ambient noise levels, though not quite as low as Al-Masri

et al. (1993). Parvin and Nedwell used a combination of two underwater speakers to collect 1/3 band octave noise thresholds between 25 Hz and 16,000 Hz (von Békésy procedure), representing the widest range of frequencies tested by any underwater study. They also made comprehensive calibration measurements to ensure the accuracy of the sound field around the divers.

While the thresholds were not as low as Al-Masri et al. (1993), Parvin and Nedwell's data were still lower than most previous studies, and their expansion at the low- and high-frequency ends represents the most comprehensive measurements to date. Their data also includes error bars to illustrate the variability between subjects.

These two 1990s studies resulted in the largest data sets and lowest measured hearing thresholds of any underwater experiment. They also worked in optimal testing environments with very low ambient noise levels compared to previous studies as well as careful calibration of the sound fields. Both of these data sets will be carried on for final analysis.

## 2000–Present Experiments

Fothergill et al. (2004) sought to narrow down the exact frequency in which neoprene hoods begin to effectively reduce measured hearing thresholds in humans. The researchers measured the underwater hearing thresholds of 20 subjects from 100 to 500 Hz with and without 3 mm hoods using a two-interval forced-choice adaptive tracking method. This study was conducted in an 11.6-m-deep Navy test pool known for its low ambient noise. Divers were 1 m below the surface in an acoustically transparent, temperature-controlled tank. The sound field was carefully calibrated. Thresholds were identical with and without hoods at frequencies below 400 Hz. There was a significant difference (around 8–10 dB) between thresholds at 400 and 500 Hz. This study established the point at which the presence of a neoprene hood starts to affect underwater hearing in divers.

Fothergill et al. (2018) further explored the attenuation properties of neoprene hoods by testing diver hearing at numerous depths. Thirteen divers wore a 7-mm-thick neoprene hood while having their hearing thresholds measured between 100 and 12,000 Hz using a modified von Békésy procedure. Depth conditions ranged from 1.2 to 40.2 m, with all depths achieved by having the diver submerged in a water-filled container within a hyperbaric chamber. Data were reported as the amount of hood attenuation relative to bareheaded thresholds which were not specifically reported but were collected at each simulated depth. At 500 Hz and greater, there was a general pattern of reduction of attenuation with increased depth, with differences of 4–25 dB between the 1.2 m depth and the 40.2 m depth, depending on the frequency.

Sørensen et al. (2022) investigated other possible underwater hearing mechanisms in humans. They measured in-air and underwater thresholds between 125 and 12,000 Hz in seven subjects using the method of limits approach. In addition to the traditional metric of sound pressure, they also collected particle motion thresholds.

Sørensen et al. were also careful to test in an environment with low ambient noise. Overall, their sound pressure level thresholds were similar to many of the previous studies with the exception of 125 and 250 Hz which were the highest of any reviewed in this chapter. No explanation was given for these higher thresholds, as the ambient noise levels at these low frequencies were well below the human responses.

Sørensen et al. hypothesize that at frequencies below 1000 Hz, skull motion would be moving in unison with the particle motion of the water due to both having the same impedance, thereby removing the possibility of bone conduction at lower frequencies. They offer an alternative hypothesis relating to the resonance (around 600 Hz) of the air cavity in the middle ear which might explain humans' underwater hearing sensitivity being greatest around 500 Hz.

These first two of these 2000s studies provide valuable information on the attenuation properties of neoprene hoods which is critical for detection as well as protection from underwater sound sources. The hearing thresholds of Fothergill et al. (2004) and Sørensen et al. (2022) were measured in a well-controlled environment, and the quality of the data is high and will be carried on for final analysis.

## Analysis

We are including six underwater hearing threshold studies from the literature review for analysis (Hamilton 1957; Brandt and Hollien 1967; Smith 1969; Al-Masri et al. 1993; Parvin and Nedwell 1995; Fothergill et al. 2004). These experiments paired underwater hearing thresholds with in-air thresholds from the same subjects, and the researchers carefully measured the sound field that the divers were exposed to with precise, calibrated techniques. They also strived to conduct the experiments in relatively quiet, controlled environments to reduce the risk of signals being masked by ambient noise.

As seen in Fig. 1, the six experiments report different results, with as high as 45 dB separating hearing sensitivity at 500 Hz. As most studies did not report the raw data for individual subjects, or standard deviations, we can only make assumptions about how much overlap might exist between experiments. Regardless, there is significant variability between underwater thresholds obtained from the different experiments. Given that the UK studies (Al-Masri et al. 1993; Parvin and Nedwell 1995) were conducted in underwater anechoic and vibration-isolated environments and have the lowest thresholds at most frequencies, these tests are considered to be the gold standard of underwater hearing.

Another conclusion that can be drawn from these studies is that humans' most sensitive hearing range while underwater is from 400 to 1000 Hz. This represents a shift toward lower-frequency sensitivity when compared to in-air hearing, which is usually centered around 3000–4000 Hz.

When comparing human underwater hearing thresholds to other aquatic animals (Fig. 2), humans seem to fall in the relative middle. Humans are more sensitive than

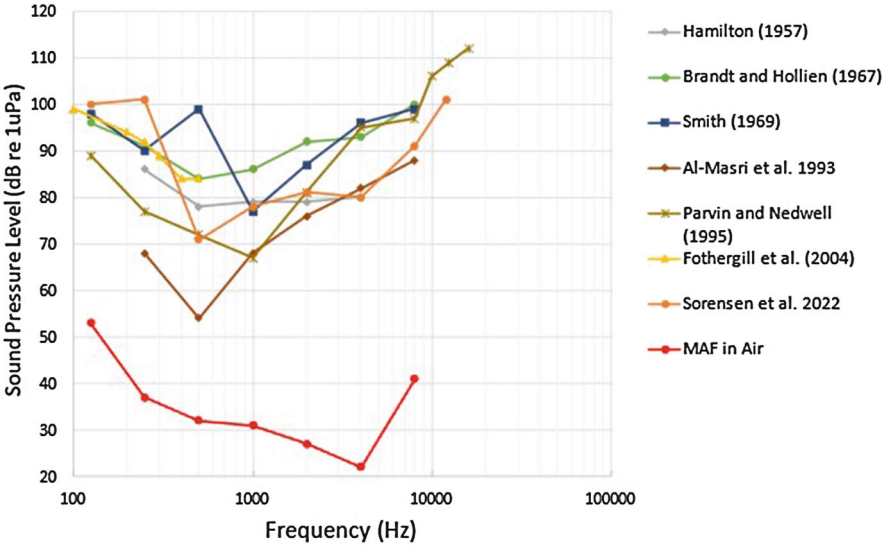

**Fig. 1** Human underwater hearing thresholds. These six studies were chosen based on methodological approaches that included calibration of the acoustic signals, quiet testing environments, and the collection of in-air hearing thresholds in addition to underwater thresholds. For comparison, MAF in air data is shown. (From Al-Masri et al. 1993)

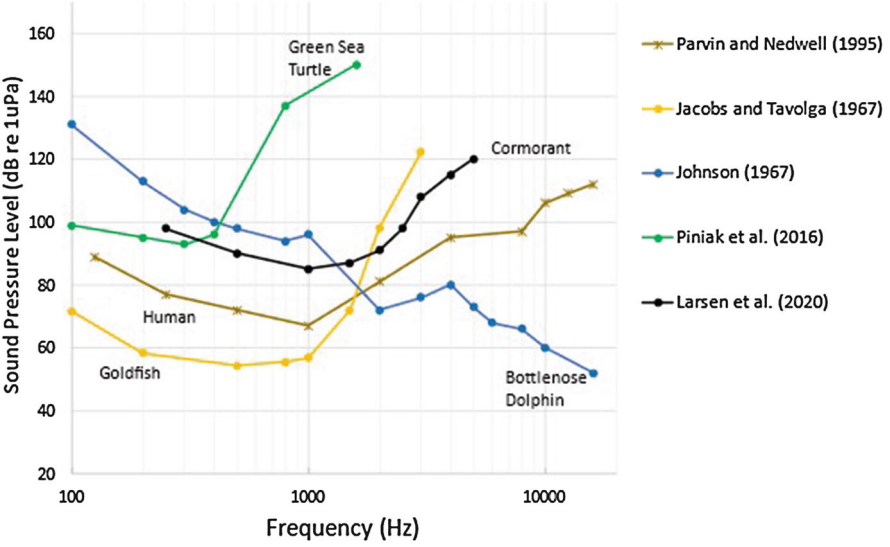

**Fig. 2** Human underwater hearing thresholds compared with aquatic animals

turtles (Piniak et al. 2016) and cormorants (Larsen et al. 2020). They are also more sensitive at lower frequencies than dolphins (Johnson 1967), but this is unsurprising, given that dolphins produce high-frequency whistles and echolocation clicks. Dolphins have more sensitive hearing at all frequencies of 2000 Hz and greater. In contrast, goldfish (Jacobs and Tavolga 1967), known for their low-frequency sensitivities, are more sensitive than humans until around 2000 Hz, after which humans are more sensitive.

## Underwater Noise Exposure Studies

Providing safety guidance to protect people from noise-induced injury is a large, diverse field of study. There is a wealth of data sets that have been used to set in-air hearing standards. However, as previously mentioned, the pathway for sound transmission to the inner ear underwater is different than in air (Casper and Babina 2022), meaning that in-air standards do not apply to underwater noise exposure. Developing safety guidance for underwater noise exposure is an ongoing effort that has been hindered by the lack of data for noise-induced injury, as reviewed in this section.

Montague and Strickland (1961) tested a hypothesis that if underwater thresholds are 40–70 dB higher underwater than in air, then the most tolerable loudness level for a given frequency underwater should be 40–70 dB higher than it would be in air as well. To test this, they exposed 17 divers to 1500 Hz, 1 s tones in an open water trial at a depth of 7.6 m. The researchers increased the sound pressure level in 1 dB steps until the divers deemed the sound level too unpleasant to continue. The tolerance level for these divers was set at 200 dB re 1 μPa. In the same study, while wearing hoods, divers were able to exceed the maximum output of 206 dB re 1 μPa without stopping the experiment. All divers reported a "rotational movement of the visual field" when exposed while unhooded beginning at 191 dB re 1 μPa that became more noticeable as the sound pressure level was increased. One diver also reported dizziness. Post-dive audiograms revealed no significant shifts in hearing thresholds.

Smith (1965) exposed two hooded divers to 1900 Hz, 700 ms signals with a 5% duty cycle at 195 dB re 1 μPa for 30 min at a depth of 5.2 m. Both divers reported that the signal was quite loud, but post-exposure audiograms revealed no threshold shifts at any frequencies.

Smith et al. (1970) built on what Montague and Strickland (1961) investigated by testing whether underwater signals that induced a temporary threshold shift (TTS) were 40–70 dB higher than those that produced an equivalent TTS in air. Six unhooded divers were exposed to a 3500 Hz signal that was 1250 ms in length every 2.5 s for a total of 15 min at 194–204 dB re 1 μPa. Five different subjects were exposed in air to 164–179 dB re 20 μPa. A TTS of 10–22 dB was observed in the divers. The difference between in-air and underwater levels for inducing equivalent TTS was approximately 68 dB, which is within the difference of in-air and underwater hearing thresholds. In addition, one diver reported a visual distortion sensation similar to what Montague and Strickland (1961) reported.

Molvaer and Gjestland (1981) measured the noise levels of underwater pneumatic rock drills and water lances as perceived by divers wearing fully enclosed dive helmets. Three divers were tested, the first two wearing a different type of helmet and the third a 5 mm neoprene hood. Their hearing was measured during a control period and pre- and post-exposure to one of the tools. There were notable threshold shifts in both helmeted divers, with shifts as high as 30–40 dB at 5 and 8 kHz. Threshold shifts in the hooded diver were less prominent, averaging 10 dB or less.

The water lance had the highest sound levels outside of the helmets at 170 dB re 1 μPa. The two helmeted divers had a microphone inside their helmets to measure the internal noise levels produced by the tools. Sounds were attenuated between 30 and 50 dB depending on frequency relative to in-water measurements. There was a general trend of increasing attenuation of the signal (as it passed through the helmet) as the frequency increased.

Smith and Wojtowicz (1985) exposed four bareheaded divers for 25 min to tones at 700, 1400, and 5600 Hz, at sound levels between 169 and 191 dB re 1 μPa. The authors suggested that this would be similar to frequency ranges and durations that divers might be exposed to with underwater tools. TTS measured at 2 min post-exposure were between 23 and 55 dB. Recovery time for these shifts lasted from 24 to over 50 h until divers returned to baseline hearing thresholds. With such high levels of TTS, the authors were not able to make a comparison between underwater and in-air sounds that would yield the same levels of TTS. Non-auditory effects that were reported included the sensation of head vibration, a tickling sensation in the middle ear, ringing in the ears, and pain and blood in ears.

Smith et al. (1988) expanded on Smith and Wojtowicz (1985) by running the same experiment but with lower sound pressure levels to determine what levels would reliably induce noticeable TTS. Again, four bareheaded divers were exposed for 10 min to 700, 1400, and 5600 Hz at sound levels between 151 and 176 dB re 1 μPa. Threshold shifts between 3 and 21 dB were observed among the subjects with increasing TTS following increases in sound pressure levels. No non-auditory symptoms were reported. Sound levels that yielded this same level of TTS in air were roughly similar to those observed in water, with the largest difference being at 1400 Hz where levels needed to be 5–15 dB higher underwater.

Smith (1988) exposed eight hooded divers to 3500 Hz tones (250 and 500 ms in length) at sound levels up to 218 dB re 1 μPa for up to 1 h. Hour-long exposures of 217 dB re 1 μPa yielded 40 dB of TTS, while shorter durations (5 and 20 min) at equal or lower sound pressure levels yielded TTS of 0 to 28 dB. Non-auditory effects that were observed included force felt on their face mask, water within the facemask bursting into spray, and some possible ocular effects.

Smith et al. (1996) conducted a series of noise exposure tests using warble tones with center frequencies between 125 and 6000 Hz. In the first test, seven unhooded divers were exposed for 15 min to warble tones of 250 Hz at 141 dB re 1 μPa; 500, 1000, 2000, and 3000 Hz at 161 dB re 1 μPa; and 6000 Hz at 171 dB re 1 μPa. TTS was less than 5 dB at all frequencies except for 500 Hz which was up to 15.5 dB. In the second test, 12 unhooded divers were exposed to 4 min of warble tones with center frequencies between 125 and 6000 Hz between 121 and 161 dB re

1 μPa. TTS did not exceed 10 dB for any of the subjects following exposures. It was concluded that divers could be exposed to 15 min of warble tones at 151 dB re 1 μPa for 500–1000 Hz, 161 dB re 1 μPa for 2000–3000 Hz, and 171 dB re 1 μPa for 4000–6000 Hz with no risk of auditory injury. Also, at lower frequencies, divers could be exposed to 4 min of 125–1000 Hz at 161 dB re 1 μPa with no risk of injury. There were no reports of non-auditory symptoms.

Steevens et al. (1997) tried to identify if an open water noise source exposure would yield different results than the more confined studies that have been reviewed so far. Utilizing the Bugg Spring Test Facility (also used by Brandt and Hollien (1967)), signals were produced using two speakers to create a plane progressive traveling acoustic wave. Six divers were exposed to a warble tone with a center frequency at 240 Hz and a slow sweep signal from 230 to 320 Hz, both at 160 dB re 1 μPa for 15 min. Divers were tested in both a helmeted scenario and bareheaded. Change in thresholds following exposure was 5 dB or less and could have been due to other non-experimental factors rather than the sound exposure.

Fothergill et al. (2001) explored the aversiveness of low-frequency sonar in recreational divers (no US Navy training). Twenty-six unhooded divers were exposed to pure tones, 30 Hz hyperbolic sweep up, and 30 Hz hyperbolic sweep down, each presented at six center frequencies between 100 and 500 Hz and between 130 and 157 dB re 1 μPa. Each signal was 7 s in duration for a total of 12.6 min of exposure. There was a general trend of increased aversiveness and subjects dropping out of the procedure with higher sound pressure levels. The frequencies that divers found most aversive were 100 and 500 Hz, with 250 Hz being the least aversive. Their final recommendations were that recreational divers could be exposed to 100–500 Hz at up to 145 dB re 1 μPa with minimal impact.

## Analysis

Many of these noise exposure studies were motivated by the need to establish a human response to a specific frequency, likely within the range of a sonar system of interest at the time. Because of this, the frequency range of sounds that have been tested is limited. Threshold shifts of varying amounts were observed at some frequencies between 700 and 6000 Hz, but the amount of TTS and the levels needed to induce these shifts were frequency dependent. Data were also collected over much of this same frequency range in which TTS was not observed at lower levels. Unfortunately, there is not enough overlap between these experiments to establish an onset of TTS, which is critical for establishing underwater hearing guidance.

Understanding the human behavioral responses (or perception) of these high-energy signals is also valuable. A few studies looked at aversion (Fothergill et al. 2001) or maximum tolerable level (Montague and Strickland 1961), but these were limited in scope. While a signal may not be loud enough to cause physical injury, it could still be perceived as uncomfortable or disturbing enough that it could disrupt a diver's ability to safely complete a dive. To some extent, this phenomenon was illustrated in these studies as subjects sometimes experienced perceptual aberrations

that presumably could affect performance and would drop out of the study once they reached a sound level that was uncomfortable enough to avoid continued exposure. But in both studies, there was no evidence of TTS from these exposures.

Expanding on the limited body of literature on underwater sound exposure is important to improve upon existing noise exposure guidance, but it is hard to recommend this line of study as it puts subjects at risk of temporary or permanent hearing damage or other non-auditory symptoms that could put the diver at risk. While it is not likely that additional data will be introduced into this limited field of study, any opportunities to better understand human response to underwater noise exposure would be valuable. Regardless, the existence of the experiments that have been conducted provides enough insight to provide recommendations as needed for this frequency range.

