**Abstract**

Since 2016, underwater noise from the construction of offshore wind in Danish waters has been addressed by guidelines from the Danish Energy Agency. These guidelines were updated in 2022 and specify technical methods for performing numerical prognosis and on-site measurements. Acoustic criteria are stated for compliance, including Permanent Threshold Shift (PTS) and behavioral impact. These criteria are based on auditory frequency-weighted levels.

Impact pile driving and vibratory pile driving installation techniques are addressed, with separate methods for modeling and measurements. Concession holder is required to carry out a prognosis to estimate the environmental impact using the given sound source and propagation properties and calculate the acoustic metrics experienced by a receptor (marine mammal) while it is fleeing away from the noise source. The prognosis must be carried out for two to three scenarios, on fully numerical or semi-empirical basis: reference case, planned construction case, and if relevant a specific case including acoustic deterrent device (ADD).

For comparison with measurements during pile installation, the prognosis is required to provide predictions for certain acoustic metrics that are suited for direct measurements.

On-site measurement of underwater sound during installation is required for two purposes: verification of the propagation model used for the prognosis and demonstration of compliance with the acoustic criteria.

**Keywords**

Acoustic criteria · Pile driving · Acoustic deterrent device · Noise prognosis · Frequency weighting · PTS · Behavioral response · Marine mammals

## Introduction

Underwater noise from percussive (hereafter "impact") pile driving is recognized as having a substantial impact on marine mammals. For this reason, the Danish 2016 Guidelines for underwater noise from installation of impact-driven piles were made (Danish Energy Agency 2016). In that first version of the guidelines, only impact in the form of permanent injury to marine mammal hearing was addressed. The reason for this was that at the time of writing, the empirical evidence of other forms of impact was found to be insufficient to establish regulatory thresholds. However, as new empirical evidence became available, a revision of the guidelines became pertinent. The relevant new material was extracted in a series of technical reviews (Tougaard 2021a, b; Tougaard et al. 2021, 2022) that served as background for the

revised guidelines. The most important changes from the 2016 guidelines are inclusion of criteria for behavioral disturbance of marine mammals and introduction of auditory frequency weighting for different functional hearing groups. Furthermore, the guidelines now specify criteria and procedures for the use of acoustic deterrent devices (ADDs), adapted procedures for impact and vibratory driving, and procedures for calculation of distance-to-threshold in assessments.

The guidelines relate to a set of standard conditions, which are usually included in the construction permit for Danish offshore windfarms. Standard conditions, the guideline document itself, and the background reports are available from the Danish Energy Agency website, www.ens.dk. This text presents an overview of the guidelines. For correct application of the guidelines, the reader must consult the guideline document itself (Danish Energy Agency 2022).

## Regulations for Underwater Noise

Over that past several decades, a steady increase in anthropogenic underwater noise has been observed in the seas, e.g., McDonald et al. (2006). The associated risk of a negative impact on a broad range of marine life has motivated regulatory initiatives worldwide. Regulation for underwater noise is an evolving topic and is handled differently among regulators. A few examples of international (European) regulatory frameworks, according to (Lucke 2020), include:

- EU Habitats Directive for conservation of natural habitats and of wild flora and fauna (European Commission 1992). Does not explicitly mention underwater noise but regulates activities and projects that can potentially injure and/or disturb animals, in this context in particular marine mammals.
- Marine Strategy Framework Directive (MSFD) (European Commission 2008). European legislation that considers a multitude of anthropogenic "stressors" and cumulative effects. Specifically addresses underwater noise and requires that EU member states establish thresholds for good environmental status with respect to underwater noise that can impact marine organisms negatively (European Commission 2017).
- The Baltic Marine Environment Protection Commission (HELCOM) has adopted a Regional Action Plan for underwater noise (Helcom 2021), which specifies actions to reduce impact from, among other sources, impact pile driving.

In Danish waters, the legal framework for offshore wind farms is the Act on Promotion of Renewable Energy (Danish Government 2008). On the technical side of regulation, significant variation exists among countries and frameworks. A multitude of acoustic metrics are referred to, and in some cases, auditory frequency weighting of metrics is mandated. In recent years, international standardization on this topic is gradually coming into shape (International Organization for Standardization 2017a,b), but the application differs greatly from one regulator to another.

For regulation of underwater noise in the context of offshore wind farms, a few country-specific examples are included to illustrate the diversity:

### USA

The seminal review by Southall et al. (2007) introduced the onset of permanent hearing loss (PTS) as a precautionary criterion for acoustic injury in marine mammals. For this purpose, marine mammals were divided into functional auditory groups, with different sets of criteria for impulsive and non-impulsive types of noise. For each type of noise and each functional hearing group, a double criterion was established, such that for each functional hearing group two levels were specified, and none of which are allowed to be exceeded. The first criterion is a cumulative sound exposure level (abbreviated as $SEL_{cum}$), frequency weighted with an auditory frequency weighting curve specific for the functional hearing group, and the second criterion is an unweighted zero-to-peak sound pressure level. These guidelines were updated recently (National Marine Fisheries Service 2018) (Southall et al. 2019).

### Germany

For more than a decade, German Federal Maritime and Hydrographic Agency (BSH) have imposed a dual-metric criterion for pile driving (BSH 2011), aligned with recommendations from the Environmental Protection Agency (German Federal Ministry for the Environment and Nuclear Safety 2013) and specifically targeted protection of harbor porpoises (*Phocoena phocoena*). Evaluation is at 750 m range from the piling, in terms of the single-strike sound exposure level and peak sound pressure level without frequency weighting. For measurements during construction, percentile statistics are required, calculated from measurements on a large number of individual pile driving strikes. The single-strike sound exposure level (unweighted) is not to exceed 160 dB re 1 $\mu Pa^2$ s and peak-to-peak pressure not to exceed 190 dB re 1 µPa.

### Belgium

In Belgium, the underwater noise from piling must comply with a zero-to-peak sound pressure level threshold (185 dB re 1 µPa) at a range of 750 m (Rumes, 2016). This criterion is without frequency weighting.

### Denmark

In 2016 the Danish Energy Agency published its first version of the guidelines for underwater noise, addressing offshore pile installation (Danish Energy Agency 2016). The main metric considered was the sound exposure level, cumulated over all pile strikes within piling of a single foundation. Corresponding threshold values were not stated directly in the guidelines, as the intention was for these to be specified in the conditions of the construction permit. No frequency weighting was required in the 2016 guidelines.

As a novel concept in a regulatory context, the first version of the Danish guidelines introduced a numerical framework for calculating the $SEL_{cum}$ of a moving receiver (animal fleeing from the noise source at a constant speed).

In the current version (Danish Energy Agency 2022), the concept of the constant speed-fleeing animal has been kept, and several new features have been implemented. The most significant being frequency weighting according to species group-specific weighting functions with associated group-specific acoustic criteria.

## Scope of the Revised Guideline

For installation of offshore wind turbine foundations, the requirements of the Danish Energy Agency for minimizing the environmental impact from underwater noise form part of the conditions of the construction permit. On this background, the concession holder is obliged to demonstrate plans for how to comply with these requirements. This means the concession holder must prepare a prognosis for underwater noise generated during construction. This prognosis must then be used as the starting point for an environmental impact assessment addressing the potential impact of underwater noise on marine mammals and selection of adequate mitigation measures. In addition, it is mandatory for the concession holder to conduct a verification measurement program. The corresponding methodologies, requirements, and criteria are described in the 45-page guideline and presented in a summarized version in this chapter.

The revised version of the guidelines presented here covers both impact pile driving and vibratory pile driving. While other installation techniques exist, these are not within the scope. Similarly, noise from operational wind turbines and service vessels is also not covered. The primary application of the guidelines is therefore installation of large-diameter monopiles and multi-pile foundations such as jackets and tripods. As an additional new aspect, the guidelines present procedures for permitting and impact assessment of acoustic deterrent devices (ADDs) when deployed as part of the mitigation strategy.

The core of the guidelines is a criterion for the onset of Permanent Threshold Shift (PTS) taken as a precautionary proxy for injury, in line with recommendations of Southall et al. (2007, 2019) and following the same grouping of species according to hearing abilities. Only species relevant in the context of Danish waters are considered, thus covering harbor porpoise (VHF cetaceans), small delphinids (HF cetaceans), minke whale (*Balaenoptea acutorostrata*, LF cetaceans), and phocid seals in water (PCW). In terms of metrics, these criteria are stated as $SEL_{cum}$ (sound exposure level) cumulated over all the impulsive sounds received by the animals during piling of one foundation, weighted by the appropriate auditory frequency weighting functions (Southall et al., 2019, Tougaard et al., 2022).

In addition, the guidelines provide threshold values for the evaluation of behavioral reactions to underwater noise in harbor porpoises. These thresholds are expressed as root-mean-squared sound pressure levels over 125 ms ($SPL_{125\ ms}$),

weighted by the appropriate auditory frequency weighting functions (Tougaard 2021a).

During pile installation, measurements must be taken with the purpose of comparison with the prognosis. To that end, and to enable direct comparison, the prognosis must provide predicted values for the following metrics at distances 750 m, 1500 m, and 3000 m:

- Single-strike sound exposure level ($SEL_{ss}$) and single-strike root-mean-squared sound pressure levels ($SPL_{125\ ms}$) for impact driving, unweighted and frequency weighted.
- Sound pressure level (SPL) for vibratory driving, unweighted and frequency weighted.

Currently, behavioral impacts are only addressed in the guidelines to the extent that indicative frequency-weighted thresholds for onset of behavioral reactions (fleeing) are provided. No hard limit to the spatio-temporal extent of the disturbance is provided. Instead, the assessment of the likely impact of the disturbance on the local and regional populations of animals is left to the environmental impact assessment. Temporary habitat loss is thus not addressed in detail by the guideline. However, for example, the reader may refer to Tougaard (2021a). It is, however, expected that this topic becomes further developed in future revisions.

The concession holder must carry out an on-site validation of the model, regardless of how the acoustic model was established. Similarly, it is a requirement to perform on-site measurements and demonstrate that the acoustic criteria are fulfilled.

## New Knowledge Since the First Guideline Version

The empirical foundation for regulation of underwater noise expands rapidly these years, which means that guidelines should always be considered interim and should be revised whenever there is significant new information about the impact of noise, biology of the animals, or change in the overarching legislation. Since the previous guidelines (2016) were established, two important developments occurred, resulting in significantly improved knowledge about prediction of the impact and means for mitigation. These developments were revised recommendations for frequency weighting (Southall et al., 2019) and the availability of efficient noise abatement technologies, e.g., Bellmann et al. (2020).