**Abstract**

Many species of seabirds dive to great depths and for prolonged intervals in pursuit of food, and they may therefore be affected by anthropogenic underwater noise. The paucity of seabird hearing data precludes the current understanding of noise impacts and limits the abilities to enact with informed mitigation efforts. One interesting family of birds in this respect is the auks (Alcidae). A previous study showed that common murres, *Uria aalge*, react to underwater sound, but no underwater hearing thresholds have so far been derived from any auk species. Here the underwater hearing abilities of a male common murre were measured using psychophysical methods. The results indicate that common murres, a deep diving seabird, respond to underwater sound at a received level of 130 dB re

## Introduction

Hundreds of species of marine birds make their living by performing extensive dives pursuing fish and invertebrates. Marine birds are considered especially vulnerable to climate change, bycatch, and other human-induced factors, making them among the most imperiled of all avian taxa (Lascelles et al. 2016; IUCN 2017). Additionally, there are recent concerns that anthropogenic noise may affect marine birds while diving, similar to how noise can affect marine mammals and fish (Popper et al. 2008; Popper and Hawkins 2012, 2016).

A key to understanding how marine birds are influenced by underwater noise is to discern which senses they use while diving. They are thought to rely on visual cues, just like most birds do in air. However, some marine birds can hunt under poor light conditions and in murky waters; they use tactile and perhaps also gustatory cues while diving (Enstipp et al. 2007; Grémillet et al. 2005; Thiebault et al. 2019; Wenzel 1980). Underwater sound is efficiently propagated through the environment and is a major sensory cue for diverse groups of marine animals, such as whales, dolphins, seals, fish, and arthropods, as well as for semiaquatic animals such as turtles and crocodiles (Thewissen and Nummela 2008). Given these sensory conditions, seabirds are also likely to make use of widely available underwater acoustic cues.

Both great cormorants and black ducks can detect underwater sounds (Anderson Hansen et al. 2017; Larsen et al. 2020; McGrew et al. 2022). Furthermore, common murres and gentoo penguins react negatively to intense underwater noise pulses, and gentoo penguins can be conditioned to pair underwater sound cues with food (Anderson Hansen et al. 2020; Sørensen et al. 2020; Rasmussen et al. 2022). Thus, there is some evidence that underwater sound cues can be utilized by marine birds while diving. But more information is needed to determine their sensitivity to underwater sound, and how they make use of underwater sound cues.

An interesting species in this respect is the common murre (*Uria aalge*), a common North Atlantic species of auk. Auks are found throughout the Northern Boreal and Arctic regions and are known for their extreme foraging abilities, diving to great depths for prolonged time and staying for months and even years at sea before gathering on land in large colonies to breed (Barrett and Furness 1990; Croll et al. 1992; Tuck 1961). There is physiological evidence that Atlantic puffins (*Fratercula arctica*) and common murres hear well in air (Smith et al. 2023; Mooney et al. 2019, 2020). They acoustically communicate in air and live in raucous seabird colonies, underscoring the importance of aerial hearing (Hansen 2018; Smith et al. 2023). Finally, as noted above, a previous study showed that common murres are

sensitive to sound and react negatively to underwater sound pulses (Anderson Hansen et al. 2020). However, their underwater sound sensitivity has not yet been determined.

Here, a common murre was trained for psychophysical measurements to begin to address underwater hearing thresholds, and the equipment and steps used to derive the bird's abilities to hear a narrowband tone of high intensity are outlined. The experimental setup offers a reliable method to obtain hearing data from an animal not easily worked with standardized psychophysical instrumentation.

## Materials and Methods

### Experimental Subject

A male captive-born common murre was tested at the University of Southern Denmark's Marine Biological Research Center in Kerteminde, Denmark. Upon his arrival in November 2017 (3 years old), he received extensive training in operant and classical conditioning for psychophysics, as well as husbandry and enrichment behaviors.

### Training

Positive reinforcement methods were used to train a yes/no testing paradigm. The murre was trained to swim through an underwater hoop, which then triggered the start of the trial via an optical sensor. The bird then swam to one of the two response targets, indicating if it heard the stimulus or not (Fig. 1). For a *YES* trial to be considered correct, the murre touched the left (red) response target with his beak after a stimulus was presented. For a *NO* trial to be considered correct, the murre touched the right (yellow) response target after no stimulus was presented. A correct response was marked with a conditioned reinforcer, a dog whistle, followed by an

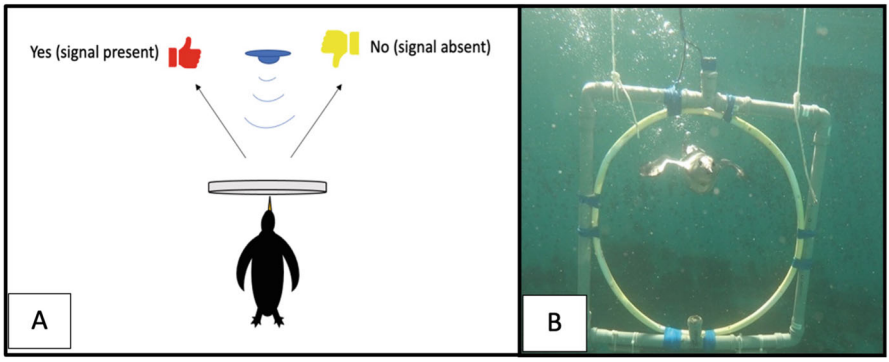

**Fig. 1** (**a**) Diagram of the experimental setup showing the general trial design; (**b**) the bird swimming through the experimental hoop, from the view of the speaker and response targets

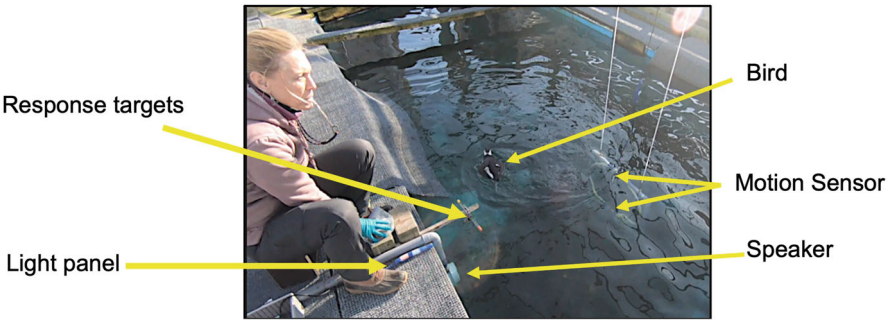

**Fig. 2** Experimental setup showing the various components as seen from above water

unconditioned reinforcer, a piece of fish, which was given by the trainer. If the bird responded incorrectly, no conditioned reinforcer was presented and no unconditioned reinforcer was given. The bird was then given the cue to start a new trial (Fig. 2).

## Apparatus

The setup was made to accommodate the bird's natural swimming behavior. A transmitter and sensor (Automation24, Essen, Germany, models OGS102 and OGE108) on the top and bottom of the hoop triggered the start of each trial, with a small light panel next to the trainer, indicating if the trial was a stimulus-present trial or stimulus-absent trial. The light panel secured impartiality of the trainer by providing a double-blind procedure as the trainer did know the type of trial (stimulus present or absent) until the bird passed through the hoop and gave its response. The trainer used a computer mouse to record the response of the bird, left click for correct and right click for incorrect. The total number of trials and the number of correct and incorrect responses, as well as the relative intensity of the sound stimulus for each stimulus-present trial, were registered and compiled at the completion of each session. For a given session, the animal received a constant sound level (for signal present trials), or no sound, following a method-of-constants paradigm. All sounds were generated, and data were recorded using a custom LabView program implemented on the nearby laptop connected with USB to a DAQPAD (National Instruments USB-9162, digital to analog converter working as sampling rate 48 kHz with 16 bits). The output of the DAQPAD was connected to a Basetech AP-2100 amplifier and to an underwater loudspeaker (University Sound UW-30).

## Stimulus

The stimulus was a 1 kHz 1 s pure tone with a received level of 130 dB re 1 μPa rms. During calibration, the stimulus was measured in different locations in and around

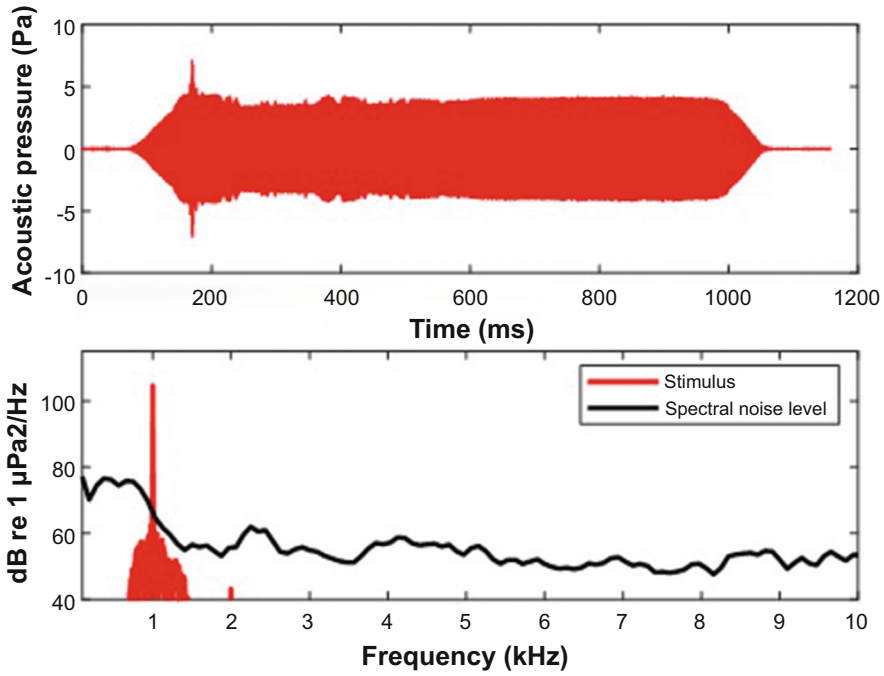

**Fig. 3** (Top) Stimulus waveform and (bottom) frequency analysis of stimulus and background noise, both in units of spectral levels (analysis bandwidth 1 Hz)

the hoop with a calibrated Soundtrap HF300 and a Reson 4032 hydrophone connected to an Olympus LS100 recorder (sample rate 48 kHz, 16 bits). The signal level varied by less than 3 dB within the hoop and ±10 cm in front and behind the hoop. Ambient noise levels were measured for 2 min before and after sessions at regular intervals with the same equipment used for stimulus measurements (Fig. 3).

## Testing Procedure

The session was run by the trainer using a custom-made Labview (National Instruments version 2018) program on a laptop. Once the session was started, a preprogrammed randomized sequence following a Gellerman protocol initiated either a stimulus-present or a stimulus-absent trial (Gellermann 1933). Both trial types were initiated in the same way with the only difference being that no stimulus was presented in signal-absent trials. For signal-present trials, the stimulus was presented when the murre swam through the hoop and triggered the motion sensor. It was not possible for the trainer to hear the underwater stimulus during testing. Each session consisted of 25 trials, out of which 10 were catch trials, with no signal present.

## Results

The murre's performance during the psychophysical tests were highly variable; however, the correct detection rate of 74% was consistently and significantly higher than the false alarm rate of 54% (Fig. 4; Wilcoxon sign rank test, $p < 0.05$). The stimulus level was believed to be clearly audible for the murre, from the following reasoning. Comparing in-water and in-air hearing thresholds has only been achieved in one species of sea birds, the great cormorant, indicating that the thresholds are comparable in units of pressure (Larsen et al. 2020). In-air hearing data on common measured by Smith et al. (2023). Extrapolating from in-air hearing data to underwater hearing thresholds under the assumption of equal pressure sensitivity indicates that the stimulus level used in the experiments were more than 60 dB higher than the presumed hearing threshold of common murres at 1 kHz.

## Discussion

Even though the response of the murre was variable between different sessions, the data clearly shows it could hear the underwater stimulus (Fig. 4). This is corroborated by the fact that the signal level was more than 60 dB above the presumed hearing threshold underwater at 1 kHz (Fig. 5). The stimulus intensity is similar to

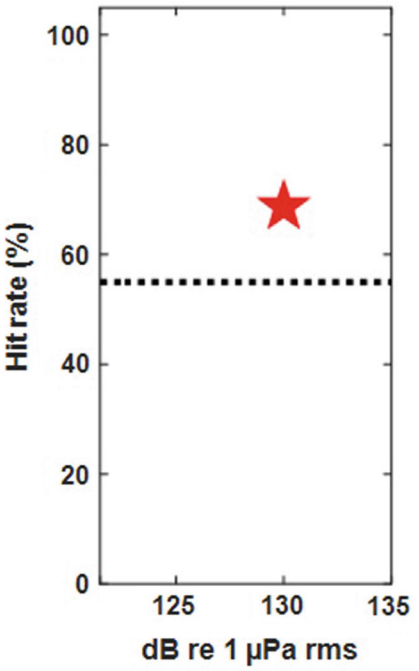

**Fig. 4** The correct detection rate at 130 dB re 1 µPa, indicated by a star, compared to the false alarm rate, indicated by a dotted line

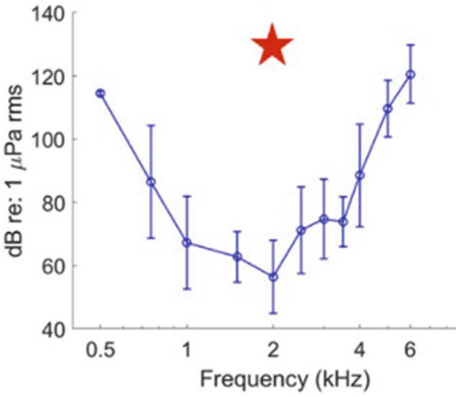

**Fig. 5** Stimulus level in underwater psychophysical experiments, compared with the estimated under water audiogram of a common murre, under the assumption of equal pressure thresholds in air and under water. (Modified from in-air ABR data from Smith et al. Smith et al. 2023)

the sound levels of signals (white noise and midfrequency sonar signals), which induced unconditioned flight responses from a feeding station (Anderson Hansen et al. 2020). The results indicate that murres can hear the stimulus level of 130 dB re 1 μPa were therefore as expected.

Notably, this animal reliably responded to the presence of the tone. With a correct detection rate of 74%, significantly above a false alarm rate of near chance, the murre certainly was conditioned to the task. This suggests that murres can be conditioned for underwater hearing tests and that it may be possible to determine auditory thresholds using psychophysical methods. The next step is to address correct detection rates at lower sound levels.

As the bird could clearly hear the stimulus, the reason for its variable performance in the psychophysical sessions cannot be explained by the bird having problems hearing the stimulus. Previous studies have shown that seabirds are extremely challenging to train for psychophysical work (Anderson Hansen et al. 2017, Maxwell et al. 2017, Rössler et al. 2022). From prolonged work with training marine birds for psychophysical work, the murres seemed less inquisitory and motivated to participate in operant conditioning tasks than, e.g., cormorants. Further work is needed to understand if the lack of motivation is caused by a lifestyle with a rather predictable environment and social behavior, or possibly some other factor.

The outlined here could be used to derive underwater hearing thresholds of the murre by reducing the stimulus level until the correct detection rate reaches the false alarm rate. The derived thresholds would be for a moving bird, which may be higher than a stationary bird due to noise created by moving through the water. As murres are dynamic swimmers, constantly moving while diving, such a threshold would more realistically indicate the hearing abilities of the bird in natural situations. Additional work could leverage these methods to determine if murres (or other seabirds) functionally use sound underwater, perhaps via auditory directionality and sound source localization experiments. Given their sensitivity to underwater sound, additional studies on noise impacts, in this and related taxa, are also warranted.

**Acknowledgments** This project was funded by the US Navy's Living Marine Resources Program (LMR; BAA N39433015R7203), and the support of the LMR's Program Committee for their support toward this project is much appreciated. Birds were loaned from Copenhagen Zoo. Work was conducted under permission from the Woods Hole Oceanographic Institution's Institutional Animal Care and Use Committee, and animal permit to University of Southern Denmark nr. 2300-50120-00003-09 from the Danish Ministry of Food and Agriculture. We thank Kasper Fjordside and other members SDU Marine Lab for their logistical support.

**Abstract**

Acoustic deterrents are popular form of behavioral guidance measure used to manage fish movements in rivers. However, despite their popularity, the reported efficacy of these systems is often quite variable. One potential reason for this is that peripheral sensory inputs can influence how fish respond to deterrent stimuli. While little research has examined these effects in relation to deterrent function, they have been well studied for many decades in different contexts. Therefore, this chapter provides a brief review of literature pertaining to how multimodal integration and masking influence fish behavior and suggests how this vast body of literature may inform the design and implementation of acoustic deterrents in the future. Highlighted is the need to understand the sensory background against which deterrents operate, as peripheral sensory information may impact the perception of and thus behavioral response to a given deterrent stimulus. Furthermore, acoustic masking may impair a fish's ability to properly distinguish acoustic deterrents from background noise. Improving acoustic deterrent efficiency will

## Introduction

The development of infrastructure for energy production, agriculture, and other purposes creates dams and other barriers which reduce river connectivity and disrupt fish movement, blocking access to important nursery, feeding, and spawning grounds (Baumgartner and Wibowo 2018; Conallin et al. 2019; Delavan et al. 2017). While fish passes are being installed and retrofitted to improve fishes' ability to safely bypass these barriers, migration delays still occur when fish encounter such infrastructure, which can lead to increased predation, reduction in energy stores, and loss of mating opportunities (Caudill et al. 2007, 2013; Fjeldstad et al. 2018; Gowans et al. 2003). Furthermore, impingement upon and entrainment into infrastructure is also common, resulting in physical damage and mortality for fish that are unable to avoid these barriers (Taft 2000). Additionally, there is a need to limit the spreading threat of invasive species which can disrupt ecosystem services and negatively impact the status of native species in river systems where they have been introduced (Cupp et al. 2021; Murchy et al. 2017).

These threats have led to the development of a range of both physical barriers and non-physical, behavioral deterrents to guide fish movements in rivers. Non-physical deterrents have become an increasingly popular option for guiding fish movements in rivers (Jesus et al. 2019; Noatch and Suski 2012; Popper and Carlson 1998). Such deterrents function by triggering the existing sensory biases to elicit avoidance behaviors in target species and are often preferred over physical barriers as they are less costly to construct and maintain and do not interfere with the normal flow of the river (Noatch and Suski 2012). Behavioral deterrents utilize a wide range of abiotic stimuli, including light (Kim and Mandrak 2017), $CO_2$ (Tix et al. 2018), electricity (Miller et al. 2022), air bubbles (Flores Martin et al. 2019), and acoustic stimuli (Deleau et al. 2020; Heath et al. 2021). While there is no "one size fits all" solution (Noatch and Suski 2012), and each of these deterrent types has their own applications, acoustic stimuli have several advantages that make them particularly suited for managing fish movements in rivers. For example, all fish are capable of detecting acoustic stimuli (Popper and Fay 2011), and many fish species have unique specially adapted hearing frequency ranges, meaning it may be possible to fine-tune and target acoustic stimuli toward a specific species or subset of species (Vetter et al. 2018). Furthermore, acoustic stimuli spread rapidly underwater due to the physical properties of the medium, and their propagation is independent of water clarity,

meaning that these stimuli can be detected at a great distance from the source in the often highly turbid environment of many rivers (Popper et al. 2020).

Despite the advantages of using acoustic stimuli as non-physical deterrents, their efficacy is often highly variable, both between sites and between species (Maes et al. 2004; Putland and Mensinger 2019). One potential reason for this variation is that they have been deployed in a wide range of environmental conditions (Jesus et al. 2019; Noatch and Suski 2012). Non-physical deterrents have historically been constructed using trial-and-error approaches, with a lack of detailed understanding of how fish respond to specific sensory stimuli (Popper et al. 2020). Studies examining behavioral responses to acoustic deterrents often focus on studying the effects of stimulus presentation such as frequency characteristics (Currie 2021; Vetter et al. 2018), inter-species differences (Deleau et al. 2020; Matsuda 2020), or temporal characteristics (Currie et al. 2020) but don't consider how other sensory information might influence how individuals respond to these stimuli. However, it is important to realize that behavior can be influenced by information received across different sensory channels (Fetsch et al. 2013), and the perception of a specific stimulus might vary depending on the presence of other sensory stimuli (Chan and Blumstein 2011; Halfwerk and Slabbekoorn 2015; Paglianti et al. 2010). So far however there has been little consideration of how the wider sensory environment influences the perception of behavioral deterrents, and it is therefore useful to provide a brief overview of how such peripheral stimuli may influence fish behavior and to discuss how these effects may influence the efficacy of acoustic deterrents.

## Multimodal Integration

Multimodal integration is a process by which animals incorporate information received across different sensory modalities into decision-making and behavioral processes (Partan and Marler 1999). Different sensory channels are capable of providing independent estimates of the environment (Driver and Spence 1998); thus integrating stimuli from different sensory channels can function to decrease environmental uncertainty, which allows the individual to exhibit more accurate behavioral responses (Munoz and Blumstein 2012, 2020). Indeed, (Partan and Marler 1999) set out a framework to explain how the integration of multimodal information influences behavior. Here, individual component stimuli are first classified as either "redundant" or "non-redundant" based on the type of behavioral response they each elicit in isolation. Redundant stimuli are those that elicit the same type of behavioral response from an individual, while non-redundant stimuli are those that elicit different responses from each other. Then, depending on if the stimuli are redundant or non-redundant, a set of potential responses to the combined multimodal stimulus can be categorized as examples of different processes relative to the behaviors elicited by each individual stimulus (redundant stimuli: equivalence, enhancement, or antagonism; non-redundant stimuli: independence, dominance, modulation, or emergence) (Fig. 1). These potential outcomes highlight the varied effect that integration can have on behavior and show that behavioral response to an

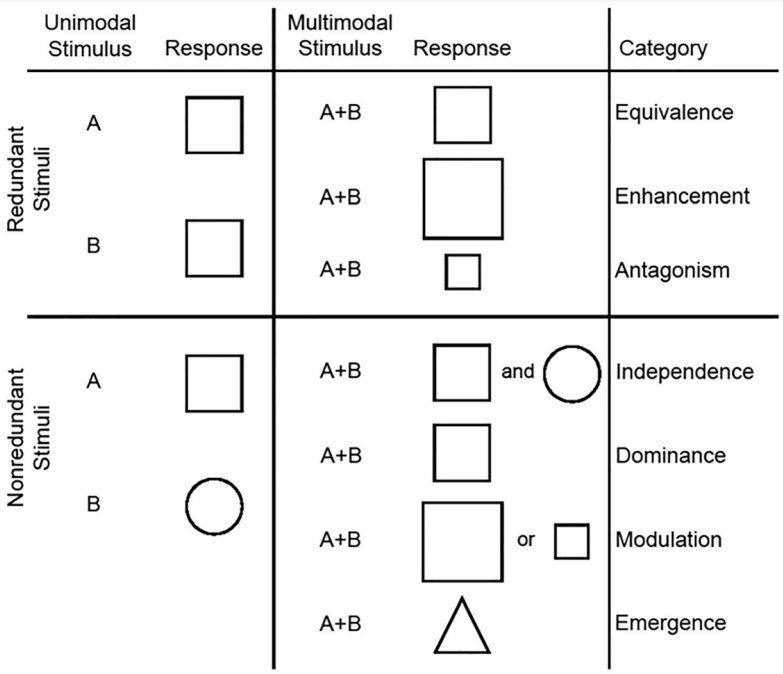

**Fig. 1** Potential behavioral outcomes from multimodal integration. Depending on how the individual responds to each component stimulus in isolation (response to unimodal stimulus), different potential responses to multimodal stimuli are possible (Adapted from Munoz and Blumstein (2012))

acoustic deterrent may differ quite significantly depending on the information available to other modalities.

Studies of multimodal integration in fish have largely focused either on elucidating the organization and function of the nervous system (as in the case of studies examining the function of the Mauthner cells under different sensory conditions (Medan et al. 2018; Otero Coronel et al. 2020) or on understanding how the environment and anthropogenic impacts influence fitness-related behaviors, such as those in predator-prey interactions (Hasan et al. 2018; Montgomery et al. 2002) and mating displays and communication (de Jong et al. 2018; Halfwerk and Slabbekoorn 2015; van der Sluijs et al. 2011).

Mauthner cells are large reticulospinal command neurons that integrate information from different sensory channels (Eaton et al. 2001) and initiate fast-start startle response behaviors. As such, these cells have been extensively studied as a model system for understanding how multiple sensory inputs inform startle response behavior in fish (Domenici and Hale 2019). Multimodal integration has been shown to enhance this behavior, with recent research showing that the probability of a startle response increases when fish are exposed to a multimodal combination of visual and acoustic stimuli (Martorell and Medan 2022; McIntyre and Preuss 2019). Specifically, these studies show that startle response behavior is more likely when

fish are exposed to pulsed tonal stimuli in combination with a concurrent looming visual stimulus in comparison to fish exposed to only one of the individual stimuli. The potential application of this research has been recognized, and acoustic deterrents that incorporate a complimentary multimodal component (usually either stroboscopic lights (Bui et al. 2013) or bubble curtains (Flores Martin et al. 2021)) are currently being designed and implemented. It has been suggested that fish may be less likely to habituate toward such multimodal deterrents, due to the presence of multiple aversive stimuli (Lecker et al. 2015); however research into the effectiveness of the systems over traditional, unimodal deterrents show that their efficacy can still vary (Bzonek et al. 2020, 2021).

Connections like these between fundamental research focused on understanding the integration of different sensory inputs within an individual and more applied work focused on designing improved behavioral guidance measures highlight the importance of multidisciplinary approaches to problem-solving. In this context, fundamental research should be used to identify stimulus-response relationships and how they change under different multimodal environments, while more applied work should focus on taking this knowledge into the field and testing to see whether or not these relationships hold in more naturalistic settings.

The effect of multiple different stimuli on startle response behavior has also been shown to depend on species-specific sensory capabilities and on the direction from which stimuli are detected. For example, Canfield (2006) showed that visual stimuli detected in the rostral visual field of *Haplochromis* depolarized Mauthner cells 1.5 times more than did the same stimuli presented from a caudal direction. Additionally, behavioral testing showed that rostrally projected visual stimuli in combination with an acoustic stimulus produced startle responses with significantly larger turning angles and turning speeds than for multimodal stimuli where the visual stimulus was projected from a caudal direction. If a deterrent stimulus is only effective from certain directions relative to the individual, then its performance will likely be severely impacted due to variations in individual behavior and approach direction. As such the specific physiology and sensory sensitivities of target species should be considered not just when determining what stimuli to use but also in the installation of the system. Transducers and strobe lights should be placed in locations where they will have the maximum chance of eliciting the desired behavior from target species.

The role of multimodal integration in guiding predator avoidance behaviors is a particularly interesting point of comparison when considering how responses to acoustic deterrents might vary with ancillary sensory stimuli. Behaviors in these two contexts are similar to each other, as deterrents seek to elicit avoidance behaviors from target species. In this sense behavioral deterrents can be thought of as predators, alerting target species to their presence with the stimuli they emit. As such, studies examining how predator avoidance behaviors vary with different sensory inputs could provide interesting hypotheses to explain why responses to behavioral deterrents might change under different sensory conditions. Paglianti et al. (2010) demonstrated that the behavioral response of Rosy barb (*Barbus conchonius*) to conspecific chemical alarm cues varied depending on the availability of visual cues. The authors found that fish did not exhibit typical startle behaviors in response to the

cue in dark conditions, suggesting that this avoidance behavior functions as a form of conspecific communication that is only beneficial in the presence of visual cues. In terms of behavioral deterrent function then, it would be interesting to explore whether or not the type of avoidance response exhibited in response to a deterrent varies with light levels or the availability of visual cues. If indeed avoidance responses vary with different light levels, then the efficacy of a deterrent system would likely suffer greatly. It is therefore vital to test the function of these systems under different conditions in order to minimize any potential negative effects.

Multimodal integration has been shown to influence behavior in other contexts as well. For example Vowles and Kemp (2012) and Vowles et al. (2014) considered how multimodal sensory inputs influence downstream migration behavior, showing that the behavioral response of brown trout (*Salmo trutta*) and chinook salmon (*Oncorhynchus tshawytscha*) is influenced by both hydrodynamic and visual cues. Juveniles of both these species avoided an increasing velocity gradient more often when visual stimuli were present than they did when visual stimuli were absent. Thus, multimodal integration appears to also play an important role in guiding migratory and movement behavior in fish. Indeed, multimodal integration can impact behavior in any context where an individual is presented with multiple sensory inputs (Bzonek et al. 2022; Kasurak et al. 2012). It is therefore likely that such integration influences how fish respond to acoustic deterrents. For example, the perceived risk associated with a deterrent stimulus might depend on the quality of sensory information across different modalities, which in turn could impact the behavior expressed by an individual in response to it. However, to the authors' knowledge, little work has been done to examine these effects, save for Currie (2021) who found that roach (*Rutilus rutilus*) avoided an insonified route during upstream migration more often under higher flow speeds. Thus, there is a pressing need to determine if the behavior expressed in response to acoustic deterrents is dependent on other sensory stimuli. Determining these relationships will help explain why the efficacy of acoustic deterrents is so often variable and may provide insights useful for developing improved acoustic deterrents in the future.

## Masking

While the theory of multimodal integration has been used to explain how multiple sensory inputs can improve behavioral accuracy, peripheral sensory information can affect behavior in other ways as well. Paying attention to sensory information received from different modalities is not always advantageous. Animals have a limited attentional budget, meaning they do not possess the capacity to process all the sensory information they receive (Dukas 2002), so splitting attention between multiple sensory inputs can also impair behavioral responses to relevant stimuli (Dominoni et al. 2020). In fact, the distracted prey hypothesis states that any perceivable stimulus is capable of distracting an individual by re-allocating some of its finite attention (Chan and Blumstein 2011). Thus, information detected by sensory modalities other than the auditory sense may also influence the perception of

acoustic deterrents. Such masking and distraction effects have been studied under various contexts for many decades. However, as with studies of multimodal integration, rarely in regard to behavioral deterrent performance, thus there is a use in providing a short introduction to these topics and how they may relate to acoustic deterrent efficacy.

Acoustic masking occurs when the presence of one sound (noise) raises the threshold required for detection of another sound (signal) above what it would be in the absence of noise (Fay 2012). An important aspect of this phenomenon is that masking can occur when noise levels are lower than those of a given signal. Studies in fish have shown that increased broadband white noise, natural ambient noise, and anthropogenic noise mask the detection of pure tones, conspecific calls, and other sounds by increasing the sound level required to detect them (Amoser and Ladich 2005; Fay 1974; Ladich and Schulz-Mirbach 2013; Wysocki and Ladich 2005). The authors are not aware of any studies examining the masking effects of noise on the detection of acoustic deterrents. However, knowledge developed from studies elucidating the structure and function of the fish ear as well as the masking effects of anthropogenic noise can serve to guide this research.

In fish and other vertebrates, the auditory system can be thought of as a series of bandpass filters, referred to as critical bands (Fletcher 1940), covering the extent of a given species hearing range, with each band only receptive to a certain frequency bandwidth. Thus, in order for noise to mask the detection of a given signal, they must share (at least partly) the same critical band. Increasing noise levels without increasing signal levels leads to a decrease in the signal-to-noise ratio (SNR). Early studies of acoustic masking in fish showed that masking effects are strongest when the frequency bands of the masker and the signal are more similar and that masking effects decrease the more dissimilar the two frequency bands are (Tavolga 1974). One important consideration for improving deterrent efficacy then could be to tune deterrent stimuli so as to minimize the overlap with frequency bands present in the ambient environment as much as possible. However, it's unlikely that a deterrent stimulus would be able to be tuned in such a way as to completely minimize such overlap with ambient noises. Freshwater soundscapes vary widely (Amoser and Ladich 2010), and the presence of transient or temporary changes in background noise levels and spectra due to anthropogenic activity such as shipping or the operation of infrastructure could make it difficult to sufficiently tune a given stimulus.

Interestingly, masking effects induced by ambient noise have been shown to decrease when that noise is coherently modulated over the time domain (Hall et al. 1984). Little work has been done to examine these effects in fish; however Fay (2011) found evidence of such comodulation masking release in goldfish. If ambient noise varies coherently in amplitude across its frequency range, then the strength of any potential masking of acoustic deterrent stimuli may be reduced in comparison to the effect of a continuous white noise masker. The author calculated this reduction to be approximately 5 dB for goldfish. Thus, determining the temporal consistency of ambient noise is important when considering the potential masking effect of ambient noise on deterrent detection.

Masker efficacy may also depend on the type of signal being detected. For example, Belanger et al. (2010) showed that the round goby (*Neogobius melanostomus*) showed lower detection thresholds for a pulsed conspecific call than they had for tone burst stimuli ranging from 100 to 600 Hz. The authors state that using pure tone stimuli to test auditory capabilities in fish may provide a biased view of sensitivity, as the fish ear evolved to detect complex acoustic stimuli as opposed to tones (Belanger et al. 2010). If increased detection thresholds for artificial stimuli are indeed common across fish species, then basing predictions about the effects of masking stimuli on deterrent signal detection may be misguided. Comparing behavioral sensitivity thresholds to artificial and naturally occurring stimuli would provide useful insights into the validity of such approaches and could help identify knowledge gaps pertaining to how fish perceive deterrent signals.

Importantly, simple detection thresholds may not be the most relevant metrics for understanding how masking impacts the perception of acoustic deterrents. Dooling et al. (2015) classifies different auditory behaviors, each of which requires increasingly large signal-to-noise ratios (SNR) to elicit. Signal detection is the least complex of these behaviors (requiring the lowest SNR), as it simply defines the threshold at which an individual can detect that a signal is present in the environment, while the more complex behaviors of discrimination and recognition each require increasingly higher SNR. Fay (2011) was the first to examine differences in SNR thresholds required for signal detection and discrimination in fish, finding that discrimination thresholds of a 400 Hz pure tone against a background of broadband noise in the goldfish (*Carassius auratus*) were around 4 dB re 1 μPa higher than those for signal detection. The author points out that this difference in threshold level could translate to a significantly reduced range at which an individual would be able to acquire sufficient information about the signal and respond appropriately. If this relationship holds for other species in more natural environments, then the effective range of acoustic deterrents in noisy locations could be significantly reduced compared to what would be assumed from examining signal detection thresholds alone.

The effects of acoustic noise on hearing sensitivity thresholds are also dependent on species-specific hearing abilities. Fish species with specialized adaptations for hearing, such as the Otophysi, possess structures which connect their swim bladder and inner ear, often through mechanical linkages or protrusions of the swim bladder (Popper and Fay 2011). Species with these adaptations are sensitive to both the sound pressure and particle motion component of sound, have lower hearing thresholds, and are more sensitive to acoustic masking effects than species that do not have such specialized adaptations (Ladich and Schulz-Mirbach 2016). Indeed, comparative studies have shown that the hearing thresholds of species lacking any hearing specializations are less affected by noise than species that have them. In similar lab experiments, both Wysocki and Ladich (2005) and Ladich and Schulz-Mirbach (2013) found not only that AEP response thresholds for species possessing specialized hearing adaptations were masked by lower noise levels but also that the magnitude of these effects is stronger for these species than for species lacking any such specializations, such that hearing thresholds for pressure-sensitive species increased more. In contrast however, Ramcharitar and Popper (2004) found that black drum (*Pogonias cromis*), a species lacking any specialized connections

between their inner ear and swim bladder, was more affected by masking than was Atlantic croaker (*Micropogonias undulatus*), a species possessing specialized swim bladder projections that terminate near their inner ear. In this study the black drum exhibited a loss of frequency sensitivity at the upper extent of their hearing range under the loudest masking level (136 dB re 1 μPa) and exhibited larger threshold shifts across much of its hearing range at that same masking level than did the Atlantic croaker. While these results appear to conflict with each other, it is worthwhile to consider if indeed masking effects are on average stronger for species that possess specialized hearing adaptations. Acoustic deterrents should be most efficacious for species that possess strong hearing abilities, as it is expected that these species will be more reliant on acoustic cues in general and should be better able to detect acoustic stimuli than species without such adaptations. Thus, any potential masking effects imposed by ambient noise on a given deterrent may result in larger-than-expected decreases in performance. It would be worthwhile for future research to determine if species selected for management with acoustic deterrents are particularly sensitive to masking effects. Determining such relationships would benefit the development of improved acoustic deterrents and minimize environmental effects on their performance.