### Frequency Weighting

The concept of auditory frequency weighting of noise in assessment of its potential to cause auditory damage is well-established for humans (see Houser et al. (2017) for a review) and was introduced in regulation of underwater noise impact on marine mammals by Southall et al. (2007). The proposed M-weighting curves were very

**Table 1** Species of relevance in Danish waters, with associated auditory frequency weighting functions and limit values for cumulative sound exposure level $SEL_{cum}$

| Species group | Weighting function | $SEL_{cum}$ limit (dB re 1 $\mu Pa^2$ s) |
|---|---|---|
| Phocid seals (harbor seal, grey seal) | PCW | 185 |
| Mysticetes | LF | 183 |
| Odontocetes, except porpoises | HF | 185 |
| Harbor porpoise | VHF | 155 |

*PCW*, phocid carnivores; *LF*, low-frequency cetaceans; *HF*, high-frequency cetaceans; *VHF*, very-high-frequency cetaceans

wideband, which meant that the difference between regulation based on unweighted and M-weighted levels in regulation of pile driving noise was very small (Tougaard and Dähne 2017). However, new empirical data on temporary threshold shifts (TTS) produced after the review by Southall et al. (2007) challenged this, as data were more consistent with sharper weighting functions, resembling inverted audiograms (Tougaard et al. 2015). Subsequently, this led to a revision of the weighting functions (Southall et al. 2019). Thus, the revised Danish guidelines now follow recommendations of Southall et al. (2019), which means that the cumulative sound exposure level ($SEL_{cum}$), weighted with the species-appropriate auditory weighting function, cannot exceed levels that are considered to represent a significantly elevated risk of inducing permanent hearing impairment (Permanent Threshold Shift, PTS). For pile driving noise, classified according to Southall et al. (2019) as an impulsive sound, the species group-specific levels of relevance in Danish waters are given in Table 1. The associated auditory frequency weighting curves are shown in Fig. 1.

Southall et al. (2019) operates with a dual criterion, one based on the cumulative sound exposure level, frequency weighted, and one on the unweighted peak pressure. As the $SEL_{cum}$ criterion is expected always to be exceeded before the peak pressure criterion for pile driving noise, only the $SEL_{cum}$ criterion is applied in the guidelines. The guidelines may be extended to other types of impulsive sources, such as seismic air guns, but not to all types. Most important exception is explosions, where the peak pressure is likely to be the better predictor of the risk of injury.

## Disturbance of Behavior

New in the guidelines compared to the previous version is that the impact from behavioral disturbance of marine mammals must now be included in an assessment, and a threshold for evaluating disturbance is provided. This threshold, valid for harbor porpoises, is expressed as an auditory frequency-weighted sound pressure level, calculated as a root-mean-squared (RMS) average over 125 ms, corresponding to the integration time of the mammalian auditory system (Tougaard et al. 2015, Tougaard 2021b). Recent empirical data supports the notion that frequency-weighted sound pressure levels are better predictors of behavioral response to pile driving noise than are unweighted levels (Kastelein et al. 2022). Based on a review

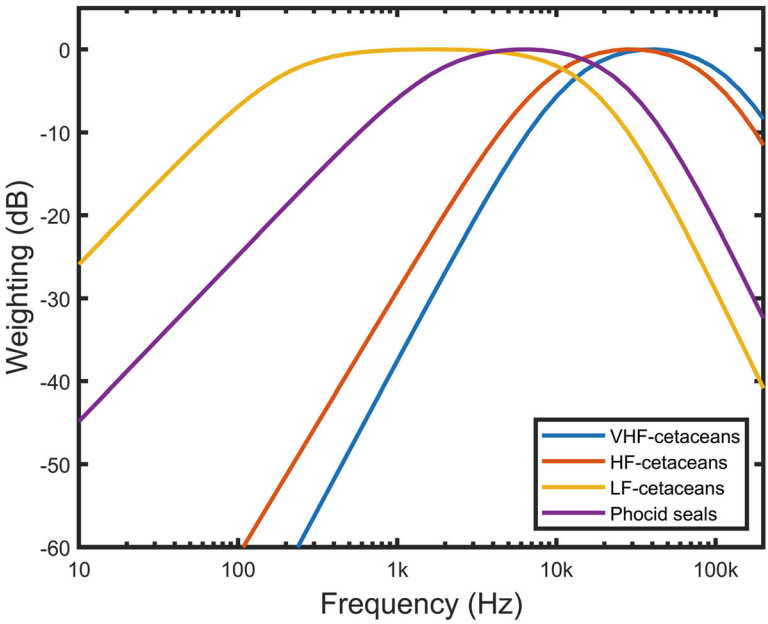

**Fig. 1** Frequency weighting functions proposed by Southall et al. (2019) and Tougaard (2021b) for auditory groups relevant to Danish waters

of experimental data (Tougaard 2021b), including both experiments on animals in captivity and studies of wild porpoises' reactions to full-scale pile driving, a threshold for behavioral reactions equal to 103 dB re 1 µPa, VHF-weighted, is provided.

## Metrics and Terms in the Revised Guideline

Metrics used in the guideline follow the definitions given in ISO 18405 (International Organization for Standardization 2017a) and ISO 18406 (International Organization for Standardization 2017b). A few additional metrics and terms are:

### Max Over Depth Across Water Column

For a fixed range step $r_i$, and considering the entire water column, the maximum metric value is determined, i.e., max over depth (MOD). With $j$ being the vertical grid-point index, MOD of a given metric $L$ is:

$$L_{MOD}(r_i) = \max_j L_j(r_i)$$

Here, all values of $j$ inside the water column are considered.

### Distance to Threshold

Distance to threshold is the largest expected distance from the source where the received level of noise equals the threshold (for onset of PTS or onset of behavioral reactions, whichever relevant). This distance is most often evaluated from a max-over-depth parameter. As such, the distance to threshold (DTT) is used for evaluating the range-dependent variation based on a given acoustic threshold value.

It is worth noting that the sound field in a shallow-water acoustic environment usually decays with distance in a non-monotonous manner. On that background, the numerical evaluation must be implemented carefully to avoid the risk of identifying local features as the global DTT of the transect.

### Exceedance Level

For an acoustic-level metric $L_x$, it is common to define an exceedance level in dB. Applying statistics to $L_x$, the percentage x is the level which during the observation period is exceeded x% of the time. One common observation period is the piling sequence. Taking as an example $L_{90}$, this refers to the metric's level that is statistically exceeded 90% of the time. Analogously, $L_{50}$ corresponds to the statistic median and indicates the level that is exceeded 50% of the time.

## Acoustic Deterrent Device (ADD)

An acoustic deterrent device (ADD) is a technical device designed with the purpose of emitting an acoustic signal that is unpleasant for the target species. The intention is that the ADD's signal causes any target animals to leave the nearby area as a non-lethal, behavioral response. Historically, ADDs were developed for fisheries and the aquaculture industry for deterring marine mammals, thereby reducing depredation and damage to fishing gear and net pens. Over time, its use spreads to other offshore industries including offshore wind and UXO (UneXploded Ordnance) removal and now includes devices known as "seal scrammers" and "pingers." Deployment of ADDs in this context is then as a mitigation device, with the intention of deterring animals out to safe distances before the onset of the main, potentially harmful noise source. An overview is given in McGarry et al. (2020).

In the context of offshore piling, an ADD serves as a marine mammal mitigation technique. In the ideal case, the ADD deters animals away from the potential injury zone. However, thereby the ADD creates an additional disturbance, on top of the disturbance caused by the pile driving itself. If the ADD is too powerful, the disturbance caused by the ADD may exceed the disturbance from the pile driving itself (Dähne et al. 2017), thereby jeopardizing the very mitigation purpose of the ADD.

In the revised guidelines, it is now a general requirement to use an ADD during the construction activity. This applies to any single foundation, with the only exception being cases that are relatively low noise. The ADD is a significant

underwater source of noise itself. In consequence, it is required to assess its acoustic impact. The revised guidelines include a procedure for this specific purpose. The aim is to assure that the distance to threshold for disturbance for the ADD does not exceed the distance to threshold for the pile driving itself, assuring that the ADD does not cause disturbance over a wider area than the pile driving itself. Furthermore, the revised guidelines now require that the ADD is activated at least 15 min prior to start-up of the pile installation activity. If the installation stops for more than 2.5 h continuously, it must not start again before the ADD has been active for another 15 min. This procedure is in line with suggestions presented in Thompson et al. (2020).

## Prognosis Overview

Figure 2 shows a flowchart representation of the sequence behind the required prognosis scenarios. The reader is referred to the guideline document for details, but a few features are highlighted in the following.

Overall, the prognosis is intended for estimating the environmental impact resulting from a given sound source and propagation properties. This is done by calculating the acoustic metrics experienced by a marine mammal receptor. The prognosis must be carried out for two to three scenarios, on a fully numerical or semi-empirical basis.

## Reference Case

This is a worst-case scenario, without noise abatement techniques and without ADD. As such, it provides a standardized setup that allows regulators to track technology

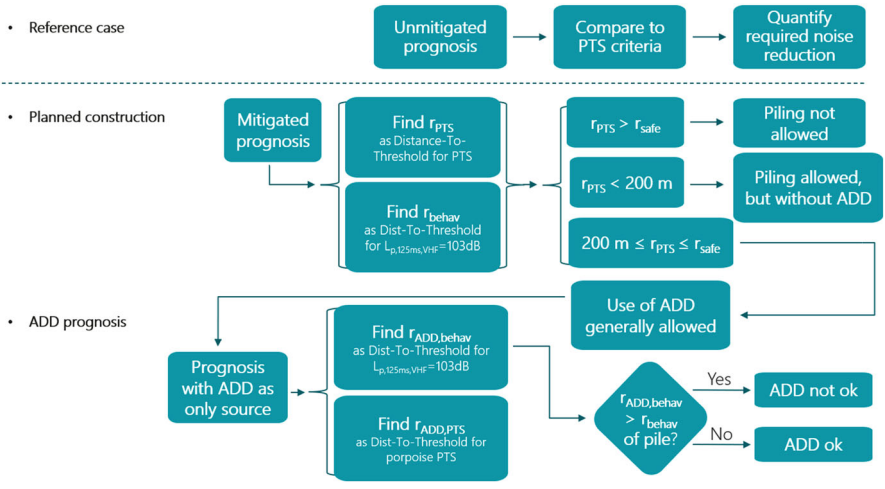

**Fig. 2** Prognosis flowchart. Please refer to the guideline document for full details

improvement across projects. In addition, it represents a worst-case indication of what might happen in case of a malfunctioning noise abatement systems. An example would be bubble-curtain compressor failure.

## Planned Construction Case

In this scenario the prognosis is based on the installation machinery (e.g., hammer) and noise mitigation techniques (if any, e.g., bubble curtain) intended for the construction. It also assumes the use of an ADD prior to the installation (if relevant, see comments below), resulting in a certain minimum displacement of any nearby animals. This distance is called $r_{safe}$ and must be provided for the study by the user. Piling according to the planned construction case may only take place if the $r_{PTS}$, the PTS-related distance to threshold of the piling, is smaller than $r_{safe}$. Furthermore, the resulting $SEL_{cum}$ must comply with the relevant acoustic criteria of Table 1. If these criteria are met, all marine mammals are assumed to be at least at distance $r_{safe}$ at the onset of piling and fleeing directly away from the noise with a constant speed ($v_{flee}$), which in turn means that by the end of the pile driving (for that particular foundation), no animal will have experienced an $SEL_{cum}$ above the PTS onset threshold.