Perhaps it is not surprising then that research has shown that hearing thresholds also vary with ambient environmental sound levels. In an early example, Chapman and Hawkins (1973) suggested that the hearing thresholds of cod (*Gadus morhua*) were masked in all but the most calm sea conditions tested in their experiment. More recently, Amoser and Ladich (2005) directly examined how the hearing thresholds of two fish species differ in their ability to detect sound pressure in different levels of environmentally generated background noise. Here, the auditory thresholds of common carp (*Cyprinus carpio*) were highly masked by river-generated noise (hearing range threshold increases up to 49 dB) but less so by lake environment noise (maximum threshold increases of 12 dB across the frequencies tested). Conversely, the hearing thresholds of European perch (*Perca fluviatilis*) did not increase by more than 13 dB in the loudest background noise treatment. Thus, the hearing thresholds of this pressure-sensitive species appear to be masked by ambient noise levels.

Ambient noise levels differ across different freshwater habitat types (Vračar and Mijić 2011; Wysocki et al. 2007), with levels in large rivers such as the Danube reported as high as 137.8 dB re 1 μPa (Amoser and Ladich 2010); furthermore, anthropogenic activities can generate noise levels greater than 150 dB re 1 μPa (Wang et al. 2020). Not only are these levels higher than the hearing sensitivity thresholds reported for many species in quiet conditions (Ladich and Schulz-Mirbach 2013), but they are also similar to the SPL levels of many acoustic deterrents reported in the literature ((Putland and Mensinger 2019) supplementary material). Thus, these noise sources may mask acoustic deterrent stimuli if their sound level is not sufficiently high enough (of course, however, any potential masking ability of ambient environmental noise will depend also on its spectral profile).

It seems likely then that ambient and anthropogenic noise sources influence fish hearing sensitivity by increasing the threshold levels required to elicit behavioral

responses and altering the frequency sensitivity of different species (Ramcharitar and Popper 2004). Therefore, it is important that ambient noise levels are quantified when determining what sound level should be used for a given acoustic deterrent. However, in a recent review of acoustic deterrent performance, Putland and Mensinger (2019) show that ambient sound levels are rarely reported in the literature, with around 10% of their cited papers having reported ambient noise levels. The authors argue that sound levels should be defined with regard to both species-specific hearing sensitivities and local ambient conditions so that appropriate signal-to-noise levels are maintained. Indeed, without an understanding of background noise levels, it is not possible to adequately assess whether or not the sound levels of an acoustic deterrent stimulus would be sufficient to elicit the appropriate behavioral response from target species.

## Conclusions

It is clear that the wider sensory environment may influence a fish's ability to perceive acoustic deterrents, with potentially important consequences for the efficacy of these systems. While significant research effort has been devoted to examining the effects of both multimodal integration and masking in fish, there is almost no consideration of how these interactions may impact the detection of and response to behavioral deterrents. Specifically studying how sensory perception in this context is dependent, environmental conditions may provide much needed answers to improve the efficacy of these systems. Testing whether or not changes in behavioral responses to artificial deterrent stimuli follow the same rules as responses to natural biotic stimuli (such as acoustic predator cues) under different conditions could help connect the more applied focus of behavioral deterrent design to fundamental biological theory. This perspective would benefit a more systematic approach to the testing of acoustic deterrents and behavioral guidance measures more widely. Indeed, efforts to improve the efficacy of acoustic deterrents will be well served by complimentary and interdisciplinary approaches. Field studies focusing on quantifying the sensory environment present upon which acoustic deterrents must operate can inform controlled, experimental approaches aimed at disentangling the complex relationships between specific sensory inputs and behavior. In turn, such studies should be validated by field experiments using more "natural" conditions. As the need for behavioral guidance systems becomes more widespread, adopting more systematic approaches to their design will not only save precious funding but will also lead to the implementation of more robust designs in the future.

**Acknowledgments** This project has received funding from the European Union Horizon 2020 Research and Innovation Programme under the Marie Skłodowska-Curie Actions (Grant Agreement No. 860800).

**Abstract**

One of the main aims of the EU Horizon 2020 research program SATURN (developing solutions to underwater radiated noise, https://www.saturnh2020.eu/) is to determine the relevant metrics of ship-radiated underwater sounds that can be related to effects on the physiology and behavior of aquatic animals. Where possible, these metrics will then be related to the corresponding ship design and operational parameters, to enable the development of mitigation solutions. As part of the approach, controlled exposure experiments will be conducted on representative fish and invertebrate species, involving playback of these representative test signals.

The relevant temporal and spectral features that can be attributed to ship-radiated sound characteristics have been characterized, based on data available in the literature. A suite of artificially synthesized ship sound signals has been developed. These signals are considered suitable for the assessment of harmful

underwater noise characteristics in the sense that they are relevant for the impact on marine life as well as subject to technically achievable mitigation measures. Using harmonized test signals in different bioacoustic playback studies facilitates the comparability of results. These signals are offered as a standard reference for external stakeholders and future projects.

## Introduction

Assessment of the impact of underwater sound on aquatic animals is complex because of the variety of taxa involved, each with their own spectral and temporal sensitivity to sound and their behavioral and physiological sensitivity to acoustic disturbance. The three large taxonomic groups in aquatic ecosystems are invertebrates, fishes, and marine mammals. Fishes and invertebrates are considered to be particularly sensitive to the particle motion components of sound and hear sounds predominantly in the lower-frequency ranges, usually below 1000 Hz (Hawkins et al. 2015). Invertebrates' low capacity or inability to escape sound sources makes them potentially more vulnerable to a continuous sound source because they are likely to receive a higher dose of sound compared with species that can escape a noisy area like fish or marine mammals. Because field studies on fish and invertebrates are complex, the SATURN project studies impact of sound on these species in the laboratory. Laboratory conditions and captive animals are considered critical for progress and essential for revealing fundamental aspects of the processes underlying negative effects of noise pollution. Controlled exposure experiments are conducted on representative species using playback of harmonized test signals and state-of-the-art analysis to determine the physiological, pathological, and behavioral effects of both particle motion and acoustic pressure on the exposed animals.

Playing back ship sound for controlled exposure experiments is not a trivial task (Erbe et al. 2019). Recordings of ship sound are affected by the characteristics of the recording equipment and by the environment in which they are made. Playbacks of these signals are affected by the characteristics of the playback equipment and by the environment. Consequently, relevant sound features may get lost in translation.

Using harmonized test signals in different bioacoustic playback studies facilitates the comparability of results. Therefore, a suite of artificially synthesized ship sound signals has been developed that are considered suitable for the assessment of harmful underwater noise characteristics in the sense that they are relevant for the impact on marine life as well as subject to technically achievable mitigation measures.

## Ship-Radiated Underwater Sound

Underwater-radiated sound has been used by navies since World War I as a means for detecting ships (passive sonar); see, e.g., Ainslie 2010. Hence, the main sound source mechanisms on ships are generally well-known (e.g., see Baudin and Mumm 2015). These are generally the propulsors (propellers, waterjets, or other) and the engines that drive these propulsors, but also other onboard machinery (such as generators, pumps, etc.) and the hydrodynamic flow around the ship hull can contribute to the underwater-radiated sound; see, e.g., Urick 1983; Ross 1976.

Propeller sound sources include inhomogeneous wake flow, turbulence at leading edge (inflow turbulence), trailing edge and blade tip, and cavitation on blades (sheet cavitation), blade root, at the hub, and in the tip vortex. These source mechanisms create tonal sound at harmonics of the propeller "blade rate" (i.e., the frequency at which the propeller blades pass one by one through the nonuniform wake of the hull, given by the product of the propeller shaft rotation rate and the number of blades) and broadband sound from cavitation and from turbulence. The amplitude of the broadband propeller cavitation sound is typically modulated at the blade rate, because the dominant cavitation dynamics occurs when the propeller blade passes through the wake peak, typically located near the 12 o'clock position. The broadband sound from turbulence can be amplified in some frequency bands by propeller blade resonances. In some cases, interaction between blade resonance and vortex shedding at the trailing edge can cause strong tonal sound known as "propeller singing." This can generally be mitigated by small modifications of the shape of the trailing edge; see, e.g., Carlton 2012.

Rotating and reciprocating machines produce tonal sound at harmonics (positive integer multiples of the fundamental frequency) of the rotation (or oscillation) rate of the machines, including, for example, gear mesh frequencies. Combustion engines produce tonal sound at harmonics of their firing rate.

These characteristics are for regular ship transit sounds. Maneuvering, switching machines on and off, and the operation of thrusters for dynamic positioning can generate additional transient sounds.

## Sound Features

The sound signals used for controlled exposure experiments in the laboratory must represent the relevant temporal and spectral features that can be attributed to ship-radiated sound characteristics. Spatial features of the playback sound field are relevant as well, but these are mainly related to the geometry of the laboratory test setup and playback devices. This chapter aims at the design of harmonized digital test signals for playback studies. The focus is on the temporal and spectral features of the sound signals. It is noted that the design of the playback system to convert these (electronic) signals into the appropriate sound pressure and sound particle motion field is an essential next task in the design of the individual controlled exposure studies for the different animal species.

## Spectral Features

During regular ship transits, the ship-radiated sound spectrum contains both broadband sounds, typically generated by propeller cavitation, and tonal components, associated with the propeller and with rotating and reciprocating machinery.

**Proportional bandwidth spectra**, for a relevant auditory bandwidth, provide the relevant information about the spectral distribution of the sound energy in the signal in relation to detection and to possible behavioral response and noise-induced hearing threshold shifts.

**Narrowband spectra** provide the relevant information about the presence of dominant tonal sounds in the signal. Humans exposed to sounds with a prominent tonal character experience higher annoyance than when exposed to broadband sounds at the same sound pressure level. Consequently, the airborne environmental noise assessment standard (ISO 1996-1, 2016) suggests adding an adjustment ("penalty factor") of 3 to 6 dB to the measured sound level of sounds with a prominent tonal character. For this purpose, ISO/PAS 20065 (2016) describes an objective method for assessing the audibility of tones in noise, in relation to human hearing. The tonal character of sound may also be relevant for behavioral response of aquatic animals to sound exposure, but this has not yet been investigated. Therefore, signals with and without tonal content are developed that allow investigating the effect of the tonality of ship sound signals in controlled exposure studies. In opportunistic acoustic measurements of ships transiting offshore California (McKenna et al. 2013), dominant narrowband tones were present in 10% of the measured ships.

## Temporal Features

The audibility of sound signals for animals is affected by signal duration; see, e.g., Kastelein et al. 2010. The integration time of harbor porpoise hearing was found to be similar to that of other mammals, including humans. Because the "ears" of fishes and invertebrates are different from those of mammals, it is well possible that these have different integration times, but data are largely lacking. One study by Art Popper (1972) did not show any dependence on signal duration, but a later study by Dick Fay and Shelley Coombs (Fay and Coombs 1983) does suggest an integration time of some hundred milliseconds in goldfish.

The sound radiated by a ship due to propeller and machinery, if the ship is sailing at a constant speed and course, can be considered "stationary" (meaning that statistical parameters remain constant) at timescales larger than the rotation period (the inverse of the rotation rate) of the main noise sources. Typically, these rotation periods are of the order of 1 s or less.

The amplitude of broadband propeller cavitation sound is **modulated at the blade rate.** Defense and security organizations use analysis methods such as DEMON (Detection of Envelope Modulation on Noise), to estimate the shaft rotation frequency of detected vessels, as a means for classification; see, e.g.,

Chung et al. 2011; Fillinger et al. 2011. Animals with a hearing time constant $\tau \approx 125$ ms can likely perceive the amplitude modulation for blade rates up to about 8 Hz ($=1/\tau$) as loudness fluctuations. In human psychoacoustics, faster (>12 Hz) amplitude modulations are qualified as "roughness" of the sound (Daniel 2008). It is likely that this perception occurs in other species as well, but this has not been investigated. Geometric differences between individual blades or shaft eccentricity may also lead to sound modulation at the shaft rotation rate.

The sound to which a static animal is exposed when a ship passes **varies in time due to the decreasing and increasing distance** to the ship, in combination with the interference effects due to reflections of the ship sound at the water surface (the Lloyd mirror effect in underwater acoustics). For typical ship speeds (<20 m/s) and observation distances (>100 m), these variations occur over time periods of the order of 5 s or more.

The relative motion between ship and observer will also cause a variation of the observed tonal frequencies due to the Doppler effect. Due to the large difference between the ship speed and the sound speed in water, this is a subtle effect which is tentatively ignored in this chapter.

In addition, propeller tip-vortex cavitation produces low-frequency broadband noise related to variations between blade passages, hence variations in time that have a timescale of the order of blade rate frequency or smaller; see Bosschers 2018. These may have various origins and may include ship motions, variations in rpm, turbulence in the wake, and variations in nuclei. These variations in low-frequency sound radiations are not well-described and hence tentatively ignored in this chapter.

## Signal Representation

Digital signals representing field quantities such as sound pressure or sound particle displacement, velocity or acceleration, characterize the time-varying amplitude of a sound signal $x(t)$ at discrete, uniformly distributed times $t_n$, with $\delta t$ the time step between the samples, so that $t_n = t_1 + (n - 1)\delta t$, with $n = 1, 2, \ldots, N$; see, e.g., Ainslie et al. 2018. The time step corresponds with a sample rate (or sample frequency) $f_s = 1/\delta t$. The number of samples $N$ that describe a signal of duration $T$ equals $N = T/\delta t$. The maximum sound frequency that can be represented by a digital signal without distortion (aliasing) is limited by the Nyquist frequency $f_s/2$. The statistics of time series $x(t_n)$ characterize the signal.

The short-time Fourier transform (STFT) of the signal quantifies the relevant temporal and spectral features of the sound signal. The frequency resolution $\delta f = 1/\Delta t$ in the STFT is inversely proportional to the duration $\Delta t$ of the subsequently analyzed sections of the signal. The STFT reveals the tonal and broadband sound components and how these vary with time.

Another statistic of the sound signal that may be relevant for predicting the risk of hearing loss or other adverse effects of sound on aquatic animals is kurtosis (the moment of order 4 in the standardized probability distribution of a random variable) (ISO 3534-1 2006); see also Müller et al. 2020. Kurtosis is recommended for

quantifying "impulsiveness," by Martin et al. 2020. They note: "Sounds from vessels are normally considered non-impulsive; however, 66% of vessels analyzed were impulsive when weighted for very-high frequency mammal hearing . . . vessel sounds that generate high kurtosis when VHF-C auditory frequency weighted are a mix of rubbing and rasping sounds, cavitation sounds, and mechanical knocking." Although there is no generally accepted definition of "impulsive" or "non-impulsive" sounds, it makes sense to include the kurtosis as a feature in studies of the effect of sound on marine animals.

## Ship Sound Signals

In order to be able to systematically investigate which features of ship sound are the most harmful to aquatic animals, it is proposed to apply synthesized sound signals with independent variation of the relevant sound features. An earlier example of synthesizing ship sound was presented by (Yağımlı and Sertlek 2013).

Selection of a harmonized set of representative test signals depends on the intended application of these signals. The following assumptions were made:

- In SATURN. the playback signals are mainly required for controlled exposure experiments in the laboratory on fishes and invertebrates.
- The main frequency range of interest for these experiments is between approximately 10 Hz and 1 kHz.
- The primary interest is in the effects of stationary "continuous" sound from ships transiting at constant speed and course.
- The main sound feature of interest is the *broadband sound level*. Here "sound level" can refer to either sound pressure level or the level of sound particle displacement, velocity or acceleration, in a specified frequency bandwidth. The sound level to which animals are exposed in playback tests depends on the design of the laboratory setup and the playback system.
- The next feature of interest is the *spectrum* (frequency content) of the signal. This depends on the combination of test signal and playback system. Where appropriate, the test signal can be adapted to correct for the characteristics of the playback system. Design of the appropriate spectrum for the test signals depends on information about the frequency sensitivity of the species that is being investigated as well as on the characteristics of the sound source and environment. The presence of dominant "tonal sounds" in the spectrum may be relevant for behavioral response studies.
- Another potentially relevant sound feature for behavioral response studies is the temporal variation of the exposure (*amplitude modulation*) and the corresponding perception of "fluctuations" and "roughness" of the sound.

The spectrum and the temporal structure have been included in the design of the test signals.

## Broadband Ship Source-Level Spectra

Average broadband source-level spectra of different classes of ships (transiting at constant speed and course) are predicted by the JOMOPANS-ECHO ship source-level model (MacGillivray and de Jong 2021). This model calculates the source-level spectrum $L_S(f)$ of ship as a function of speed, length, and (AIS) ship type. The model is based on the statistics of a large database of ship source-level measurements from the Vancouver Fraser Port Authority-led Enhancing Cetacean Habitat and Observation (ECHO) program.

In a subsequent vessel noise correlation study, again carried out in the ECHO program, MacGillivray et al. 2020 confirmed that "speed through water and actual vessel draft (i.e., the two primary operational parameters) were generally the most influential predictors for underwater noise," while "vessel size (represented via length overall) was ranked as the design parameter with the strongest correlation to underwater radiated noise." An important feature is that "the loud vessels exhibited a distinct cavitation noise hump near 50 Hz, as e.g. discussed by (Wittekind and Schuster 2016), whereas the quiet vessels exhibited a flatter spectrum below 100 Hz." Such a "hump" is tentatively included in the JOMOPANS-ECHO model for all cargo vessels (container ships, vehicle carriers, bulkers, tankers). The origin of the hump in the radiated noise spectrum is still unexplained. It may be due to propeller vortex cavitation, but the Lloyd mirror effect and cavitation excited hull-plate vibrations also have an effect.

The JOMOPANS-ECHO ship source-level model calculates the ship source-level spectrum, for an assumed fixed source depth of 6 m below the water surface. The received sound in a given environment will depend on the propagation conditions. These will affect the shape of the sound spectrum. For the synthesis of ship sound signals, a deepwater Lloyd mirror propagation loss correction such as suggested by ISO 17208-2 has been incorporated, to avoid overemphasizing the lower frequencies in the playback spectrum.

Two widely different source-level spectra have been taken to construct the following two synthetic ship signals:

A. Broadband continuous sound (10 Hz–4 kHz) for a typical fishing boat of 50 m length at a speed of 11 knots (5.7 m/s).
B. Broadband continuous sound (10 Hz–4 kHz) of a typical large containership of 300 m length at a speed of 18 knots (9.3 m/s)

## Ship Signal Synthesis

To generate the corresponding time signal, the following steps are taken:

1. Select duration ($T = 10$ s) and sample frequency ($f_s = 2^{13}$ Hz $= 8192$ Hz ). This also determines the following parameters:
   (a) Time resolution: $\delta t = 1/f_s \approx 0.122$ ms.
   (b) Number of samples: $N = T \cdot f_s = 81920$
   (c) Nyquist frequency: $f_{\max} = f_s/2 = 4096$ Hz
2. Evaluate the source-level spectrum at discrete frequencies $f_k = k \cdot \delta f$, with frequency resolution $\delta f = 1/T = 0.1$ Hz and $k = 1..N/2$.
3. Convert to spectral density:

$$L_{S,f}(f_k) = L_{S,\mathrm{ddec}}(f_k) - 10\log_{10}\left(\left(10^{\frac{1}{20}} - 10^{-\frac{1}{20}}\right) \cdot \frac{f_k}{1\ \mathrm{Hz}}\right)\ \mathrm{dB}$$

4. Convert to root-source factor with amplitude $Y(f_k)$:

$$Y(f_k) = 10^{\frac{L_{S,f}(f_k)}{20\ \mathrm{dB}}} \cdot 1\ (\mu\mathrm{Pa\ m})^2/\mathrm{Hz}$$

5. Convert this one-sided spectrum to a full double-sided Fourier spectrum:

$$Y'(f_k) = \begin{cases} 0, & \text{for } k = 0 \\ Y(f_k), & \text{for } k = 1..\left(\frac{N}{2}+1\right) \\ Y(f_{N-k}), & \text{for } k = \left(\frac{N}{2}+2\right)..(N-1) \end{cases}$$

6. Next, add a random phase $\phi_k$ (uniformly distributed in the range $0..2\pi$, with $\phi_0 = 0$) to each element of the spectrum, to represent random noise:

$$Y_k = Y'(f_k) \cdot e^{i\phi_k}$$

7. Apply the inverse Fourier transform and keep the real part:

$$y_n = \mathrm{Re}\left\{\frac{1}{N}\sum_{k=0}^{N-1} Y_k e^{\frac{i2\pi kn}{N}}\right\}$$

8. Normalize to the maximum amplitude in the resulting time series to generate the sound signal for playback: $y(t_n) = y_n/\max(|y_n|)$, so that the amplitude in the wav file is in the range $[-1\ ..\ 1]$. The amplitude at which the signal is played back will depend on test configuration, equipment, and settings.

### Amplitude Modulation

The temporal structure ("roughness") associated with blade rate amplitude modulation is added in the next two signals:

A. Fishing boat signal A enhanced with blade rate amplitude modulation, representing a single four-bladed propeller rotating at 180 rotations per minute (rpm). This corresponds with a blade passing frequency ($f_b$) of 12 Hz.
B. Containership signal B enhanced with blade rate amplitude modulation, representing a single five-bladed propeller rotating at 90 rotations per minute (rpm). This corresponds with a blade passing frequency of 7.5 Hz.

The amplitude modulation is incorporated in the sound signal by multiplying the times series $y(t_n)$ with an amplitude modulation function:

$$y_{\mathrm{am}}(t_n) = y(t_n) \cdot [1 + A_{\mathrm{am}} \sin(2\pi f_b t_n)]$$

The modulation amplitude $A_{\mathrm{am}}$ is not generally known. The test signals are synthesized with a tentatively assumed $A_{\mathrm{am}} = 0.25$.

## Tonals

Next, the spectral structure is modified by adding tonals in the following signals:

A. Fishing boat signal A enhanced with tonals at propeller blade rate (12 Hz) harmonics and at harmonics of a ship service diesel generator (30 Hz and harmonics).
B. Containership signal B enhanced with tonals at propeller blade rate (7.5 Hz) harmonics and with two dominant tonals at 350 Hz and 580 Hz, as observed by McKenna et al. 2013.

The following signals represent the combination of amplitude modulation and tonal structure:

A. Fishing boat signal C enhanced with tonals at propeller blade rate (12 Hz) harmonics and at harmonics of a ship service diesel generator (30 Hz and harmonics).
B. Containership signal B enhanced with tonals at propeller blade rate (7.5 Hz) harmonics and with two dominant tonals at 350 Hz and 580 Hz.

The tones are added via the following:

$$y_{\mathrm{t}}(t_n) = y(t_n) + \sum_{m=1}^{M} A_{\mathrm{t},m} \sin(2\pi f_m + \phi_m)$$

The phase angles $\phi_m$ of the individual tonals are randomly drawn from a uniform distribution between 0 and $2\pi$.

**Table 1** Statistical properties of the audio signals for the synthesized ship sound signals. Different spectral features are represented by the two ship types and the signals with and without tonals; different temporal features are represented by the signals with and without amplitude modulation. The zero-to-peak levels are equal to 0 dB, indicating that the signals in the wav files are normalized relative to the maximum amplitude in the 10-s signal. In playback studies, the properties will be modified by the playback system

| | Signal | $L_{pk}$ [dB] | $L_{rms}$ [dB] | Kurtosis $\beta$ |
|---|---|---|---|---|
| A | FishingBoat_broadband.wav | 0 | −13.4 | 3.01 |
| B | ContainerShip_broadband.wav | 0 | −13.2 | 3.06 |
| C | FishingBoat_broadband_modulated.wav | 0 | −14.1 | 3.34 |
| D | ContainerShip_broadband_modulated.wav | 0 | −13.2 | 3.42 |
| E | FishingBoat_broadband_tonals.wav | 0 | −12.3 | 2.93 |
| F | ContainerShip_broadband_tonals.wav | 0 | −12.3 | 2.89 |
| G | FishingBoat_broadband_modulated_tonals.wav | 0 | −14.7 | 3.27 |
| H | ContainerShip_broadband_modulated_tonals.wav | 0 | −12.0 | 2.96 |

### Ship Signal Spectra

The statistical properties of the signals are given in Table 1. The peak level and the kurtosis are calculated over the 10 s signal. The scaled root-mean-square level ($L_{rms}$) is calculated over 1-s segments of the signal, with 50% overlap and a Hann window, and then averaged. Figures 1 and 2 show corresponding waveforms and spectra.

## Conclusions

This chapter describes an approach for selecting and synthesizing ship underwater-radiated sound signals for playback studies. This approach has been applied to generate eight test signals for laboratory studies in the EU Horizon 2020 project SATURN, representing various aspects of the radiated sound of a large containership as well as a typical fishing vessel. Signals are available from https://www.saturnh2020.eu/resources proposed in this chapter and can easily be extended to synthesize signals that are independent of the average spectra of ships but focus on specific sound features, such as band-limited noise, transient signals, or tonal sounds, if required by the test hypotheses for the controlled exposure studies. These could, for example, represent the transient sound due to switching of engine or gear or tonal sound from propeller singing such signals.

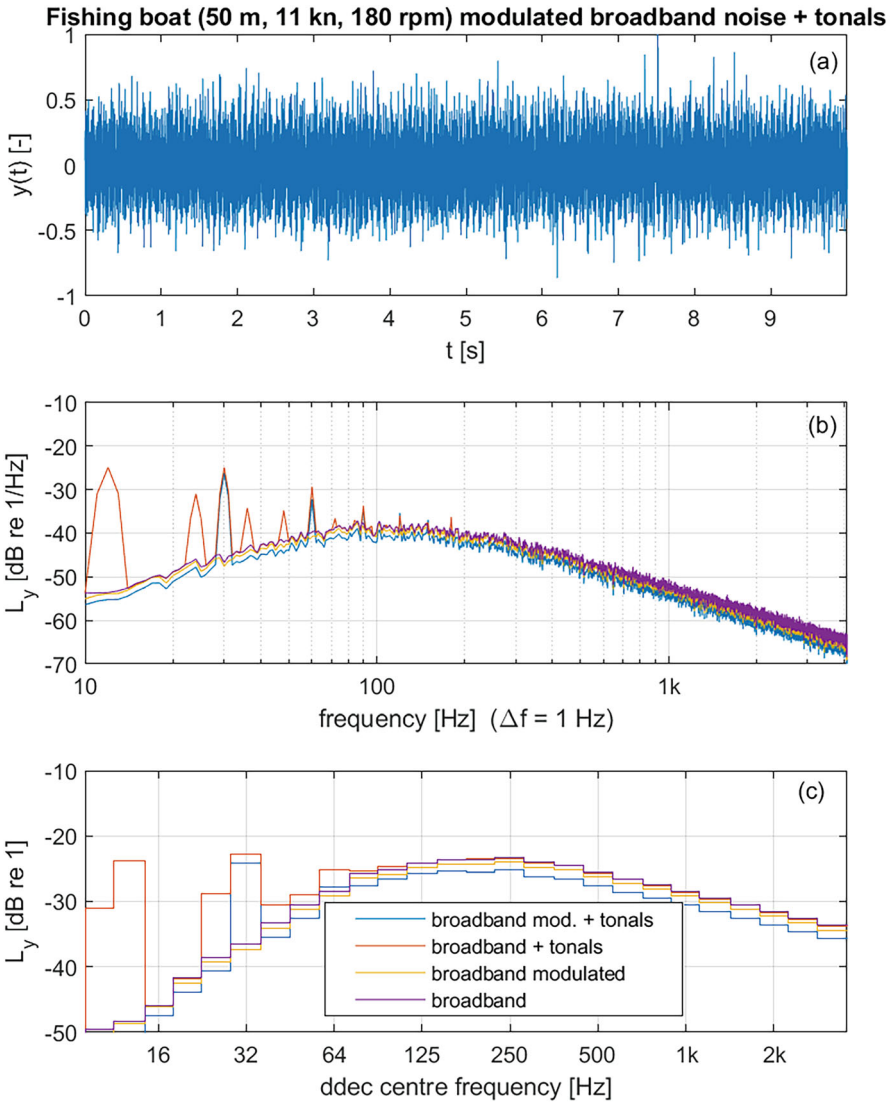

**Fig. 1** Waveform (**a**), narrowband spectrum (**b**), and decidecade spectrum (**c**) of the fishing boat sound signal G that represents the blade rate-modulated broadband noise plus tonals (in blue). The spectra are compared with those of the sound signals A, C, and E, without tonals and without modulation, scaled so that the total power in the spectra is equal for the three signals

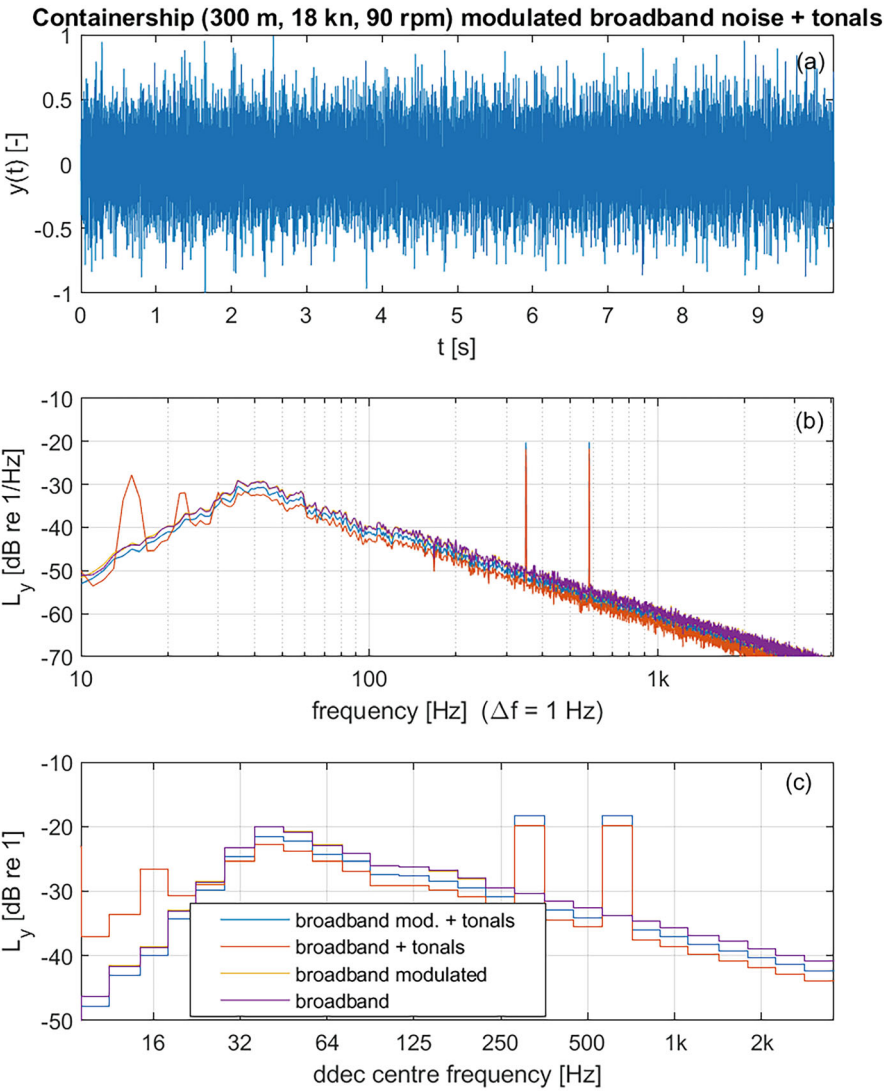

**Fig. 2** Waveform (**a**), narrowband spectrum (**b**), and decidecade spectrum (**c**) of the containership sound signal H, that represents the blade rate-modulated broadband noise plus tonals (in blue). The spectra are compared with those of the sound signals B, D, and F, without tonals and without modulation, scaled so that the total power in the spectra is equal for the three signals

**Abstract**

Underwater noise is legally recognized in the European Union as a pollutant of the marine environment. An increasing number of countries are initiating monitoring programs to study the levels of underwater noise. There is a need to compare these levels as well as share experience in order to forecast possible monitoring difficulties. This chapter shows that levels of underwater noise in the Baltic Sea (Poland) and in the Mediterranean Sea (Malta) were similar in the given monitoring periods as were the issues met during work. The article also presents a summary of the studied impact of underwater noise on organisms found in both localities. Based on the analysis, it can be deduced that species living in both localities can be negatively affected by the present noise. Actions are required to control and minimize underwater noise in both places. Although there are studies showing impacts of noise on aquatic organisms, there is still a lot of data missing. Dedicated programs should be created to make it

## Introduction, Motivation, and Aim of the Study

This is a perspective of an oceanography student who happened to study both in Poland and Malta as well as of scientists from both countries. Monitoring was carried out in these countries to evaluate the levels of noise in the coastal waters. The aim of this work is not only to compare the data but also to highlight how common the problem of underwater noise is, how important it is for future studies to cooperate, share knowledge and monitoring experience. Scientists from other countries (e.g. Morocco) are also expressing their interest in the problem (Chahouri et al. 2021) and might as well attempt to measure levels of underwater noise.

Noise is recognized as a pollutant of the marine environment by law according to the European Union Marine Strategy Framework Directive (MSFD) Descriptor 11 as well as within Regional Sea Conventions (e.g. the Barcelona Convention, the Helsinki Convention). Nevertheless, the problem has not been sufficiently explored and addressed. Another part of this work will present information gathered from published studies on the impacts of underwater noise for the organisms observed in the Baltic Sea in Poland and in the Mediterranean Sea in Malta. The aim of the summary is to emphasize the seriousness of this issue as well as to point out the need for more studies. A great complexity of the phenomenon of underwater noise pollution requires combined efforts of many people (e.g. policymakers, scientists, etc.).

## Monitoring in Malta and Poland

Data in Malta were obtained from the preliminary deployment of an underwater noise meter. Monitoring took place over 44 days. In this analysis, recordings collected consecutively over 15.2 days were used (30/06/2020 to 16/07/2020). The data were collected using the "SoundTrap ST300" by "Ocean Instruments" instrument model (Fig. 1). This was deployed at a depth of 30 m just outside Valetta's Grand Harbor.

Data in Poland were obtained from the Baltic Sea Information on the Acoustic Soundscape (BIAS 2023) program monitoring (Sigray et al. 2016) – one out of five stations has been chosen (located in the Gulf of Gdańsk) for the aim of the comparison and the monitoring was done throughout the year 2014. The data were collected using WildLife Acoustics SM2M (Fig. 2). It was deployed at a depth of 71 m. As the noise logger was in an area in which trawling takes place, a protective cage was used.