## ADD Prognosis

If the planned construction case results in relatively low noise impact, identified as a very short distance to threshold for the onset of PTS, piling is allowed without an ADD, as there is no significant risk of injury to mitigate. Otherwise, and in most cases for large-diameter piles, a separate prognosis must be done, based on the planned ADD as the only noise source. The intention behind the criteria for this ADD prognosis is to avoid the ADD itself having a larger impact than the piling operation.

## Fleeing Animal Concept

An important feature of the prognosis concept is that of a fleeing animal, introduced to avoid the unrealistic overestimation of predicted impact if it is assumed that the receiver (animal) remains stationary throughout the entire exposure. A numerical framework is given that represents an animal fleeing radially away from the noise source at a constant speed. At present times, a speed of 1.5 m/s is suggested regardless of species, but alternative values (see, e.g., (Tougaard 2021a)) are permitted as long as they are justified. Its practical use has shown that in terms of $SEL_{cum}$ the numerical difference between a stationary vs. constant speed-fleeing receiver is significant and easily more than 10 dB depending on sound field properties. At the same time as being a better approximation to actual behavior, the moving animal assumption may be regarded as reducing an unwarranted but significant worst-case assumption (of a stationary animal) from the prognosis.

## Prognosis Options

It is permitted to base the prognosis on numerical modeling (examples include finite element, parabolic equation, or wavenumber equation schemes) or alternatively using semi-empirical methods. The latter allows for a range of techniques based on artificial sound sources such as airguns.

A general approach stated several places in the guidelines is freedom for choice of method. For several assumptions and methodologies, alternatives are allowed. The requirement is that the user provides adequate justification that the alternative provides similar or better representation than what is stated in the guideline. Examples where this might become relevant are:

- The prognosis formulas for vibratory driving assume constant driving force amplitude over time, which in some cases might be over-simplified. The user might have more detailed information and may modify the $SEL_{cum}$ formulas to accommodate this.
- Similarly, the formulas for impact driving assume a constant time interval between hammer impacts.
- Currently, a fleeing speed of 1.5 m/s is assumed regardless of animal species. If well-documented data justifies other speed(s), these may be used.
- A simple, semi-empirical formula is suggested in the guidelines for correction of differences in applied hammer energy compared to that assumed for the prognosis. The user may apply alternative expressions or approaches for the correction.

## Verification Measurements Explained

It is an inherent challenge of the acoustic criteria of Table 1 that the corresponding $SEL_{cum}$ metric is not easily evaluated from measurements during the installation, particularly because the limit values refer to a non-stationary receiver (a fleeing animal). On that background, it is required for the prognosis to prepare certain sets of data that are more readily derived from field measurements. For the transect identified as having the longest distance to threshold for PTS criteria, the following is calculated:

- Single-strike sound exposure level $SEL_{ss}$ in the case of impact driving.
- Sound pressure level SPL in the case of vibratory driving.

At the construction site, measurements must then be made for two purposes:

- Verification of the propagation model used for the prognosis. This is based on evaluation of the transmission loss, which must be demonstrated to match the prognosis data. The guidelines permit both the use of an artificial underwater sound source and the actual pile driving operation.

- Demonstration of compliance with the acoustic criteria, based on the above-mentioned measurable output from the prognosis. These must be prognosticated in 1/3-octave bands and at specified reference ranges. The measured broadband values corresponding to 5% exceedance levels, with and without appropriate frequency weighting, must be reported.

In both contexts, prognosis and measurements must match within tolerances specified in the guidelines. The idea behind the above sequence is to first establish confidence in the acoustic model, which then leads to confidence in the absolute noise levels resulting from the prognosis.

Finally, there is a risk that the hammer protocol (i.e., impact hammer energy vs. time or vibratory force amplitude) assumed in the prognosis deviates to some extent from that applied during the actual installation. A simple expression is provided in the guidelines to correct for such differences if relevant. After that, the $SEL_{cum}$ of the prognosis must be compared to the limit values of Table 1 to demonstrate compliance.

## Conclusion

New scientific advances in the knowledge of marine mammal hearing led to a revision of the Danish guidelines for underwater noise. The revision kept the basic approach of the original 2016 version, addressing the cumulative sound exposure level of an animal fleeing at constant speed away from the noise source. However, several additions and modifications were implemented, in particular that of frequency weighting based on auditory groups.

It is believed that the current guidelines' approach is an improved representation of the acoustic impact on marine mammals caused by offshore pile driving.

It is expected that future revisions will accommodate updates to reflect new knowledge. In particular, it is foreseen that behavioral response to underwater noise will become better understood from ongoing and upcoming research.

**Acknowledgments** This work was funded by the Danish Energy Agency, and a large part of the work was done within a workgroup, which consisted of the authors, as well as Anna-Grethe Underlien Pedersen and Nynne Elmelund Lemming (Danish Environmental Protection Agency) and Søren Enghoff, Danish Energy Agency. Also, the authors would like to thank their colleagues and industry partners who provided valuable feedback to the process.

**Abstract**

Since underwater noise has been recognized as a source of pollution, affecting all compartments of underwater ecosystems, efforts have been made to reduce its effects and design management tools to assess and regulate it. Consequently, over the last decades, governance regulations have been implemented internationally, and converging risk assessment methodologies emerged to define threshold values. However, including the complexity of impacts on species and marine habitats at the heart of the process is an ambitious challenge. Given the sparseness of the knowledge, it is difficult to define and set threshold values for common

regulation and management. The aim of this chapter is to investigate risk assessment conditions in regard to threshold value setting. The assessment framework relies on the definition of a sound pressure-level threshold, related to biological impacts, and temporal and spatial thresholds, related to habitat degradation. As the choice of thresholds still needs to be researched, several ranges of values for each threshold are investigated to estimate their relationships in the decision-making process. This chapter focuses on a practical implementation of a threshold-based assessment over the French coasts. It demonstrates how noise mapping can effectively support regulators to identify and prioritize impacted areas depending on availability of scientific knowledge.

## Introduction

Over the last decades, world marine traffic intensity has increased globally, and new navigation routes were established (UNCTAD 2019). Noise generated by the propellers of modern ships can propagate over hundreds of kilometers. It has been characterized as a continuous component of ambient noise at low frequencies, as it can be recorded almost everywhere and all the time (Wenz 1962). Such major modification of the underwater soundscape has been suspected to affect marine species, by masking their communication and the cause of disturbance at the different steps of their life cycle (Erbe et al. 2016; Tyne et al. 2018; Weilgart 2007; Southall et al. 2007; Popper and Hawkins 2016). This observation highlighted by scientists led to a consideration of underwater noise in environmental policies (Duarte et al. 2021; Thomsen et al. 2021; Merchant et al. 2022). The political response to underwater noise requires support from scientific communities to establish (1) reliable assessment methodology and (2) threshold values using the best available knowledge to quantify the risk (Juretzek et al. 2021; Verling et al. 2021; Merchant et al. 2018).

In order to provide the most reliable assessment, stakeholders have to quantify where and when the risk is too important (Ascough Ii et al. 2008). Thus, maps of risks over given periods are usually considered as the main input for management (Halpern et al. 2015). For underwater noise, the pressure covers large areas that could hinder the capacity to make accurate assessment, in particular regarding the lack of consensus in the methodology and in the threshold value definition. It became a major challenge for researchers and stakeholder to provide methodology that reflects the decision-making process to present robustness to uncertainties and data gaps while being sensitive to mitigation measures (Lajaunie et al. 2023).

At the European level, in the Marine Strategy Framework Directive (MSFD 2008/56/EC), a common assessment methodology was adopted in 2021 for underwater noise (Sigray et al. 2021). It aims to be applied across all European waters that includes various bathymetric depths and reliefs, various shipping activities, as well as large biodiversity sensitive to noise. The proposed approach considered that noise levels, time, and space should be assessed according to a decision tree, to be able to identify areas where the risk is too high too often. This risk-based approach follows a DPSIR (driving forces, pressures, states, impacts, responses) framework, by making it possible to measure a phenomenon (noise pollution), identify and monitor pressure (underwater noise), and evaluate the effect of public policies (mitigation measures as speed reduction).

The associated threshold values to quantify the risk were investigated in a second document of the MSFD. Options for spatial, temporal, and noise-level threshold values for continuous noise were adopted in 2022 (Sigray et al. 2022). For all single months assessed over a year, the recommendation has been that the exposed area of the habitat should be equal to or below 20%. The remaining threshold value (or range of threshold values) on the noise level was suggested to depend on additional biological knowledge. The choice of the threshold values on noise level remains to be defined at the subregion level. Still it appeared that defining thresholds requires a deep knowledge of the biology of species which are often lacking or incomplete (Geijzendorffer et al. 2016; Welsh et al. 1996). However, these gaps should not be an obstacle for the assessment of the impact of noise on the environment.

In this chapter, a parametric approach is performed on the assessment methodology for various marine subregions of French Economic Exclusive Zone (EEZ) in 2019. The objectives are twofold: (1) to perform a sensitivity analysis of the methods and impacts on the risk assessment and (2) to provide and validate possibilities for threshold values. For these reasons, an approach integrating scenario multiple threshold values directly related to the pressure makes it possible to test several scenarios of risk. It enables to consider assessment with limited biological knowledge, at large scale and for the three dimensions of noise pressure, the spatial, the temporal, and the noise level. Thus, this chapter proposes to investigate the relationship between noise dimensions and how the risk assessment is impacted by the choice of threshold set on each dimension. The chapter is organized as followed. Section "Material and Method" introduces the area, the noise mapping process, and the decision tree defined in Sigray et al. (2021). Section "Results" presents the results of the parametric assessment and support for the interpretation. Section "Discussion: Implementation of Risk Assessment" discusses about the marine subregion properties for the assessment and concludes on possibilities to set threshold values.

Symbols and notations used in the chapter are presented in Table 1.

**Table 1** Table of symbols

| | | |
|---|---|---|
| $m$ | Cell number | |
| $N(m, t)$ | Noise level in the cell $m$ at time $t$ | (dB re 1 $\mu$Pa) |
| $\mathbf{N}$ | Matrix of noise levels | (dB re 1 $\mu$Pa) |
| $T$ | Assessment period | |

| $\boldsymbol{\tau}$ | Test threshold values for relative time $\tau$ | **[**0:100%**]** |
| $Z$ | Number of days in the cell when $\lambda$ is exceeded | % |
| $Y$ | Number of cells where $\tau$ is exceeded | % |
| $X$ | Status of the habitat | Boolean value |

## Material and Method

### Study Area

This chapter focuses on the French Economic Exclusive Zone (EEZ) off metropolitan waters on the Atlantic coast, composed by three marine subregions, namely, English Channel and North Sea (ECNS), Celtic Seas (CS), and Bay of Biscay (BoB) in January 2019 (Fig. 1). The three subregions are geographically composed of 44° and 51° North, −10.0° West, and 2.0° East.