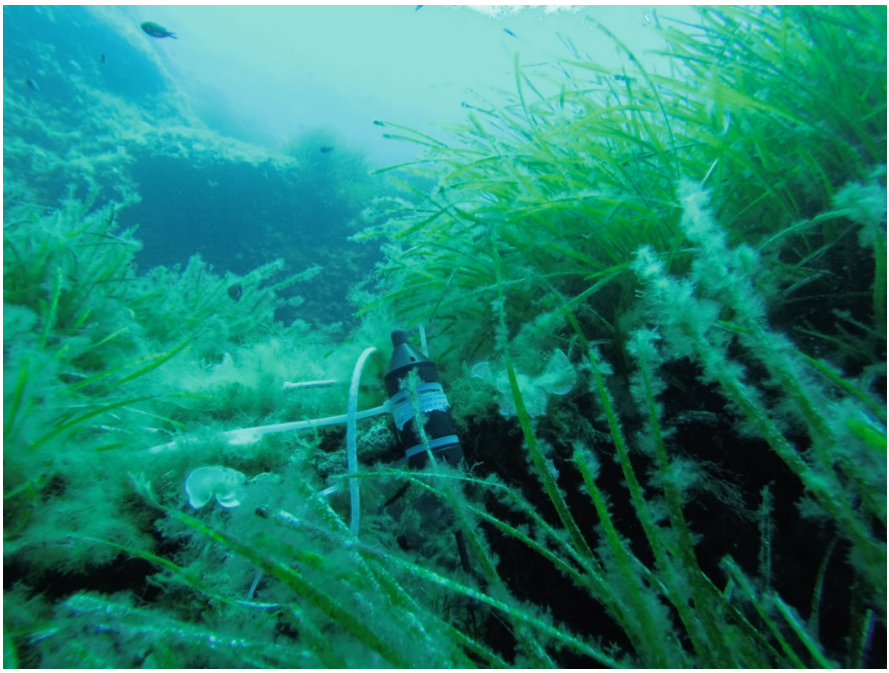

**Fig. 1** Noise logger in Malta – Ocean Instruments SoundTrap ST300

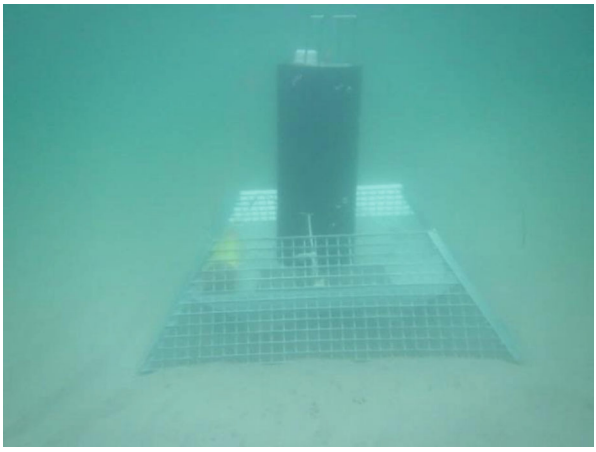

**Fig. 2** Noise logger in Poland – WildLife Acoustics SM2M secured with a metal cage

The comparison of data collected in Poland and Malta was focused on the frequencies 63 Hz and 125 Hz, which are usually the indicator of the low-frequency sound produced mostly by vessels (Mustonen et al. 2019).

Sound pressure levels (SPL) were obtained and compared as percentage exceedance levels. The 90% exceedance level of 77.1 dB re 1 μPa meant that for 90% of time the sound recorded was exceeding 77.1 dB. (For more information regarding general underwater noise monitoring, see Dekeling et al. 2014.) In both locations 90% of the time SPL were exceeding 70 dB re 1 μPa. As a result of comparison, although Poland had slightly lower SPL, both locations are characterized by very similar and high SPL for low-frequency sounds (63 Hz, 125 Hz).

Although Malta and Poland are far away from each other, and their coastal waters differ greatly in many characteristics, they both share the same problem of underwater noise pollution.

The monitoring locations were associated with shipping traffic, which explains the high levels of underwater noise. It is worth to notice that the monitoring of underwater noise should be focused on regions of particular importance for marine organisms. Nevertheless, due to the ubiquity of shipping traffic, the resulting underwater noise can impact multiple species in various areas. It can particularly affect organisms that require large areas to live, leading to noise pollution, chemical pollution, ship strikes, and habitat fragmentation (Pirotta et al. 2019) (Figs. 3 and 4).

## Different Basins, Same Challenges – On the Importance of Sharing Experience

Both research groups had to deal with a displacement of the monitoring equipment. In Poland, it was caused by trawling nets. Therefore, noise loggers were further secured using protective cages. In Malta one of the loggers was lost due to strong currents or fishing nets. This example clearly shows that sharing information about

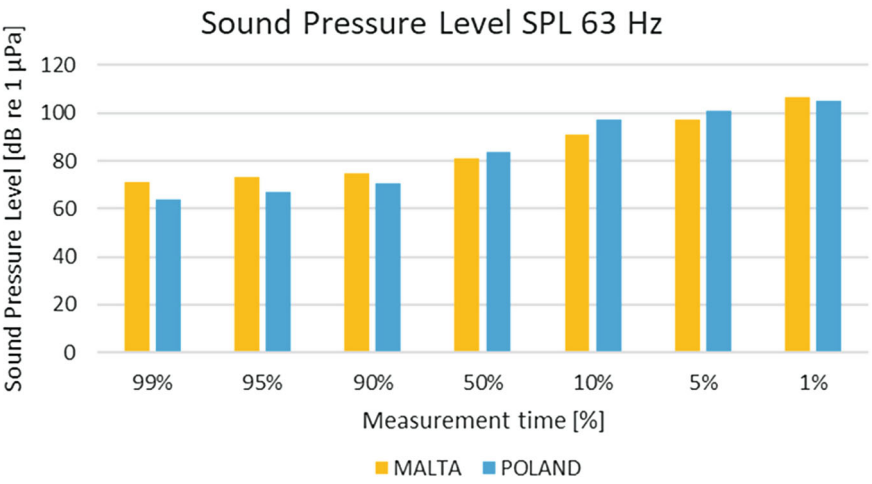

**Fig. 3** Comparison of the exceedance levels of SPL (63 Hz) between Poland and Malta

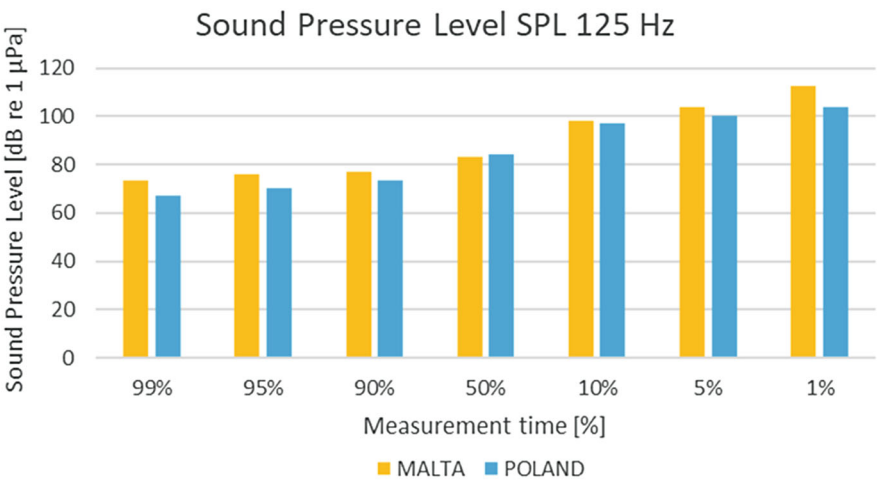

**Fig. 4** Comparison of the exceedance levels of SPL (125 Hz) between Poland and Malta

the problems met and ways to deal with them can help researchers avoid disturbance of the monitoring and additional costs. It also indicates that common protocols for data collection need to be presented.

## The Known Impact of Noise on Aquatic Organisms Found in the Baltic Sea (Poland) and the Mediterranean Sea (Malta)

Monitoring of underwater noise is not enough. Data on how such noise can influence organisms that live in the region is necessary in order to properly address the issue. Hence, information on how noise can influence some of the organisms that exist in the Baltic and Mediterranean Sea has been summarized in Tables 1, 2, 3, and 4.

This preliminary study intends to emphasize the real threat imposed by underwater noise levels. Studies already show the negative impacts of underwater noise on organisms. However, more studies are required to properly assess and address this issue.

The summary indicates that boat noise is a cause of multiple negative effects for organisms found both in the Baltic and in the Mediterranean Sea (Tables 1, 2, 3, and 4). Based on the monitoring data from Malta and Poland that has shown high levels of noise for the frequencies 63 Hz and 125 Hz that can be used as indicators of boat noise it can be assumed that species living in both localities could be negatively affected by the present noise. Thus, actions are required to control and minimize underwater noise pollution in both places.

It is worth adding that noise caused by explosions and other naval activities can be a cause of some animals being stranded (Table 3). Conflicts and wars are known for causing cetaceans strandings (Mahreen 2022). An example of this can be how the

**Table 1** Species of mammals that occur in the Baltic Sea (Poland)

[a]*CR* critically endangered, *(EN)* endangered, *VU* vulnerable, *NT* near threatened, *LC* least concern, *DD* data deficient

Russia's invasion of Ukraine and the naval activities involved in the war have been recently mentioned in grey literature as a possible cause of increased numbers of stranded cetaceans along the coast of the Black Sea (Kroeger 2023).

Some of the species that are negatively influenced by underwater noise pollution have been assessed as critically endangered (e.g., harbor porpoise and european eel) (IUCN 2022). Furthermore, underwater noise is not the only problem that is affecting them. Chemical pollution, overfishing, and global warming are also a major threat. Together these can cause cumulative detrimental effects. With echolocation, harbor porpoises already find it difficult to detect fishing nets in time to avoid collision (Kastelein et al. 2000). Anthropogenic noise can add to their problems. On the other hand, acoustic deterrents might help cetaceans and other animals not to fall victim to bycatch. It can be also a challenge to use acoustic deterrents that would be effective but not harmful for the marine environment.

Some studies on the influence of noise on organisms are outdated and there is still a lot of data missing. It could be investigated how noise affects marine organisms based on the studies that are available and the similarities between different species, e.g. fish that have a swim bladder usually have higher hearing sensitivity than fish that do not have it (Wiernicki et al. 2020). At the same time, fish, as Friedrich Ladich observed, can be called "insects" among vertebrates, giving their variety that includes variety of their hearing organs (Ladich 2014). For that reason, one has to be cautious when making assumptions about how noise influences fish in general based on the studies on some of their species. More data is needed to introduce and enforce legislation. As the European Union Marine Strategy Framework Directive states, one of the descriptors of good environmental status of the marine environment is introduction of noise at levels that do not adversely affect the marine environment. Therefore, there is a need to assess these levels and control them.

**Table 2** Fish species that occur in the Baltic Sea (Poland)

| Species | Observed impact of noise | Type of noise | Reference | The IUCN Red List Category[a] |
|---|---|---|---|---|
| **Atlantic Cod** (Gadus morhua) | Stress response (increased cortisol levels);<br>Freeze reaction;<br>Lower fertilization rate (lower spawning performance);<br>Lower viability | Noise generated in the laboratory with a frequency range of 100–1000 Hz | Sierra-Flores et al. (2015) | VU |
| | More frequent startle reaction of newly hatched fish when exposed to noise;<br>Larvae exposed to regular noise used their yolk sacs faster after 2 days of exposure to noise;<br>Survival-related factors during development can be influenced by the timing of noise | Ship noise recordings | Nedelec et al. (2015) | |
| | Flight reaction | Trawling | Ona (1988) | |
| | Masking | Broad-band noise | Hawkins and Chapman (1975) | |
| | Lowering abundance | Seismic shooting | Engås et al. (1996) | |
| **European Eel** (Anguilla anguilla) | Compromised antipredator behavior (becoming easier prey);<br>Diminished spatial performance;<br>Increased ventilation and metabolic rates (stress) | Recordings of ships passing through harbors | Simpson et al. (2015) | CR |

## Ideas to Implement

At the moment, studies are done ad-hoc. Common standards need to be applied (e.g. Adeon project, ADEON 2023, Ainslie et al. 2018, Warren et al. 2018) so that all data collected can be more easily compared. A common and updated base of data on the underwater noise levels as well as the resulting influence on the marine environment and its organisms could prove to be a useful tool to improve regulations and work practice when it comes to activities that can introduce noise to the marine environment.

Finally, it is important to popularize knowledge about this issue both among the general audience, ship owners as well as scientists and students. Dedicated programs should be created to make it possible for them to get involved in addressing this problem (e.g. citizen science programs, study programs, internships, training programs).

**Abstract**

Previous investigations into the effects of impulsive anthropogenic noise in the marine environment have focused on mammals, while few have focused on how harvested demersal species may respond behaviorally to this sound. This chapter assesses the impacts of noise borne from a geophysical seismic survey of the Cascadia Subduction Zone along the Oregon coast on the movement and

behavior of three fish – lingcod, black rockfish, and China rockfish – and Dungeness crab using telemetry data from an in situ tagging effort in summer 2021 before, during, and after the geophysical seismic survey. Received sound levels were obtained using a vector sensor array and are presented in Raghukumar et al. (this issue). To understand whether the soundscape influences short-term behavior, patterns in detected acceleration and depth were analyzed. Preliminary results presented in this chapter suggest that there are differences in black rockfish instantaneous acceleration as well as distance from the surface in the defined "during" and "after" periods of time as the research vessel passed near the area as compared to the "before" period. There were also differences in China rockfish acceleration during and after as compared to before the period of noise, but there was little difference in acceleration values after the noise event compared to during.

## Introduction

Sound is a crucial aspect of the underwater environment for fishes – various species use sound to communicate, identify predators, navigate, and many other activities needed for survival in their habitat (Montgomery et al. 2006, Carroll et al. 2017). Disruptions and disturbances in the natural soundscape can have important impacts on all these activities and likely have important implications for the functioning of the ecosystem at large (Rossi et al. 2016). Human-generated noise has become increasingly prevalent in the past few decades (Slabbekoorn et al. 2010; Duarte et al. 2021) as humans explore more of the oceans, extract resources, and increase global commerce. In the northeast Pacific, marine species are impacted by ever-increasing levels of acute and chronic anthropogenic noise (Hildebrand 2009), as human activities offshore are increasing in frequency and magnitude; pile driving, offshore renewable energy, and seismic surveying are all becoming more commonplace (Frisk 2012). Many large-scale activities in the ocean are accompanied by regulation and required discussion on the impact that noise generated by such activities may have on the ecosystem using best-available science. However, most of the available research is focused on charismatic and well-studied marine mammals (Hawkins and Popper 2017). Current regulatory decisions regarding the impacts of noise-generating activity are being made with relatively little research that focuses on noise impacts on fish and other demersal organisms. This has been identified as a significant issue for the conservation of aquatic life, as noise can affect myriad aspects of the ecosystem. For example, noise can mask acoustic communication in fish (Codarin et al. 2009). This paucity of data on nonmarine mammal effects has been a point of concern for recreational anglers, commercial fishers, as well as resource managers. There is clearly a significant need for further research and attention on this issue to protect fisheries and conserve ecosystems in the northeast Pacific.

In the summer of 2021, a geophysical seismic survey was conducted along the northwest coast of the United States, mapping the Cascadia Subduction Zone off the shores of Oregon and Washington with an array of 36 air guns. This event was a rare opportunity to observe the behaviors of demersal fish in situ to an infrequent energetic noise stimulus. In this chapter, behavioral responses were examined in two rockfish species – black rockfish, *Sebastes melanops*, and China rockfish, *S. nebulosus*. The study was completed within the Redfish Rocks Marine Reserve (RRMR) in Southern Oregon as the geophysical survey research vessel made three passes near the area, allowing for replicate observations, and previous data shows site fidelity of rockfish within this marine protected area (Calvanese 2016). Previous *s*tudies of rockfish (genus *Sebastes*) responses to seismic survey noise used animals in field enclosures with only a single air gun (Pearson et al. 1992), so little is known about how they may respond to the differing aspects of seismic survey noise in situ and how habitat use of specific species will influence their behavioral responses to the noise. The study aims to assess how behavioral metrics differed between the two rockfish species in response to a changing soundscape, and this chapter includes preliminary results of the analyses.

## Methods

A vector sensor array of hydrophones (the NoiseSpotter®, Raghukumar et al. 2020) was deployed in the Redfish Rocks Marine Reserve (RRMR) near Port Orford, Oregon, USA, at 36-meter depth near the rocky reef structures within the site to measure the received acoustic levels corresponding to the three passes of the seismic survey research vessel. Further methods and data on changes in the soundscape before, during, and after the seismic survey passes are described in Raghukumar et al. (this issue). Three days with detectable air gun pulses were identified – June 11, 17, and 18 – within the 52-day study period (May 20 – July 11). Periods of the study are defined as before (prior to June 11), during (June 11, 17, and 18), and after (after June 18). Raghukumar et al. (this issue) report cumulative sound exposure levels (cSEL) were highest on June 11 but also note an increase in cSEL in the after period as compared to before due to high wind speeds.

An array of 45 Vemco VR2W acoustic receivers (Innovasea Systems, Nova Scotia) was also deployed within the RRMR for overlapping coverage of the site and to enable triangulation of acoustically tagged animal positions (Fig. 1). Three fish species were captured – lingcod, *Ophiodon elongatus*, black rockfish, and China rockfish (using hook and line gear) – and one invertebrate, Dungeness crab, *Cancer magister*, (using crab pots) for tagging. Fifteen individuals of each species were tagged with Vemco acoustic tags (V13A) to capture acceleration and position as well as depth (using V13AP tags) for the semi-pelagic black rockfish.