### Noise Mapping

The shipping noise maps are computed by propagating the noise from shipping activities in the marine environment. The modeling process had been documented in several studies (Le Courtois et al. 2016; Sertlek et al. 2016; Folegot et al. 2016; Jesus et al. 2022). Depending on the environment and the data availability to consider, the process can differ, but they follow the same general principles: (1) computation of the source levels of the ships and (2) computation of the propagation losses between the ships and a receiving position and depth (Aulanier et al. 2016).

Automatic Identification System (AIS) provide the locations of the sources and additional information for the modeling of the source level modelling. Speed, length, and categories of the ships are usually considered as the dominant parameters in the source level (McKenna et al. 2012). As there is no consensus, the RANDI 3 model is used in this chapter (Breeding Jr et al. 1996).

The equivalent source is assumed to emit at a 5 m depth. In spite of being widely used, comparative studies with measurements have criticized results of RANDI 3

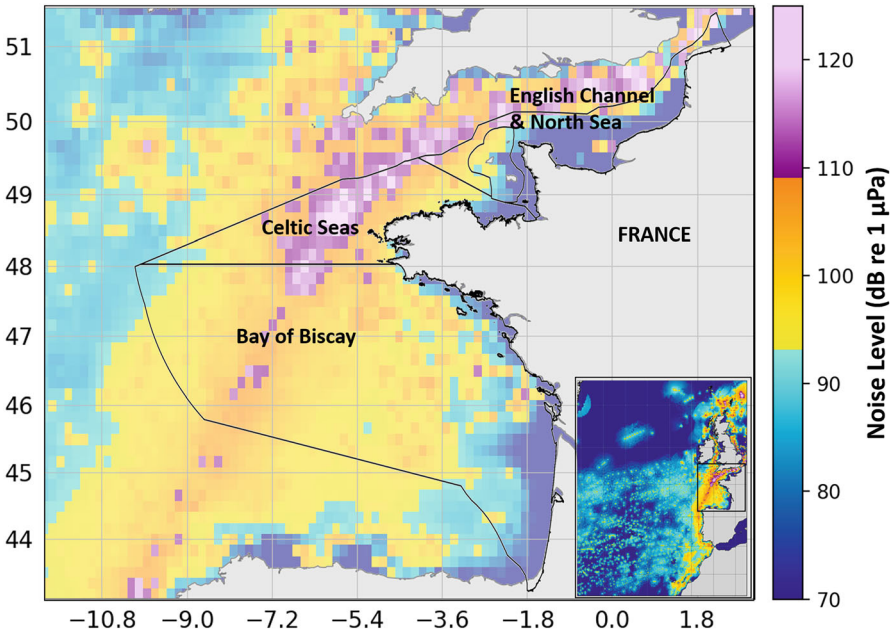

**Fig. 1** Noise levels from for the month of January 2019 and marine subregions of French Economic Exclusive Zone

**Table 2** Environmental and anthropogenic data used for the noise map computation. The seabed is classified according to its geoacoustic properties (density, compressive $c_P$ and shear $c_S$ wave celerity, and attenuation $\alpha_P$, $\alpha_S$)

model and the equivalent source depth, in particular at low frequencies (Wales and Heitmeyer 2002; Sarkoulis et al. 2017; McKenna et al. 2012). Other modeling paradigms were proposed recently, in particular to match a large set of data for newer ships to long-term acoustics measurements (Wales and Heitmeyer 2002; Simard et al. 2016; MacGillivray and de Jong 2021).

The propagation equation is solved using RAMS (Range dependent Acoustic Modeling, with shear wave modeling at the seabed interface) model (Collins 1995, 1998). RAMS model uses a parabolic approximation which is relevant for range-dependent medium at low frequency. Bathymetry, SSP, and seabed data used to compute the propagation losses are listed in Table 2.

The resulting noise levels in a given cell $m$ (whose center is located by its longitude and latitude), at a given time $t$ and depth $z$, are $N(t, m, z)$. In the following,

the maximum value over depth is selected in order to simplify notation and follows a conservative approach. Noise maps are computed with a spatial resolution of 10 arc minutes with a daily interpolated average AIS situation. The resolution is mainly restrained by the computation cost. These units were chosen as a compromise between information and computation cost to support decision making.

Thus, following a matrix formulation, $N$ has two dimensions: cell number $m$ (longitude and latitude) and $t$ (time). In Fig. 1, the whole map is 1,057,069 cells, i.e., 199,454; 165,416; and 692,199 cells for subregions ECNS, CS, and BoB, respectively.

## Decision Tree Aggregation

The risk is assessed following a decision tree. The method was proposed by the technical group for underwater noise (TG Noise) as a common approach for European waters (Sigray et al. 2021) but can be generalized to other scales and locations. It aims to support stakeholders for identifying high-risk areas for the management.

The decision tree can be formalized as the algorithm presented in Fig. 2. The assessment is performed over an area $M$ that contains the known habitats and over a

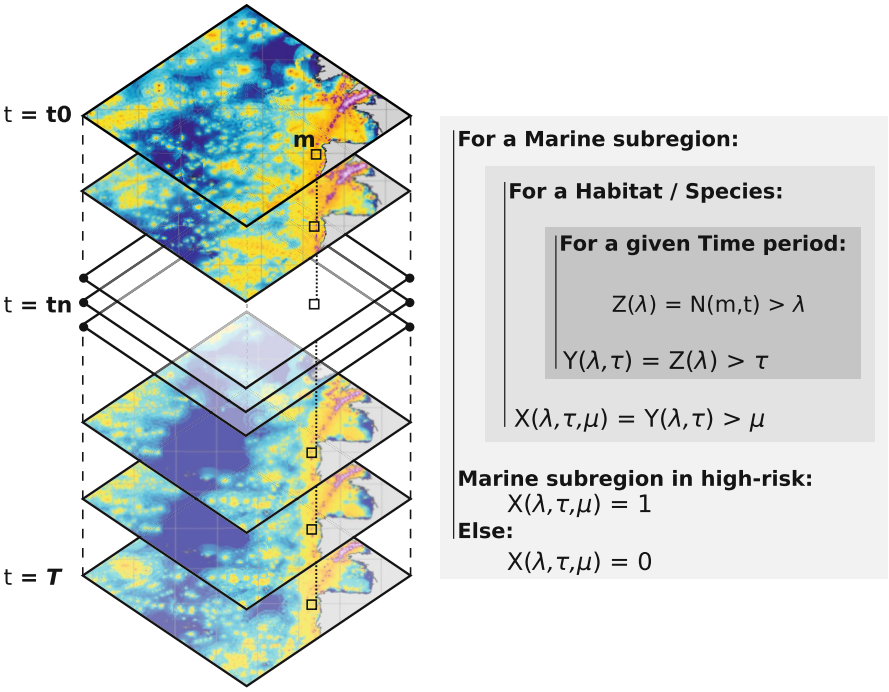

**Fig. 2** Decision tree algorithm (see text for symbol definition)

period $T$. The elementary unit is a cell $m$. The noise level in a cell of the habitats at a time $t$, $N(m, t)$ has to be lower than a level threshold $\lambda$. Let $Z(m, \lambda)$ be the number of days when $\lambda$ is exceeded. The number of days in a cell of noise exposure too loud has to be lower than a temporal threshold $\tau$. The number of cells where $\tau$ is exceeded is $Y(\tau, \lambda)$. The last step to conclude of the risk level on the habitat level is to compare $Y(\tau, \lambda)$ to a spatial threshold $\mu$. The risk is defined by a Boolean quantity $X(\tau, \lambda, \mu) = Y(\tau, \lambda) > \mu$, $X(\tau, \lambda, \mu) = 0$ means the risk is low, $X(\tau, \lambda, \mu) = 1$ means the risk is too high. Additional interpretations are discussed in section "Decision Tree Aggregation."

For the sake of simplicity, in the following, the assessment is performed at the subregion level, assuming that $M$ is fully covered by a single habitat and $T$ is a month. As there is no consensus on any of the threshold values to apply, i.e., the level of noise, the number of days, as well as the spatial extent, the decision tree is investigated by defining uniform distribution of the values, respectively, $\boldsymbol{\lambda}$, $\boldsymbol{\tau}$, and $\boldsymbol{\mu}$. Uniform prior is assumed to be the less informative distribution of every possible combination. Such hypothesis is discussed in section "Perspectives."

## Results

The proposed method produces a set of two-dimensional matrixes of all the combination of threshold values explored in the selected area. The three dimensions represent the values used as test thresholds: noise level, temporal, and spatial. For a set of three thresholds, the risk value is stored as a Boolean value (conditions reached or not for these selected thresholds).

For the sake of simplicity, each graph is obtained by averaging over the third dimension, i.e., marginalization, and displayed by a color scale in Fig. 3 and by averaging over two other dimensions as a curve in Fig. 4. Columns (A), (B), and (C) in Fig. 3 contain the results for ECNS, CS, and BoB subregions, respectively. The line (1) contains results along the temporal and the noise-level threshold values for the spatial threshold values that would lead to high risk. In a similar way, the lines (2) and (3) contain results along spatial and temporal threshold values for the noise-level threshold value and along noise level and spatial threshold values for the temporal threshold value, respectively. In a column, the lines contain the relevant information to link all threshold values and their relation with the decision tree.

Chart B1 in Fig. 3, in the CS subregion, displays the relationship between the three threshold dimensions: the x-axis represents the percentage of time thresholds ($\tau$), the y-axis represents the range of noise-level threshold values ($\lambda$) in dB re 1 $\mu$Pa, and the color range represents the percentage of the selected area ($\mu$). By selecting threshold values for noise level and temporal dimensions, one can determine how much space in the subregion is affected by noise. For example, the figure shows that 30% of the CS subregion is affected 50% of the time by noise levels of at least 100 dB re 1 $\mu$Pa. Chart B2 shows that each noise level is stable spatially and over the month.

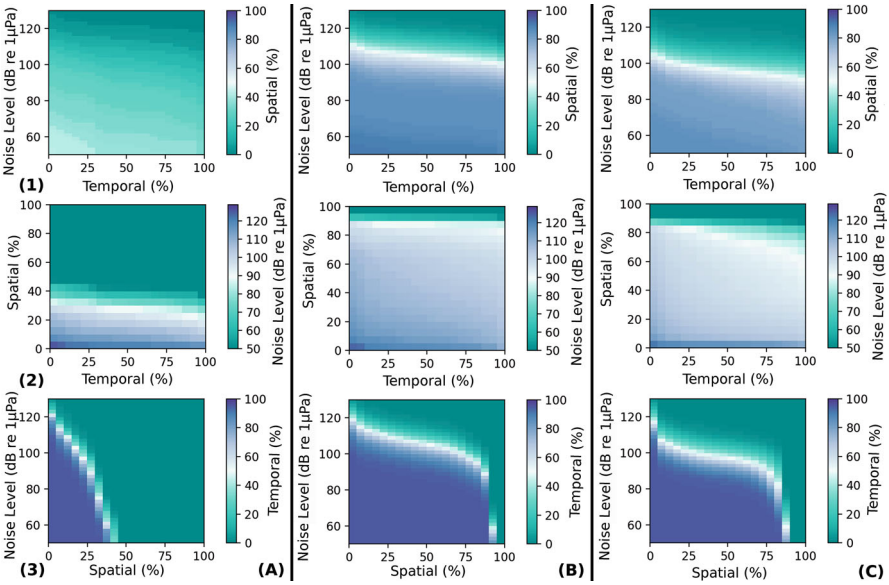

**Fig. 3** Threshold relationships by marine subregion are represented in columns for (**a**) ECNS, (**b**) CS, and (**c**) BoB. Each representation of threshold relationship for the three subregions is represented in lines (1), (2), and (3)

Chart B3 reveals that levels of noise over 120 dB re 1 $\mu$Pa are restricted locally on 5% of the area and are present less than 50% of the time. Levels of noise below 85 dB re 1 $\mu$Pa are distributed also on 5% of the subregion.

Chart A1 indicates that the ECNS subregion is not affected by shipping noise to a significant degree. It appears that high noise levels between 120 dB re 1 $\mu$Pa and 130 dB re 1 $\mu$Pa are present on 20% of the area, when levels between 50 dB re 1 $\mu$Pa and 120 dB re 1 $\mu$Pa are distributed on only 20–45% of the area. It reveals that even if a strict noise-level threshold value of 60 dB re 1 $\mu$Pa is imposed all the time (0% of the time), more than 60% of the area would still meet this low-level standard. This suggests that the shipping noise modeled in this area is relatively low.

The A2 chart shows that all levels of noise continuously occur during the month. It appears that levels of noise over 120 dB re 1 $\mu$Pa are more stable over time than other noise levels. Levels of noise comprised between 50 dB re 1 $\mu$Pa and 60 dB re 1 $\mu$Pa dominate the area (60%) all the time. The A3 chart displays that none of the noise level is distributed on more than 55% of the subregion. All the range of noise levels are represented on 40% of the area.

In chart C1, for BoB subregion, almost half of the areas (45%) is dominated by noise levels over 90 dB re 1 $\mu$Pa all the time. Chart C2 shows that a whole range of noise levels is stable spatially and over the month, except for the 90 dB re 1 $\mu$Pa noise level which displays a spatial coverage from 80 dB re 1 $\mu$Pa to 65%. Chart C3 reveals that levels of noise over 120 dB re 1 $\mu$Pa are restricted locally on 5% of the area and are present less than 40% of the time.

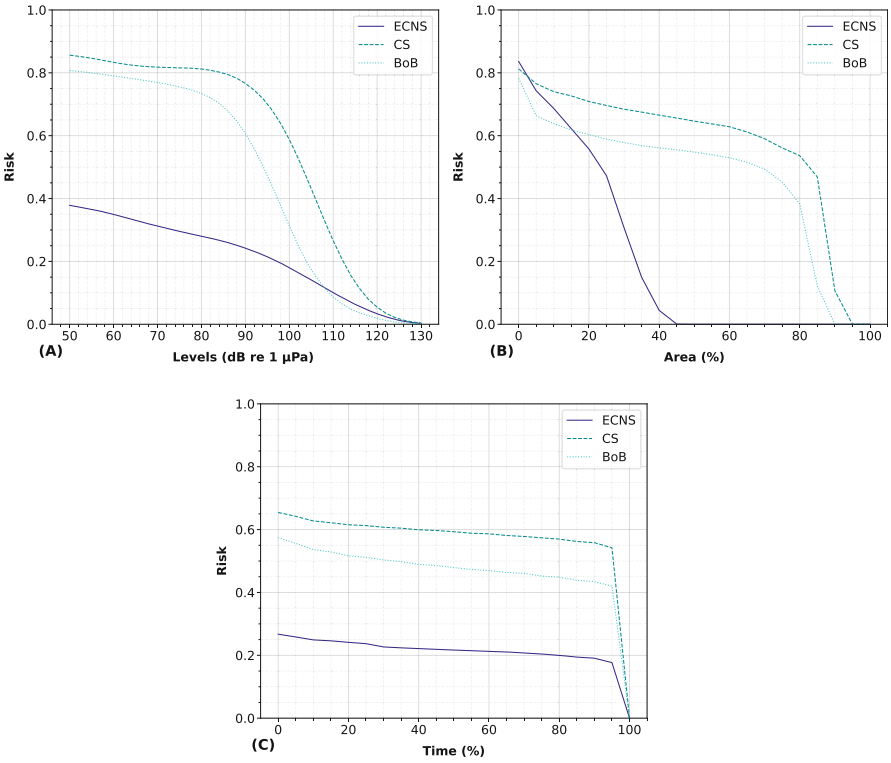

**Fig. 4** Averaged risk levels for ECNS, CS, and BoB marginalized for (**a**) noise level, (**b**) spatial threshold values, and (**c**) temporal threshold values

The marginal curves in Fig. 4 provide an averaging over an additional dimension. This allows studying the evolution of the risk assessment depending on the selection of the threshold value for the noise level, the spatial extent, and the temporal extent, respectively, in Fig. 4a–c. For example, in Fig. 4a, the risk values are expressed as a percentage of the subregion, in terms of space and time, that meet the set noise-level threshold. Here, the lower the noise-level threshold is set, the more difficult is the risk assessment conditions to be meet, which is expressed by higher-risk values (closer to 1). As a general observation, all curves show a similar behavior of decreasing monotonic function of the risk regarding the threshold values. They can have quasi-stationary phases, depending on the subregion and the threshold values. Looking at the subregion differences, it appears that CS and BoB have a similar and close behavior independently of the averaging method chosen, ECNS subregion being an outlier in these representations.

In Fig. 4a, the tensor is averaged over the temporal and spatial thresholds considered. This representation makes it possible to observe quasi-stationary states of the risk assessment for up to a threshold of 85 dB re 1 $\mu$Pa for both CS and BoB subregions. After this threshold, more cells of these subregions (in space and time)

manage to reach the objectives, thus showing a decrease of the risk values. The ECNS subregion is showing a softer decrease of the risk values over all the noise-level thresholds considered. In Fig. 4b, the averaging is performed over the noise-level and temporal thresholds. A similar stationary behavior is observed between spatial thresholds of [0–80%] for both CS and BoB subregions. After this point a steep decrease of the risk values is observed [0.55–0.00]. For the ECNS subregion, the steep decrease of the risk values [0.80–0.00] is observed for relatively low spatial threshold values [2–45%]. In Fig. 4c, the averaging is performed over the noise-level and spatial thresholds considered, which enable to observe a large quasi-stationary state [0–98%] of the temporal thresholds considered. This is closely related to the observations made in the marginal distributions described in Fig. 3.

## Discussion: Implementation of Risk Assessment

### Comparison of Subregional Results

The results from Figs. 3 and 4 suggest that the choice of threshold values influences the risk assessment depending on the selected dimension, affecting the reliability of the decision. Exhaustive analysis of the threshold value combination was investigated.

According to the findings, it appears that high noise levels [110–130 dB re 1 $\mu$Pa] are permanent and spatially concentrated in the three subregions. Moreover, fewer variations are observed over the range of temporal threshold values, demonstrating a certain amount of stability of underwater noise over the time during the studied month. It can be explained in Fig. 1 by the major shipping rails, as Ushant rail, which concentrate the shipping traffic on dedicated routes from English Channel to the south of the Bay of Biscay over the year. The results would probably be similar for longer periods of assessment. Indeed, the traffic rails are stable, and they remain very concentrated on the shelf and the continental slope.

The study found that noise-level thresholds ranging from 60 to 110 dB re 1 $\mu$Pa are more prevalent in the CS and BoB subregions, but not as much in the ECNS subregion. This suggests that the spatial threshold value definition seems to have a different effect depending on the area selected, thus may be influenced by the size of the subregion. This could be explained by different factors such as the proportion of noisy and quiet areas, the physical complexity of the area which includes shipping lanes, and local characteristics of sound propagation such as the depth of the water and environmental parameters.

Marginal representations can serve as a useful addition to noise maps as they provide more general information regarding the distribution of noise values across different thresholds in relation to the decision tree. By comparing the temporal, spatial, and intensity distributions of noise in the three subregions through charts, it becomes evident that CS and BoB subregions have similar characteristics, whereas

the ECNS subregion shows a clear distinction in terms of noise distribution. Indeed, the ECNS subregion is spatially dominated by noise, all levels combined, at almost 45% of the area, all the time. While, in CS and BoB, about one-third of the areas are dominated by the noise level over 100 dB re 1 $\mu$Pa. Furthermore, in the three subregions, high noise levels (over 110 dB re 1 $\mu$Pa) are permanent and concentrated in a reduced part of the areas (5%).

Consequently, the choice of noise-level threshold value and the choice of the size and the complexity of the assessed area may influence the confidence that can be placed in the results of the risk assessment and then on the validity of the decision-making.

## Impact of Threshold Dimensions

The results presented using the marginal distributions (Figs. 3 and 4) make it possible to observe the impact of threshold values setting on the different dimensions studied.

Large differences between temporal threshold values [0–100%] lead to relatively small variations, from 0.05 to 0.15 of the resulting risk assessment (Fig. 4c and Fig. 3a2, b2, c2 of each region). This demonstrates a certain stability of underwater noise over time during the studied month and over the studied areas. When compared to the other dimensions, the choice of the temporal threshold value has the smallest impact on the assessment outcome. The highest impact comes from the value of the noise-level threshold. The spatial threshold value definition seems to have a different effect depending on the area selected. The subregion ECNS is the smallest and the most exposed to low noise levels (below 80 dB re 1 $\mu$Pa) as shown in Fig. 1. Following the results of Fig. 3a3, the choice of the spatial threshold value seems to be important. Here, for different noise-level threshold values, this choice is reduced to a narrow band formed by the sharp transition from low to high temporal threshold values [0–100%]. This narrow band is related to the limited impact of the temporal threshold value when compared to the other two threshold values considered. In the larger subregions CS and BoB (Fig. 3b3 and c3), this same chart presents a different shape, with this sharp transition occurring for a wider range of spatial threshold values. This observation is related to the higher impact of the spatial threshold values on the ECNS area than on the CS and BoB areas. The stability of the temporal dimension is confirmed by Fig. 4c, where the risk is steady for each subregion until 0.95 and then drops to zero for the range of level and spatial threshold values.

Hence, the choice of temporal threshold values has a little impact on the result of the risk assessment, thus allowing a fairly reliable decision for the time period considered in the study. Conversely, the noise-level dimension has a strong influence on the risk assessment, thus on the reliability of the decision. Knowing that noise-level threshold values are directly linked to the biological knowledge of marine species, it becomes decisive in the management process.

## Application for Policymakers

Decision tree has been previously investigated in relation to pollution management, including noise pollution (Singh et al. 2013). The proposed algorithm follows a decision-taking process from the unitary cell to the larger scale of the habitat. If the risk is assumed to be too high in the habitat, the decision of mitigation responses follows and then a reverse order: from the habitat to the unitary cell. Such algorithm provides relevant supports to identify periods and areas that have the highest risk level regarding the defined thresholds. In addition, if the risk at the habitat level is considered as not too high, intermediary steps have to be considered depending on the values of calculation of the steps $Y$ and $Z$. $Y$ informs on the habitat level and could suggest the use of local mitigation measures to avoid the number of impacted cells to be to important. At a local scale, $Z$ informs on risk regarding the noise level, and it can be related to a particular set of activities of shipping in order to investigate dedicated mitigation.