Most lingcod and Dungeness crab individuals tagged in this study exited the acoustic array either before or during the period of the seismic survey, although some lingcod returned after the survey (Fig. 2). Due to low sample sizes for these two species during the periods of the seismic survey noise, it is not possible to ascertain

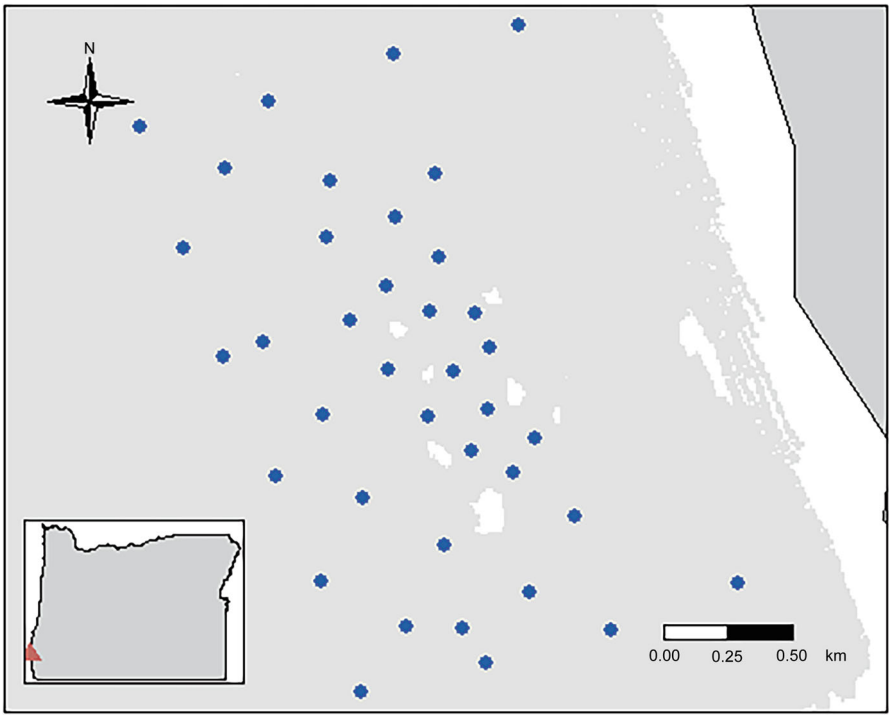

**Fig. 1** Acoustic receivers deployed in the RRMR in Southern Oregon. White polygons within the array depict emergent rocks in the marine reserve

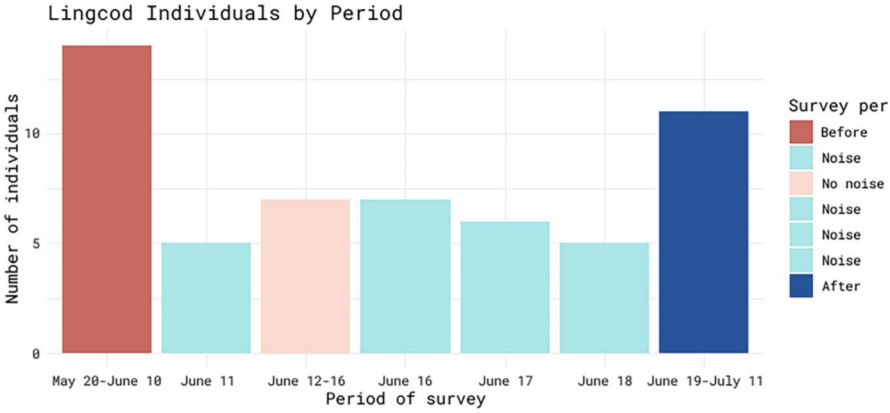

**Fig. 2** Number of lingcod individuals detected in each of the study periods

whether there are any behavioral changes due to the noise, so no further analyses for Dungeness or lingcod are presented in this chapter.

To standardize the total number of observations for comparisons of behavioral patterns, 3 full days within each of the before and after periods (6 total) were randomly

chosen to compare to the 3 days with the seismic survey vessel presence (defined as the during period). These same days were used for analyses of both rockfish species. Violin plots with means were used to visually assess differences in acceleration values for each rockfish species. Differences in acceleration values (and depth for black rockfish) among periods were tested with a mixed-effects model, with study period as a fixed effect and transmitter (i.e., individual), water temperature (degrees Celsius), and salinity as random effects. As a proxy for spatial use, the number of unique acoustic receivers that each rockfish individual was detected on for each period of the study and a repeated measures ANOVA were used to compare between periods. All analyses were conducted using RStudio; important packages included lubridate for working with dates and times (Grolemund and Wickham 2011), ggplot2 for data visualization (Wickham 2016), and lme4 for analyzing mixed-effects models (Bates et al. 2015).

## Results and Discussion

Black rockfish had more incidences of higher acceleration (Fig. 3) in the survey periods with detected air gun pulse noise (mixed-effects model, $p < 0.001$ for survey period) as compared to before. Post hoc Tukey tests showed a significant difference for before to June 11 ($p = 0.0002$, coefficient estimate $= 0.547$ m/s$^2$), before to June 17 ($p = 0.0096$, coefficient estimate $= 0.378$ m/s$^2$), and before to June 18 ($p = 0.0036$, coefficient estimate $= 0.374$ m/s$^2$). Potential habituation over the three passes of the seismic survey vessel was observed as the coefficient of the change in acceleration values decreased for each of the dates with detected air gun pulse noise.

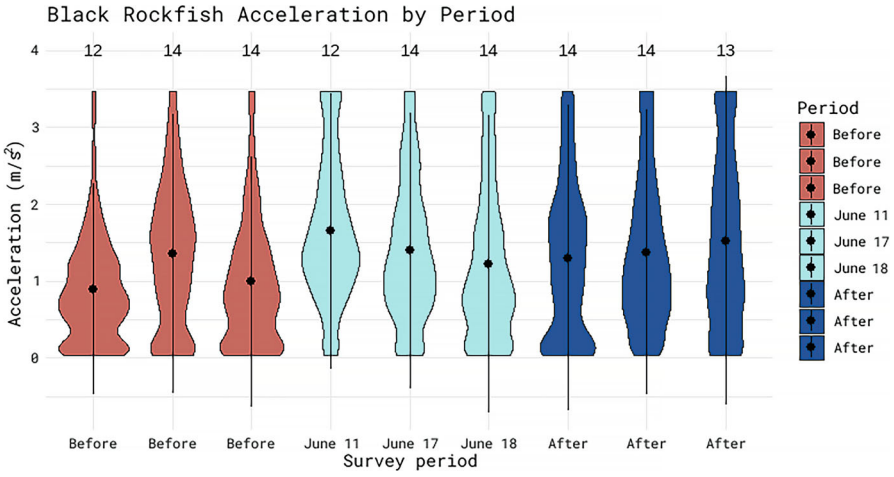

**Fig. 3** Distributions of black rockfish acceleration values within each of the selected study days. Numbers above the plots depict the number of fish included in each date. Each of the study dates with noise from the seismic survey had higher acceleration values than the average of the before days. The average of the after days was also higher than before

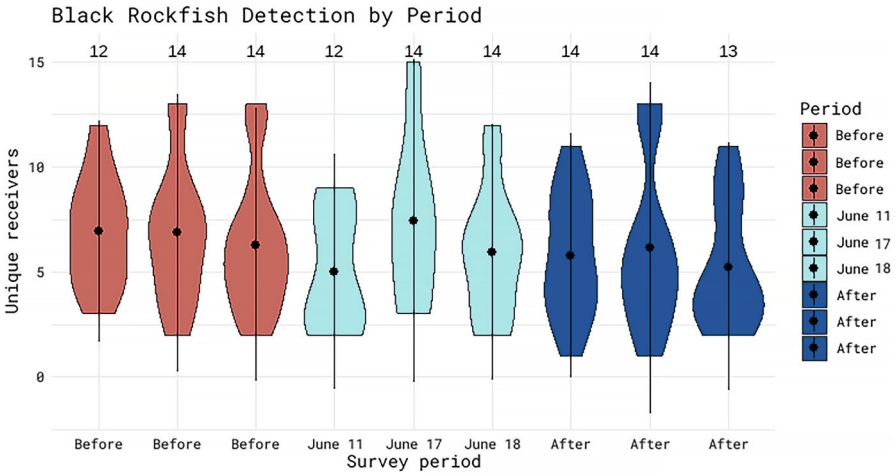

**Fig. 4** Number of unique receivers black rockfish individuals were detected on for each of the selected study days

The acceleration in the after period was also significantly greater than the before period ($p < 0.0001$, coefficient estimate $= 0.34$ m/s$^2$), but the after period was not different than any of the during dates. This behavioral response aligns with what is known about black rockfish behavior (Love et al. 2002, Hannah and Rankin 2011); individuals of this species are more mobile than other rockfish species, and startle responses are what we might expect in response to a noise disturbance. Black rockfish appear to traverse less area on two of the dates in the during period, as they were detected on fewer receivers (Fig. 4) as compared to the before period. A repeated measures ANOVA assessing the number of receivers an individual was detected on over each period (average of 3 randomly chosen days) showed that the date of the survey was significant for the number of receivers for individual black rockfish ($p = 0.043$). Post hoc tests further show a significant difference between the before and after period ($p = 0.03$). The difference in number of receivers between the before and during periods also appears interesting, although not statistically significant ($p = 0.17$), as there is a large amount of variability in the number of unique receivers fishes were detected on in the during period. Overall survey period was not significant for variability in black rockfish depth positions, although post hoc tests show significant differences in pairwise comparisons between before and June 11 ($p = 0.0186$, coefficient estimate $= -2.24$ m) and June 11 and after ($p = 0.0058$, coefficient estimate $= 2.25$ m). These estimates show that black rockfish traveled up in the water column (negative depth indicates closer to the surface) on the first day of the pass of the survey vessel and then further down in the water column in the after period as compared to the initial survey period. However, further exploration into the bathymetry of the site should be conducted to convert distance from surface to height off the bottom, as the distance from the seafloor may be more ecologically relevant than distance from the water's surface due to the highly rugose seafloor, including emergent rocks, within the study area.

China rockfish acceleration values were higher in the first day of seismic survey noise and in the after period with high wind-generated noise as compared to the before period (Fig. 5) (mixed-effects model, $p = 0.0093$ for survey period). Post hoc Tukey tests showed a significant difference for before to June 11 ($p = 0.0022$, coefficient estimate $= 0.413$ m/s$^2$) and before to after ($p < 0.0001$, coefficient estimate $= 0.171$ m/s$^2$). Overall, this species appears to have a smaller use area within the RRMR than the black rockfish (Fig. 6); this is expected as this species is

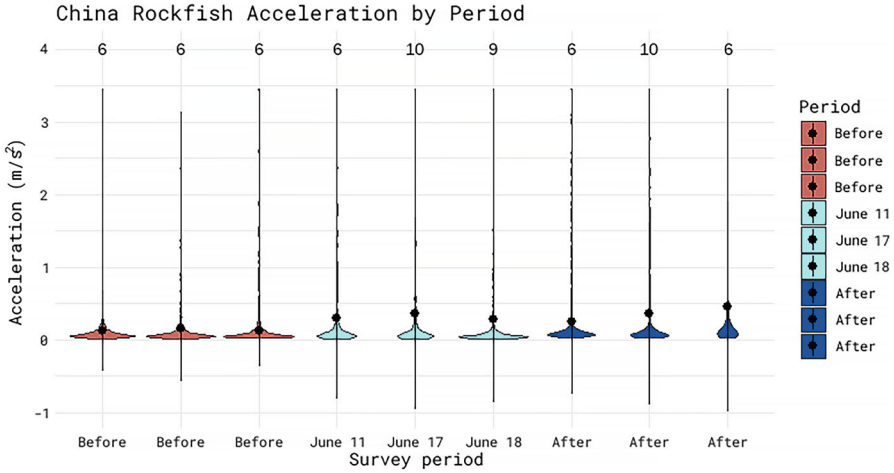

**Fig. 5** Distributions of China rockfish acceleration values within each of the selected study days. Numbers above the plots depict the number of fish included in each date. The first date with noise from the seismic survey (June 11) had higher acceleration values than the average of the before days. The average acceleration across the after days was also higher than before

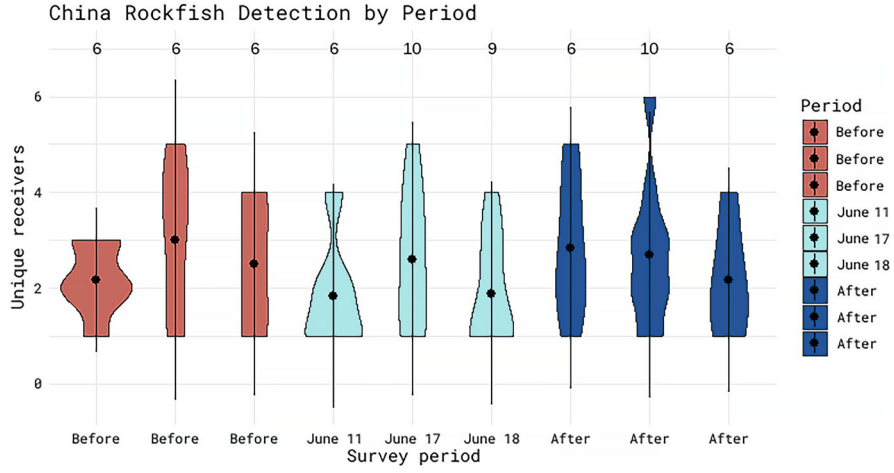

**Fig. 6** Number of unique receivers China rockfish individuals were detected on for each of the selected study days

known to move around less than black rockfish. A repeated measures ANOVA for the average number of receivers each individual was detected on over three periods (before, during, after) shows no significant difference between periods ($p = 0.279$). All post hoc pairwise tests show no significant differences in comparisons. China rockfish may be staying near high-quality rocky habitat at all times, not just in times of noise disturbance.

## Conclusions

An understanding of how anthropogenic noise impacts the soundscape is important to understanding potential effects on species that exist along the Oregon coast. The study in this chapter will contribute to an understanding of Oregon's nearshore, characterizing how fish will likely respond to increasing human activity and noise in the future, and is broadly applicable to the NE Pacific shelf as the study species range from California to the Aleutian Islands. Anthropogenic noise can influence fish movement which can impact other economic activities. Changing distributions of animals or increasing stress in the long term, for example, can affect fishing success. As Bejder et al. (2009) note, a decrease in a specific behavioral response (as our data indicate for black rockfish acceleration) or changes in tolerance may not be a habituation response, as there could be less visible physiological effects. Improper assumptions about fish response to chronic noise over time may have harmful impacts to species if a decrease in response is noted without further investigation, and approval for projects that generate chronic, constant noise in the ocean is granted. Noise impacts on lower trophic level species can also have bottom-up effects on top predators and/or highly migratory species with high economic value. Overall, there is a clear need for further research as well as attention by regulators and managers to the impact of anthropogenic noise on fish behavior, ecology, and physiology to ensure resilient nearshore ecosystems.

**Abstract**

Globally, invasive non-native species (INNS), due to anthropogenic activities, are a form of aquatic pollution that severely affects the environment, ecological diversity, and economics. INNS are often unconstrained by competition and predation, exploit resources throughout their range, and thus continuously expand into vulnerable environments. Isolation attempts, targeted removal, and intentional fragmentation involve the use of deterrents and barriers in freshwater systems to control species movement and population expansion. Underwater acoustics is currently the only non-structural deterrent or attractant that can be agnostic or specific to a group of fish based on their hearing range, thereby reducing ecosystem impacts and risk to humans compared to other non-structural technologies. In addition, the costs to deploy and maintain underwater acoustics systems can be significantly lower than other options. An

underwater acoustics deterrent system (uADS), along with an electrical deterrent, flushing, automated barge clearing deterrent, and dispersal bubble curtain, is proposed as a multi-deterrent system for Brandon Road Lock and Dam (BRLD; Joliet, Illinois, USA) on the Des Plaines River to control the spread of invasive carp. Herein, we will provide updates on the current deployments of uADS. Results of ongoing underwater acoustic research will help managers and stakeholders understand the effectiveness of uADS and, most importantly, provide considerations for introducing noise into an ecosystem and characterizing impacts on native species.

## Introduction

The United States Army Corps of Engineers (USACE) manages over 48,500 $km^2$ of public lands, 40,230 km of coastal and interior waterways and channels, 250 water resources projects, and globally supports other countries through technology exchange and subject matter expert (SME) knowledge access. Due to the complexity of habitats, structures, and missions, management of threatened and endangered (T&E) species and invasive non-native species (INNS) species are an ever-present issue for the USACE. Species management is further compounded by changes in the need for training operations, coastal development, aging infrastructure, removal of infrastructure, new navigation criteria, growing coastal and waterway human populations, and climate change. Land and aquatic species management, however, is conducted in such a manner that it complements the mission of the USACE and the surrounding areas (e.g., residential, urban, industrial). For this reason, the USACE often balances economic, social, and environmental needs by managing the impacts of the INNS, commercial and recreational activities on the environment, on navigation (and thus the economy), on humans and human safety, and on costs (near-term installation, long-term operation, and maintenance). As a result, the USACE has invested in and supported research and development of structural and non-structural deterrents (NSDs) and management alternatives for over two decades to reduce effects on T&E species or maximize impacts on INNS (Structural deterrents or barriers: They may have significantly different primary functions, such as water flow control structures, that result in a secondary impact, such as blocking or constraining species movements or passage. There are some physical barriers whose primary function is fish deterrent or removal, such as exclusions screens.) (Non-structural deterrents: They include any stimulus or non-solid obstruction that discourages or prevents a targeted species from passing through a region of interest. Non-structural deterrence systems [typically] do not constrain water flow or restrict navigation.). One of the better examples of long-term INNS efforts conducted by the

USACE is the electric barrier installed in the Chicago Area Waterway System (CAWS) (Fig. 1).

In the early 2000s, the USACE explored options to prevent the transfer of INNS between the Mississippi River and Great Lakes basins through the CAWS. The CAWS consists of five hydrologic pathways; however, only one, the Chicago Sanitary and Shipping Canal (CSSC) is an open connection between the Mississippi River and Great Lakes basins via the Chicago Harbor Lock at the confluence of the Chicago River and Lake Michigan in Chicago, Illinois, USA. The CSSC has previously allowed the movement of aquatic species between the basins. After the Eurasian Ruffe (*Gymnocephalus cernua) and the* Round Goby (*Neogobius melanostomus*) became established in the Great Lakes, there was sufficient concern that these species could spread into the Mississippi River Basin through the CSSC. The construction of a demonstration electric barrier in the CSSC was proposed and approved (Sparks et al. 2011) to reduce the likelihood of interbasin transfer of these two species. Subsequent barriers (Barrier IIA, IIB) were constructed in 2009 and 2011, respectively. In 2021 the demonstration electric barrier was upgraded to increase electrical output and is referred to as Barrier 1. The three barriers now operate to deter the spread of INNS, particularly invasive carp, from the Mississippi River to the Great Lakes (Veraldi et al. 2011; Parker et al. 2015). The operational parameters of the electric barriers were established based on tests with subadult Bighead and Silver Carps (Holliman et al. 2015). Currently, the adult population front of invasive carp is located approximately 75 km from Lake Michigan, with three locks and an electric barrier in between the carp and Lake Michigan (Fig. 1).