Analysis of the marginal charts informs as well on the covariance between steps of the decision tree. It contains valuable relation for decision-making but requires stronger expertise for the interpretation. In addition, such relation depends on the area because of the traffic intensity and acoustic propagation. A first reading proposition can be to identify areas of the marginal charts where the value of the risk assessment can be strongly impacted by errors. They can be located where

$$\frac{\partial^3 X}{\partial \mu \partial \lambda \partial \tau}$$

is the greatest. In Fig. 4, the strongest gradient value is located at the inflexion point. Thus, the strongest sensitivity can be located around [95–100%] of the time for all areas; [80–95%] of the areas for BoB and CS and [55–60%] of the area for ECNS; and [100–110] dB re 1 $\mu$Pa for BoB, [95–105] dB re 1 $\mu$Pa for MC, and [60–70] dB re 1 $\mu$Pa for ECNS.

By considering the combination of all threshold values, marginalization provides an effective operational tool for the future integration of habitats and target species. It is built on the methodological basis developed at the European level and promotes the integration of threshold values recommended by the TG Noise (Sigray et al. 2022). It can also be implemented with the methodology developed by technical groups of Sea Regional Conventions (Merchant et al. 2018). In case of lack of biological knowledge, it supplies alternative possibilities to set threshold values and contribute to the effectiveness of mitigation measures (Lajaunie et al. 2023). It is essential to have a spatialized approach, in connection with mapping, because the physical environment is at the center of public policies in marine spatial planning (Tew-Kai et al. 2020).

In the event that the threshold values recommended by TG Noise are integrated in the proposed method, this would mean that 20% of the surface is affected by noise levels ranging from 100 dB re 1 $\mu$Pa to 110 dB re 1 $\mu$Pa most of the time in the three subregions. And as the studied areas are affected by a shipping rail, traffic and thus

noise are spatially concentrated. In this case, setting a spatial threshold value at 20% or lower is relevant to effectively manage the noise while also identifying the most at-risk areas.

## Perspectives

This chapter is a preliminary step for further developments for the application of underwater noise assessment and regulation. It relies on investigating a parametric test of all threshold value combinations, assuming to be a poorly informative methodology. It can be seen as a major caveat at the moment, as the threshold value definition has to be supported from the best available science. The construction of the appropriate prior distribution on $\lambda$, $\tau$, and $\mu$ using literature review is a required step. Among other, one can already mention researches on noise levels (Di Franco et al. 2020; Gomez et al. 2016; Southall et al. 2007, 2019, 2021; Weilgart 2018), as well as spatial and temporal extents (Rompré et al. 2010; Swift and Hannon 2010).

In a similar fashion, uncertainties on noise modeling and habitat distribution would expand the analysis of the decision tree. The proposed framework can easily consider additional complexity layers that would help in having a more comprehensive definition of the risk of impact while considering uncertainty at the heart of the decision-making process.

Other approaches have been investigated to assess underwater noise (Merchant et al. 2018), in particular regarding the aggregation of time and space dimension or measuring excess noise levels compared to non-anthropogenic sounds or by considering noise values over depth in a different way (Sertlek et al. 2016). As they rely on dedicated methodology, the framework has to be adapted. The impact of uncertainties of the areas at risk will be the main outcome for the comparison, as it is a major challenge to provide robust assessment.

Even considering the difficulty to define the right prior distributions, the probabilistic assessment has to be considered as a strong framework to extend to other pressures. By increasing dimensions to hypercube, it can be generalize to multi-pressures and multi-impacts. The forward modeling of combined pressure effects remains complicated, but an additive modeling would help stakeholders prioritize the knowledge acquisition.

## Conclusion

In this chapter, a multi-dimensional approach based on modeling and threshold definition for risk assessment was used to study the impact of anthropogenic noise on the marine environment in the French Exclusive Economic Zone. Such assessment remains challenging and strongly impacts the capacity to define relevant threshold values. This chapter investigates a decision tree to define the risk assessment and explore its sensitivity to threshold values and dimensions.

The decision support provided by the study is presented through a three-dimensional chart that highlights the covariance among spatial, temporal, and noise-level dynamics. The results strongly vary based on the environment and traffic intensity. It reflects as well that the decision tree allows considering where and how often the risk level can be too high.

The parametric test of the threshold values for the decision tree provides a comprehensive analysis of the relation among threshold values. Risk levels are strongly related to the selection of thresholds, and certain dimensions have a greater impact on the risk assessment. Considering the spatial, temporal, and noise-level dimensions could aid in prioritizing the acquisition of knowledge and planning of mitigation measures. Furthermore, the chapter identifies combinations of threshold values that may lead to erroneous conclusions.

The chapter provides valuable insights for policymakers and stakeholders in the management of marine noise pollution. The results were consistent with the recent work of setting options of thresholds for continuous noise in the MSFD. This framework can be generalized to include future developments regarding acoustic modeling, habitat, and knowledge on the impact.

**Acknowledgments** The authors acknowledge the Ministère de la Transition Ecologique et Cohésion des Territoires for supporting and funding this work under the convention concerning the mission of scientific and technical support for the implementation of the MSFD and partners of JONAS (Joint Framework for Ocean Noise in the Atlantic Seas) project financed by the INTERREG Atlantic Area-funded research project (EAPA52/2018) for providing noise maps.

**Abstract**

Offshore wind (OSW) energy development is a fast-growing international industry. A range of sounds that potentially affect marine life are produced during preconstruction surveys, construction, and operations of offshore wind farms. However, the effects of these sounds on marine life, and particularly on fishes and aquatic invertebrates, are not well understood since there have been few studies of noise-induced OSW effects on these animals. Thus, building from recent efforts to identify research and coordination needs for environmental OSW research, this chapter suggests several priorities for further research to improve understanding of the effects of OSW on fishes and aquatic invertebrates. This chapter also identifies several areas where further coordination to prioritize taxa for study, standardize data collection, explore mitigation measures, and centralize research funding could help fill key gaps in knowledge and inform development decisions and mitigation measures. These gaps are relevant to floating and fixed-foundation OSW, as well as to other marine renewable energy sources such as wave and tidal energy. Filling these research and coordination gaps would help to improve understanding of the effects of sound and vibrations on fishes and aquatic invertebrates at both the individual and population levels and provide important information to help in the assessment of the potential for cumulative impacts to populations and ecosystems.

## Introduction/Background

### Responses by Fishes and Invertebrates to Anthropogenic Sound

There are substantial gaps in knowledge of the potential effects of, and responses to, underwater sound by fishes and aquatic invertebrates (e.g., Popper et al. 2014; Hawkins et al. 2015; Di Franco et al. 2020; Chahouri et al. 2021), including anthropogenic (human-generated) sound generated from vessels, geophysical and geotechnical surveys of the ocean floor, and marine renewable energy installations used to harvest wave, tidal, and wind energy, among other sources. Moreover, while significant attention has been given to marine mammals, there is a fundamental lack of knowledge regarding the detection, production, and use of sound by many fishes and aquatic invertebrates, making it particularly difficult to determine how various anthropogenic sources might impact these animals. An additional issue is that most of the earlier work on anthropogenic sound and its effects on these animals focused on the sound pressure component of a sound, whereas most species of fishes and aquatic invertebrates primarily detect and respond to particle motion (e.g., Nedelec et al. 2016; Popper and Hawkins 2018) and/or substrate vibration (Roberts and Elliott 2017; Hawkins et al. 2021) rather than sound pressure. For a definition of terms, see Popper et al. (2022). For an extended discussion of underwater sound directed at nonexperts, see www.dosits.com.

### Background on Offshore Wind and Potential Effects

Offshore wind (OSW) energy development is a fast-growing industry around the world. The amount of planned OSW energy development is substantial, and projections of the scale of development needed to achieve climate change reduction scenarios indicate that a large proportion of some countries' marine waters may be affected by OSW energy development in the coming decades (Freeman et al. 2019). Furthermore, the technologies associated with OSW are rapidly changing to maximize efficiencies and reduce operational risks, resulting in highly variable structural components and installation and operation methods.

OSW energy development drives a variety of ecosystem changes, including in hydrodynamic conditions and primary production (Daewel et al. 2022) and the development of artificial reefs on turbine foundations and scour protection (Degraer et al. 2020). Sounds are also generated by geophysical and geotechnical surveys (primarily during the preconstruction period), pile-driving and other construction activities (including multiple piling technologies with different sound

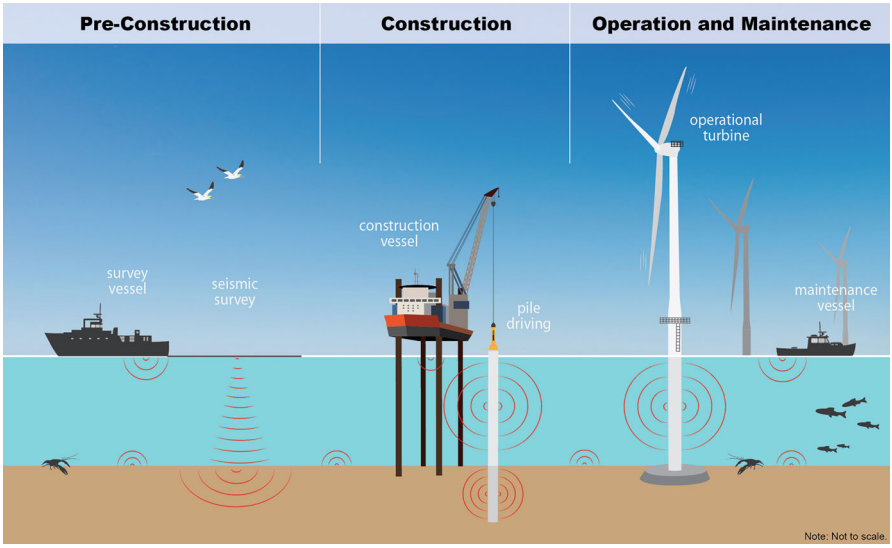

**Fig. 1** Major sources of sound generated during different phases of offshore wind energy development. Sound (shown as red lines) may include pressure, particle motion, and substrate vibration. (Figure © 2022 Iain Stenhouse/Biodiversity Research Institute, all rights reserved, used with permission)

characteristics), the operation and maintenance of offshore wind turbines and associated infrastructure, and vessel activity during all development phases (Fig. 1).

The effects of OSW pile-driving sound on aquatic life have only been studied in detail for a few marine mammal species in European waters including harbor porpoise (*Phocoena phocoena*), harbor seals (*Phoca vitulina*), and gray seals (*Halichoerus grypus*) (Madsen et al. 2006; Thomsen et al. 2006, 2015; Brandt et al. 2018). A growing concern, however, is that OSW-related sound may also affect fishes and aquatic invertebrates. Such effects may include behavioral changes such as movement from areas of spawning or feeding, the inability of animals to detect sounds of biological importance due to masking by the OSW sounds, or changes in migration routes (e.g., Siddagangaiah et al. 2021; van der Knaap et al. 2022). Moreover, even if there are no overt behavioral changes, detected sounds may result in physiological effects (e.g., increases in stress levels) that have the potential to reduce fitness (Filiciotto et al. 2014, 2016).

The geographic scale at which masking and behavioral or physiological effects might occur depends on a variety of factors, including the frequency range and sensitivity of hearing for a given species, ambient noise levels, OSW sound levels (which can vary with weather during operations; Wahlberg and Westerberg 2005), and other factors. Direct physical harm from sounds is also possible (e.g., from high level construction sounds generated when driving turbine pilings into the seabed) in situations where sensitive species are located close to impulsive sound sources or when exposure to sufficient energy occurs over a long duration (e.g., Thomsen et al. 2006; Halvorsen et al. 2012; Dahl et al. 2020).

## Origin of Findings and Recommendations

This chapter is based, in part, on the outcomes of a workgroup established during the 2020 State of the Science Workshop on Wildlife and Offshore Wind Energy Development (www.nyetwg.com/2020-workshop) that identified a set of clear, focused recommendations for research on the effects of OSW-related sound on fishes and aquatic invertebrates (Popper et al. 2021, 2022). The workgroup included researchers, resource managers, offshore wind energy developers, and other stakeholders with relevant technical expertise who identified and prioritized research needs and defined seven short-term priorities (i.e., within the next five years) that include a mix of research and coordination efforts (Popper et al. 2021, 2022).

Several other efforts have further informed the discussion in this chapter and recommendations in sections "Recommendations – Research and Coordination" and "Recommendation – Funding: Net Positive Impact Fund," including recent studies (e.g., van der Knaap et al. 2022) and reports such as those produced by the Regional Synthesis Workgroup of the Environmental Technical Working Group and the Responsible Offshore Science Alliance (Regional Synthesis Workgroup 2022, 2023; ROSA 2022). Additional regionally focused research, monitoring, and mitigation efforts underway in the United States that have influenced the recommendations in section "Recommendation – Funding: Net Positive Impact Fund" include:

- *Draft guidance issued in 2022 by the U.S. Bureau of Ocean Energy Management (BOEM) for mitigating OSW impacts to commercial and recreational fisheries* (BOEM 2022b). This guidance includes the recommendation to develop a compensatory mitigation fund to address unavoidable impacts to fisheries targeting both fish and invertebrate (e.g., shellfish, squid) species. The guidance suggests that such a fund could be specific to each individual wind farm or could encompass the effects of multiple wind farms, but that regardless, the OSW energy developer(s) should consider hiring a neutral third party to manage the fund. Further scoping of a regional compensation fund indicated that there are clear benefits to managing fisheries in a consistent way across the region, rather than handling compensation on an individual basis for each state or OSW farm, as the latter may fail to address cumulative impacts to resources of interest (North Atlantic Coast States 2022).
- *The requirement from several states for OSW energy developers to fund regional environmental and fisheries research.* These requirements are implemented via power purchase agreements between offshore wind energy developers and the states that include a minimum funding commitment to support regional research (e.g., BPU 2020; NYSERDA 2020, 2022).
- *Biodiversity offsetting, otherwise known as compensatory mitigation of ecological losses caused by infrastructure development, which can be used to achieve net positive biodiversity impacts* (Moilanen and Kotiaho 2021). OSW energy developers are increasingly committing to "net positive" gains in biodiversity from OSW energy development (e.g., Dupont et al. 2022; Jedele et al. 2023) and

compensatory mitigation has been identified as a necessary step to achieve no net loss of biodiversity from OSW energy development (Croll et al. 2022).

It is clear from the ideas in Popper et al. (2022) and the additional studies above that focused, well-planned research is needed to target essential data gaps and best improve the state of knowledge on potential effects of sound on fishes and aquatic invertebrates as the OSW industry continues to grow. Thus, this chapter, and particularly the section "Recommendations – Research and Coordination," identifies critical research and coordination needs to improve understanding of the effects of OSW energy development and operational sound on fishes and aquatic invertebrates. The chapter also identifies several commonalities between these data gaps and those that have been recognized for other aquatic energy sources such as marine hydrokinetics, and from this foundation, makes suggestions that may help to direct future research and coordination activities.

## Recommendations – Research and Coordination

To advance our understanding, additional research must be conducted into the effects of OSW sound on detection, production, and use of sound on fishes and invertebrates, as well as on their behavioral responses to anthropogenic sound and vibration. Baseline data prior to sound exposure will be essential to help understand the effects of anthropogenic sound, though such data may become increasingly challenging to obtain as the industry grows and animals become exposed to the development of multiple offshore wind facilities in a region over time. Thus, interactive effects relating to the presence of multiple individual OSW farms in close proximity to each other should also be explored. These research studies will be most effective at increasing our understanding if there are substantial coordination efforts to ensure that new studies are focused on the highest priority data gaps and are coordinated and standardized such that data can be aggregated to maximize gains in knowledge.

Importantly, this work should be supported by a dedicated funding stream that is regional in focus (rather than specific to individual OSW farms) to facilitate both research and coordination efforts. This would also further help to ensure that funding is directed toward regional priorities that best inform a broader understanding of the potential for cumulative impacts to populations and ecosystems from a variety of renewable energy activities (see section "Recommendation – Funding: Net Positive Impact Fund").

The recommendations below build directly from Popper et al. (2022), while introducing or expanding upon several ideas that were not emphasized in that paper. These new suggestions include the use of consequence models as a framework for directing research efforts as well as the formation of a regional fund to help coordinate, prioritize, and conduct necessary research and coordination in a timely fashion. Moreover, these recommendations are inclusive of all aspects of sound (particle motion and substrate vibration, as well as sound pressure). They also

include research on a variety of life history stages and species with differing mobility (e.g., ability to escape sound to which they are exposed). Examination of benthic invertebrates will be important to assess the effects of substrate vibration.

It should be noted that the recommendations are not presented in any particular order, though Popper et al. (2022) do provide a partial list of prioritized recommendations. From a logical sequencing standpoint, it would make sense to address many of the coordination needs before research is conducted – for example, to identify priority taxa for further research first, and then target those priority taxa in studies of behavioral responses to offshore wind energy development. However, the reality of funding availability, the time required for data standardization and other coordination efforts, and the immediacy of OSW energy development in the United States and elsewhere, all preclude an orderly, consecutive approach to addressing priorities. Indeed, it is likely that the best approach would be to address, where possible, these needs concurrently, and to balance needed coordination and standardization with the need to collect field data from imminent commercial-scale OSW projects. In the longer term, the primary end goal of all of these research and coordination efforts is to inform an understanding of the potential for cumulative impacts to populations or ecosystems; as such, this topic is presented as our first recommendation in the below list, to provide context for those following it.

## Inform Cumulative Impact Estimates (Consequence Models)

The end goal of all the suggested research studies in this chapter is to understand the cumulative biological impacts to fishes and aquatic invertebrates from OSW energy development. However, developing this understanding will require substantially more data for more fish and invertebrate species than now available. In the longer term, data from new studies must be aggregated into cumulative impact frameworks for assessing the effects of OSW sound on populations of interest (e.g., Pirotta et al. 2018; Slabbekoorn et al. 2019; Mortensen et al. 2021). Additionally, OSW can affect aquatic taxa via multiple mechanisms (for example, via the development of artificial reefs on hard substrates; Degraer et al. 2020), and a range of studies on such phenomena are needed to provide context for species- and sound-specific studies of OSW effects to aquatic taxa.

## Examination of Animal Displacement and Other Behavioral Responses to Sound

There are some data, primarily from Europe, on the responses of fishes to sound generated by OSW energy development and operations (e.g., Thomsen et al. 2012; Debusschere et al. 2016; Kok et al. 2021). For example, recent tagging studies of free-ranging Atlantic cod (*Gadus morhua*) are adding to our knowledge of the effects of geophysical exploration and pile-driving sound on the behaviors and movements of this species (van der Knaap et al. 2021; van der Knaap et al. 2022).

There are also data from other anthropogenic activities such as the driving of piles for wharfs and bridges (e.g., Hawkins et al. 2014; Iafrate et al. 2016a, b).

From the available data, the OSW sound sources with the highest risk of causing behavioral or physiological changes with the potential to affect animals' fitness are likely to be some of the lower frequency sounds associated with geophysical and geotechnical surveys (primarily occurring during the preconstruction period), as well as impact pile driving during turbine installation. The explosive removal of unexploded ordnance (UXO) on or in the seabed during construction may also be a concern in some locations. If sound causes displacement from important spawning areas, for example, this could affect breeding success and thus impact individual or population fitness. Changes to predator-prey dynamics and changes in survival could likewise have the potential for cumulative impacts.

Thus, it is necessary to first determine whether changes in behavior or physiology are occurring, and then to determine the individual or population implications of such changes. In addition to examining displacement from spawning or foraging areas, studies should also examine other changes in movement behavior, reproductive behavior, predation success, foraging activity, and changes in acoustic behaviors.

To the extent possible, behavioral studies should occur in the field in the presence of actual OSW activities to make the study results more representative and thus useful for management. However, such studies are not always possible since field work requires very high effort and experimental conditions are extremely difficult to control, particularly for more physiologically focused studies or studies of phenomena that remain particularly poorly understood, such as the effects of substrate vibration on benthic invertebrates. Thus, laboratory studies should aim to reproduce real-life conditions as much as possible, for example by employing a real sound source for controlled exposure and designing enclosures that allow experimental animals to respond to sound exposure in realistic ways. Best practice could be to combine field efforts with laboratory studies. Ecological/spatial models can also be utilized to help to identify parameters to be measured in the field (Heinänen et al. 2018).

In any case, focal species should be carefully selected (see section "Identification of Priority Taxa on which to Focus Research") to include species present in OSW areas (e.g., Friedland et al. 2021) and that possess the hearing capabilities to be affected by OSW-generated sound, inasmuch as this is known.

## Hearing Sensitivity Studies Related to Particle Motion, Substrate Vibration, and Sound Pressure

Some of the above research on the effects of OSW-related sound to fishes and aquatic invertebrates can be conducted without a thorough understanding of sound detection capabilities of the animals under study. However, understanding of species' hearing capabilities is focal to informing interpretation of the results of behavioral studies. Moreover, it is crucial to understand the applicability of results to other species, sites, and research questions. Thus, it will be difficult to effectively

assess the potential for cumulative impacts across OSW areas without tying observed behavioral responses to a species' ability to detect the sounds and vibrations to which they are exposed.

Studies of species hearing capabilities, as discussed by Hawkins et al. (2015), must include a focus on the range of frequencies that are detectable as sound pressure and particle motion, as well as frequencies detectable via substrate vibration for those animals living on, in, or near the seabed. Much more also needs to be known about the potential masking of biologically relevant sounds (e.g., those of conspecifics and sounds used to attract mates or detect the presence of predators or food) due to sound generated by OSW and other anthropogenic sources. While some studies might involve examination of electrophysiological responses of the ear or auditory system, these physiological responses do not necessarily represent the sounds to which an animal will change its behavior in the wild, and studies using behavioral approaches will be essential (Popper and Hawkins 2021).