Even though electrical barriers allow for hydrological connectivity and navigation between the Illinois River and the Great Lakes, they have two critical disadvantages. The first disadvantage is the severe risk to humans and human safety, which has not resulted in a loss of human life. Secondly, the electrical barriers limit the migration of many native and desirable fish (estimated 80–100%) (Maceina et al. 1999; Holliman et al. 2015; Parker et al. 2015; Weber et al. 2016). The CAWS electric barriers are non-selective and, depending on settings, water quality, and the presence of commercial navigation, can result in the incapacitation, injury, and even mortality of any fish attempting to migrate through this corridor regardless of direction. This significant limitation to native species migration is a strong motivation for resource managers to continue to push for "selective" non-structural deterrents that function on desired INNS, or groups of fish, rather than all species.

## Invasive Carp

The spread of invasive carps (*Hypophthalmichthys molitrix*, *H. nobilis*, *Ctenopharyngodon idella*, and *Mylopharyngodon piceus*) continues to threaten aquatic ecosystems (Pegg et al. 2002; Solomon et al. 2016; Sullivan et al. 2018) across the United States (US). Since the 1960s, the importation and subsequent introductions of invasive carp have led to broad-range expansion and population increases (Sullivan et al. 2018; Altenritter et al. 2019) in the Mississippi River Basin

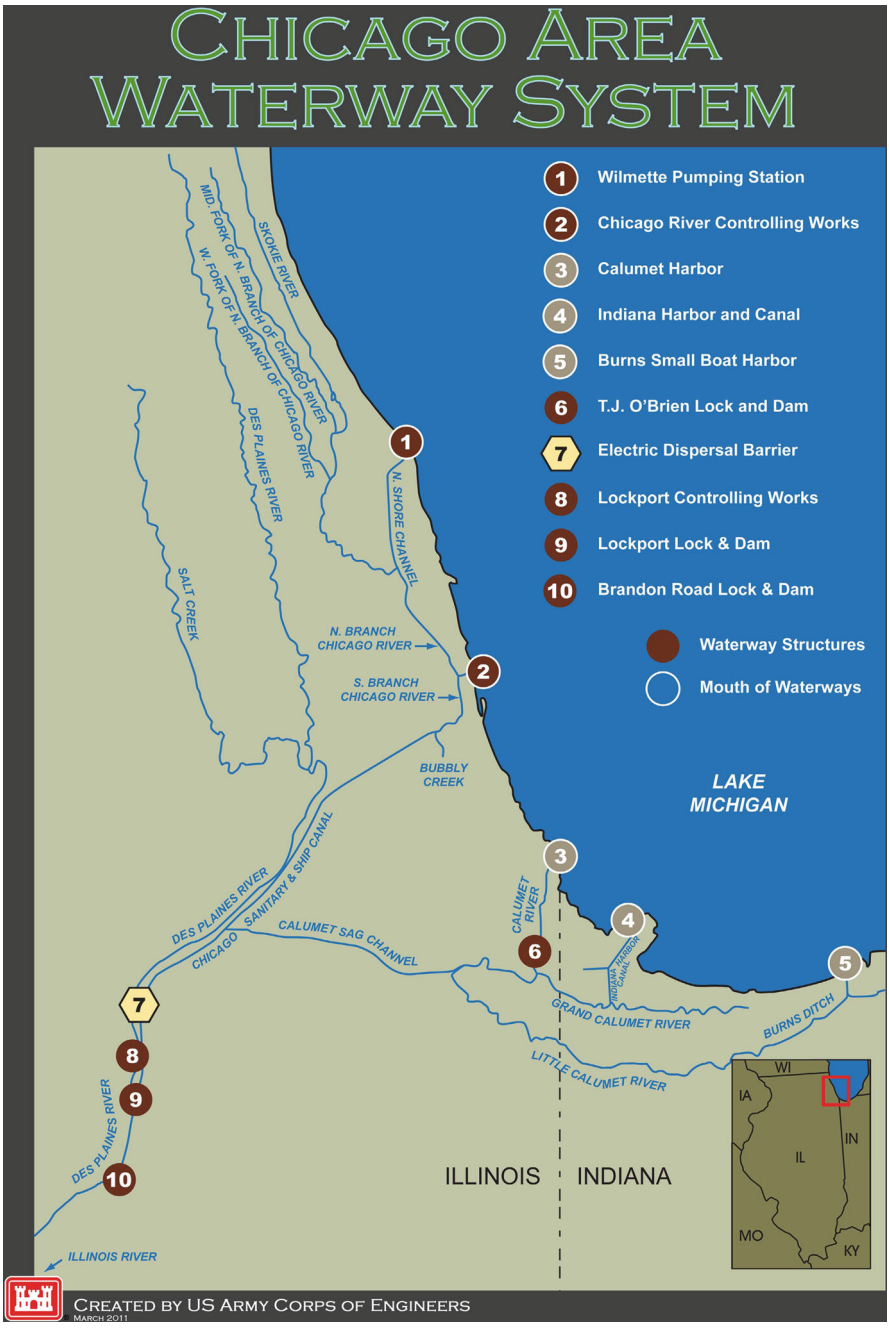

**Fig. 1** Area of interest within the United States. (Inset) The inset shows the location of Brandon Road Lock and Dam (BRLD) is noted by a "1," and the Chicago Area Waterway System (CAWS) is noted by a "2" (Image Credit: USACE Chicago District)

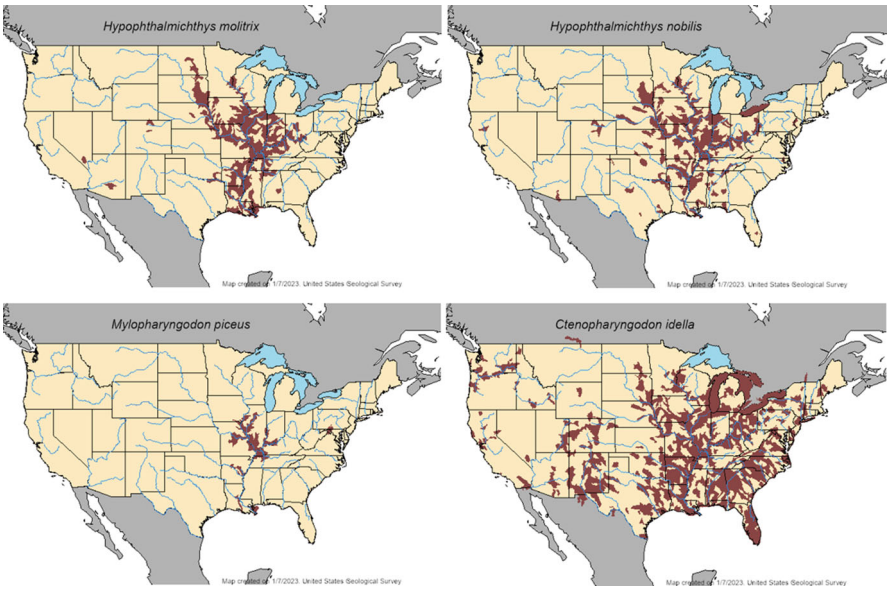

**Fig. 2** Distribution maps of the four invasive carp species within the United States. (TOP LEFT) Silver carp, *Hypophthalmichthys molitrix*. (TOP RIGHT) Bighead carp, *H. nobilis*. (LOWER LEFT) Black carp, *Mylopharyngodon piceus*. (LOWER RIGHT) Grass carp, *Ctenopharyngodon idella*. (U.S. Geological Survey. 2023. Nonindigenous Aquatic Species Database, Gainesville, FL. http://nas.er.usgs.gov. Accessed 13 Jan 2023)

and smaller water bodies across the United States (Fig. 2). These large-bodied planktivores (*sans M. piceus*, a molluscivore) compete for resources with native planktivores and the early life stages of other native fishes resulting in adverse effects on aquatic species populations, fish communities as well as impacting water quality directly and indirectly (Solomon et al. 2016; Phelps et al. 2017; Sullivan et al. 2018; Altenritter et al. 2019). Furthermore, invasive carp can negatively affect recreational boating, commercial navigation, and fishing, resulting in negative economic impacts (Solomon et al. 2016; Chick et al. 2020). The establishment of invasive carp in the Great Lakes may jeopardize fisheries valued at USD 7B per year (Lauber et al. 2020).

An international effort has been underway to address the density, dispersal, and adverse impacts of invasive carp through research and development of various methods, technologies, and management approaches. Population reduction efforts have focused on commercial harvest programs (Love et al. 2018), marketing for human consumption (Bouska et al. 2020), and the development of novel equipment and techniques (Butler et al. 2019; Ridgway et al. 2021). New prototype technologies to manage the spread of invasive carp include non-structural deterrents such as the electric barrier (Clarkson 2004), light deterrents (Kim et al. 2019), overhead attractants (Ribeiro et al. 2022), carbon dioxide (Cupp et al. 2021), air bubbles (Zielinski and Sorensen 2016), underwater acoustics deterrent system (uADS)

(Bzonek et al. 2021), pheromone treatments, or combinations of these (Dennis et al. 2019). Placement of non-structural deterrents at strategic pinch-points (e.g., locks and dams, and narrow corridors where fish passage is reduced to a confined area) impedes the movement of invasive carps while reducing costs of managing large river reaches and aids in achieving the management objective (Noatch and Suski 2012; Cupp et al. 2021; Jones et al. 2021).

## Single and Multiple Non-structural Deterrents

Once an INNS is established, it is often challenging to eliminate the invading species; thus, mitigation and management efforts focus on limiting the spread of the INNS (Van der Zanden and Olden 2008). Physical barriers (e.g., concrete structures, weirs, exclusion screens) can be effective measures for limiting or blocking INNS; however, they may result in a hydraulic disconnect between the upstream and downstream corridors (Jones et al. 2021). Physical barriers prevent the movement of non-target biota, including invertebrates (Grill et al. 2015), aquatic vegetation (Jones et al. 2020), mammals, reptiles, amphibians, and fishes. Additionally, physical barriers can influence hydrological flow, accrue debris, and thus impact navigation (Van der Zanden and Olden 2008; Grill et al. 2015).

In recent years, exclusion and/or attraction have been increasingly used as a management strategy to control the spread of aquatic INNS species in the United States and globally. Generally, these technologies are often not 100% effective at blocking INNS. The efficacy of deterrence for NSDs typically ranges between 60% and 99% due to a wide range of deployment equipment, locations, and site-specific challenges (Noatch and Suski 2012; Jones et al. 2021). The efficacy of NSDs varies with the sensory capabilities of fish species – much like with humans – changes with species, age, and life history experiences (Noatch and Suski 2012). NSDs offer the distinct advantage of maintaining hydrological flow and low to no impact on humans, human safety, and commercial and recreational vessels (*sans* the electrical and chemical deterrents). Scientists, resource managers, and stakeholders must be diligent and evaluate how to maximize the efficacy of a NSD. This requires a technical understanding of the strengths and weaknesses of each NSD technology, how the NSD will be deployed, what is expected of the NSD within the variabilities of the environment, and how the NSD elicits a chosen behavior of a species at a given life stage, and other biological aspects.

Where non-structural deterrents are a feasible option to provide selective fish passage, managers can mitigate impacts of habitat fragmentation and impacts on T&E and other desirable fishes. There is growing interest to further develop the use of physiological and behavioral stimulants as a powerful approach to control and influence INNS while limiting impacts on T&E and native species. This requires that technology be developed to elicit sensory or physiological responses shared by an INNS species or a group of fish (Noatch and Suski 2012). Since non-structural technologies tend to target altered behavior, the primary response variable often is movement-based. A successful research and development effort for a NSD is based

on the ability of the research and manager team to support lab studies, mesoscale field studies, and large-scale field studies to allow for feedback on lessons learned to improve the next generation of full-scale NSDs. Underwater acoustics is one technology that can target the hearing capabilities of INNS, can be engineered to be moderate to highly effective in both attraction and deterrence scenarios, assessed through movement and performance metrics, and ultimately, can be finessed through collaborations between lab and field studies.

## Underwater Acoustics as a Selective NSD?

In 2018, the USACE stepped in to further the uADS progress, explicitly focusing on navigation lock approaches. The effort started by examining several variables such as the bathymetry, water quality, lock operations, ambient sound and noise associated with a typical shallow-water lock (i.e., BRLD), and the 100-horsepower signal recommended in the literature as a possible noise source for modulating invasive carp behavior (Vetter et al. 2017). At BRLD, sound was collected using a passive underwater acoustic monitoring system of eight-channels, 24-bit Autonomous Multichannel Acoustic Recorders (AMARs, JASCO Applied Sciences). Each AMAR was fitted with three M36-100 hydrophones and one M20 vector sensor (GeoSpectrum Technologies Inc). The spectral noise floor, then, was 20 dB re 1 μPa2Hz-1 and the nominal ceiling is 171 dB re 1 μPa. Next, we examined capabilities of commercial off-the-shelf technologies for underwater transducers that were tolerant of shallow-water locks and capable of handling commercial navigation prop wash and debris that passes through the USACE locks (USACE-ERDC 2022). Much of the vessel noise generated within the BRLD approach was contained in the 100–1000 Hz range (Fig. 3). In addition, many of the noise events, that accounted for the sound energy, were relatively short-duration events (vessel traffic, lock drainage, biological calls, and vehicle/bridge traffic) and primarily under 700 Hz.

From the BRLD campaign, the development of an ambient sound map and a three-dimensional propagation model, using range-dependent parameters and out-of-plan reflections (Marine Operations Noise Model [MONM, PE 3D, JASCO Applied Jasco Sciences]), suggested that the sound generated by a uADS should focus on generating deterrence signals with a frequency content greater than 500 Hz to be above the majority of the ambient sound levels (<700 Hz) and outside the hearing range of most native Mississippi-basin fish species (estimated 800 Hz) (Table 1), yet below the estimated 5 kHz of the upper limit of invasive carp (Fig. 4).

The results confirmed that the underwater acoustics production would propagate through the BRLD downstream approach, that care should be taken when developing signals due to the reverberant environment, and that lock approaches could provide infrastructure to protect a uADS from navigation strikes or objects caught in downstream flows. In addition, the variability in river stage, seasons, flood pulses, sediment fluxes, and temperature are dampened within the lock approaches. Thus, the operational parameters of a NSD would require fewer continual adjustments during a long-term deployment.

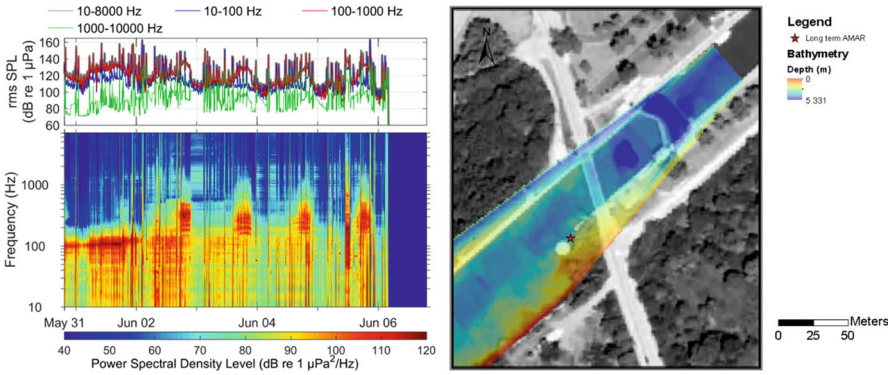

**Fig. 3** (LEFT) Band limited spectral levels and long-term power spectral density from an Autonomous Multichannel Acoustic Recorder (AMAR, JASCO Sciences). The 100–1000 Hz band (red) is approximately the same as the total energy band 10–8000 Hz (grey), indicating almost all sound energy. The lowest sound energy levels were in the 1000–8000 Hz band (green). (RIGHT) The location of the long-term AMAR set between the mooring cell and lock wall in the approach channel of Brandon Road Lock and Dam. The overlay is the bathymetry of the approach channel

**Table 1** Examples of hearing capabilities based on auditory evoked potentials (AEPs) of native and T&E species associated with the Mississippi River and Des Plaines rivers where uADS could be deployed for invasive carp deterrence

| Species | Hearing sensitivities (#Hz: # dB re 1 µPa) | | Reference |
|---|---|---|---|
| Northern Pike *Esox lucius* | 100 Hz: 99 ± 3.5 | 200 Hz: 87 ± 3.6 | Mann et al. 2007 |
| Channel Catfish *Ictalurus punctatus* | 100 Hz: 96.44 ± 1.53 | 200 Hz: 89.11 ± 0.92 | Wysocki et al. 2009 |
| Paddlefish *Polyodon spathula* | 250 Hz: 131 | 500 Hz: 143 | Lovell et al. 2005 |
| Lake Sturgeon *Acipenser fulvescens* | 200 Hz: 133 | 500 Hz: 144 | Lovell et al. 2005 |

In March 2021, an experimental uADS was deployed in the downstream lock approach of Lock No. 19 (Mississippi River, Keokuk, Iowa). Lock No. 19 was identified by stakeholders as a viable location for assessing the impacts of underwater acoustics on the behavior of invasive carp and had a current population of invasive carp; thus, INNS were not introduced, nor surrogate species needed to examine the large-scale field assessment (USACE 2021). A prior study of the fish community near and in Lock No. 19 indicated that invasive carps and native fishes commonly use the lock for upstream passage (Fritts et al. 2021).

For this system, the USACE conducted several acoustic analyses before installation to establish a sound propagation loss model (using a geometric spreading loss), examine design configurations for ensonification of the lock approach, and assess the ambient noise pollution. Similar to the campaign conducted at BRLD, this campaign was conducted using HP 1424 (Lubell Labs, Whitehall, Ohio) positioned on a