## Identification of Priority Taxa on which to Focus Research

There are a very large number of fish species and an even larger number of aquatic invertebrate species that are likely to detect and use sound in their normal behaviors (e.g., Rice et al. 2022). As such, it is impossible to investigate behavior or hearing in a sizable proportion of extant species. At the same time, because of the extraordinary diversity in the biology of fishes and aquatic invertebrates, and the associated diversity in hearing organs, extrapolation from one species to another requires considerable caution and a solid scientific understanding of their similarities. This issue was discussed by Popper et al. (2014) who recommended focusing on groups of fishes and aquatic invertebrates with differing hearing capabilities, as well as different hearing mechanisms, in hopes that collecting data on representatives from each group could help to inform predictions of effects for like taxa (Popper et al. 2014; Hawkins et al. 2020).

Thus, identification of a suite of preidentified taxa of interest would focus studies on those taxa, so that research can most effectively contribute to the state of knowledge regarding potential effects of OSW. Focal species must: (1) occur in the vicinity of OSW development areas (e.g., Friedland et al. 2021); and (2) have the potential to be affected by OSW-related sound. This vulnerability could draw from the regularity of their occurrence in OSW areas (for example, structure-oriented species; Degraer et al. 2020 or from their use of OSW areas during important life history stages such as spawning and migration toward reproduction locations. Species known to be sensitive to displacement from OSW energy development activities should be carefully considered, not least because species with known sensitivity have by definition already been studied, and thus, there is a foundation upon which to add knowledge. Species about which very little is known could also be a focus, as they may have the potential for severe effects that have not been studied to date. Species should also be drawn from a range of ecological niches and may include species of regulatory or commercial concern, such that research studies can help to inform OSW decision making and potential management actions.

## Standardization of Methods and Sharing of Data

To ensure that results are comparable between studies and can effectively inform our understanding of cumulative impacts over the long term, it would be of particular value if studies were conducted in standardized ways. Data should also be made publicly available. To date, studies on fishes (and the few on aquatic invertebrates) have focused on diverse species and used a variety of methods and metrics, making it difficult to compare results, much less begin to extrapolate to other species. There are several existing standards from which to build (e.g., Dekeling et al. 2014, 2016; Merchant et al. 2022) but these are primarily focused on marine mammals and leave substantial gaps in standards that are applicable to other taxa.

Existing standards, as well as detailed recommendations on further methods and metrics standardization, are discussed in Popper et al. (2022). In general, there is a need for:

- Reporting received signal levels (in the appropriate metrics/units).
- Standardized methods and metrics for studying particle motion and substrate vibration, including the measurement of particle acceleration where predictions of acceleration are not reliable (e.g., near boundaries and in shallow waters).
- Effect size reporting to facilitate future meta-analysis and other efforts to compare or compile data between studies.
- Publishing and acceptance of data where no effects are shown (assuming care is taken to avoid Type II errors) to help guide the direction of future work.

## Development of a Long-Term, Highly Instrumented Field Site to Support Research

Field-based research is an essential component of a research strategy to understand the effects of OSW-related sound on fishes and aquatic invertebrates, as noted above. However, it can be quite challenging to characterize ambient soundscapes and control environmental variables such that animal responses can be properly attributed to causal mechanisms or linked to specific sound characteristics. If an ecologically relevant long-term field site was identified and made available for OSW sound-related research, it could help to address some of these challenges while also facilitating inclusivity/access and standardization of research methods. Investigators could develop a baseline understanding of the site's acoustics and substrate vibration (and ideally control both as much as possible), install a variety of instruments for measuring acoustic conditions and animal responses, and study focal species, substrates, and research questions in a more controlled (but still ecologically and acoustically relevant) environment. Such a long-term research site would need to be carefully selected to be as similar as possible to OSW areas of interest, while allowing control of the local soundscape (or at least effective characterization).

## Preliminary Assessment of Sound Mitigation Options for Fishes and Aquatic Invertebrates

Development of OSW noise mitigation approaches has focused primarily on mitigating effects to marine mammals (e.g., Verfuss et al. 2016, 2019; Thomsen and Verfuss 2019). These approaches have included the development of noise exposure thresholds, noise abatement systems such as bubble curtains, vibratory pile-driving approaches, and animal deterrents. It is unclear the degree to which such mitigation approaches are likely to be effective for fishes or aquatic invertebrates. The frequencies and types of sound (e.g., sound pressure) for which these mitigation methods have been developed may not match those relevant to fish and invertebrate hearing and do not take into consideration particle motion or substrate vibration. One approach, at least at first, might be to do a desktop feasibility study that assesses the utility of existing sound mitigation options for fishes and aquatic invertebrates. Such a study could help to identify key knowledge gaps to inform the development of effective mitigation measures for these taxa.

This assessment must take into consideration several factors. First, there is no purpose to developing or employing mitigation unless there is a significant risk that the animals of interest are potentially impacted by the sounds (Popper et al. 2020; Thomsen et al. 2021). Second, it must be determined whether the mitigation method is likely to be effective in reducing sound levels at frequencies for which the animals in question are sensitive. Third, virtually all OSW sound mitigation methods developed to date focus on sounds in the water. Yet, vibrations and sounds in the substrate can travel considerable distances to be detectable by benthic animals (e.g., Hawkins et al. 2021). Thus, an assessment of sound mitigation approaches must include explicit consideration of substrate vibration and its potential impact on animals living in or near the ocean floor.

## Recommendation – Funding: Net Positive Impact Fund

It will be difficult to address these research and coordination needs on a timeline that allows results to inform OSW energy development in the United States and around the world. Thus, development of a centralized funding mechanism is recommended to support environmental research and mitigation – a "net positive impact fund." As described below, there are several ongoing activities in the eastern United States and elsewhere that indicate the timeliness and relevance of such a recommendation.

The regional OSW fisheries compensation fund currently being planned in the eastern United States is focused on compensating fishermen for effects to their livelihoods from OSW energy development – e.g., if they cannot fish in a given area for some period of time during or after construction. Several European countries as well as U.S. states have already established some kind of compensatory mitigation process for fisheries in relation to OSW energy development (F-TWG 2022).

A similar fund that OSW developers pay into to support environmental research could help ensure that studies are conducted in standardized ways and funds are

directed toward key priorities that can best contribute to understanding cumulative impacts. Moreover, OSW energy developers are increasingly committing to "net positive" gains in biodiversity from OSW energy development (e.g., Dupont et al. 2022; Jedele et al. 2023). Such biodiversity offsetting, otherwise known as compensatory mitigation of ecological losses caused by infrastructure development, can be used to achieve net positive biodiversity impacts (Moilanen and Kotiaho 2021) and has been identified as a necessary step to achieve no net loss of biodiversity from OSW energy development (Croll et al. 2022). As little is currently known about the effects of OSW-related sound on fishes and aquatic invertebrates, the degree of compensatory mitigation that may be required is unclear. As such, in the immediate term funding could be focused on understanding the scale of impacts to inform the degree of mitigation that may be required. There are several models for collective funding of offshore wind environmental research, including the Offshore Renewables Joint Industry Programme for Offshore Wind (http://bit.ly/3XjDDXZ; http://bit.ly/3ITLqqZ).

There are several regional or national collaborative bodies in the eastern United States that could house such a "net positive impact" fund. The Regional Wildlife Science Collaborative for Offshore Wind (RWSC – https://rwsc.org/) and Responsible Offshore Science Alliance (ROSA – https://www.rosascience.org/), collaborative groups focused on OSW and the environment and fisheries, respectively, were both developed with this coordination and funding role in mind. Existing funding mechanisms at the state level (e.g., BPU 2020; NYSERDA 2020, 2022) are also being implemented to increase available funds to support regionally important research and coordination efforts. Additionally, the National Offshore Wind Research and Development Consortium (NOWRDC) could increase their current focus on sound-related research and mitigation measures and expand the scope of this interest beyond marine mammals. The Center for Marine Acoustics at BOEM and the Passive Acoustics Program at the National Marine Fisheries Service Northeast Fisheries Science Center could play a role in the guidance and standardization necessary to ensure that a net positive impact fund would effectively prioritize and coordinate research efforts.

Many of the above-mentioned groups focus largely or exclusively on OSW, but it may be more efficient to broaden the scope of a net positive impact fund to also incorporate research into the effects of other types of marine energy development as well as OSW.

## Application to Other Industries and OSW Technologies

Technologies used within the OSW industry are undergoing substantial advancements that will influence the types of sound to which fishes and invertebrates may be exposed. Turbines in shallow waters typically have steel monopile or jacket foundations that are installed via pile driving, but offshore wind is advancing into deeper waters where floating foundations will become the norm. Floating turbines still require anchoring to the seabed, and are connected to these anchors via at least

three large mooring lines; depending on the design, these lines may drag along the ocean floor, leading to a larger physical footprint (Maxwell et al. 2022). Construction is generally less noisy for floating foundations (Carduner et al. 2022), as the anchors are smaller than the turbine foundation itself, so driving them into the seabed requires substantially less energy. Some types of anchors (such as gravity anchors) do not require pile driving at all (Maxwell et al. 2022). However, movement of the mooring lines during turbine operations represents a new source of sound and vibrations for the lifetime of these offshore wind projects (Carduner et al. 2022; Maxwell et al. 2022). Thus, the specific sounds produced by floating wind energy may differ somewhat from fixed-platform technologies. The locations in which floating technologies will be deployed may also lead to the exposure of new taxa that have not previously interacted with OSW energy development. The above research recommendations hold true regardless of foundation type, but research focused specifically on floating wind may need to adjust objectives, focal taxa, and other specifics to examine this new type of development.

More generally, while the focus of this chapter is on research needs associated with OSW with respect to fishes and aquatic invertebrates, there are a variety of other devices in various stages of development that will potentially harness energy in the marine environment. These include devices to extract energy from tidal or wave motion (Clément et al. 2002; Wolfram 2006). Some devices are similar to fixed-foundation OSW turbines in that they require some amount of pile driving during construction, while others have much reduced sound footprints during the construction period. All such devices are likely to produce some sound during the operational period within the range of hearing of fishes and aquatic invertebrates, and thus have the potential to impact behavior and possibly fitness. Indeed, while the exact nature of the sounds may vary between devices, including (but not limited to) sound spectrum, amplitude, and repetition rate, it is likely that there are more similarities than differences in the sounds produced by marine renewable energy devices. While the habitats in which devices are placed are likely to vary, particularly tidal devices (which are generally targeted in coastal locations) vs. open-water OSW and wave energy generators, there remains a lack of information about sound detection and behavioral responses to sound for all such devices.

Thus, it is reasonable to suggest that what is learned about responses to OSW sounds may also inform understanding for other types of marine renewable energy development, and coordination of research may be valuable not just among different OSW sites but also among studies of fixed and floating OSW as well as other marine renewables. Indeed, in addition to marine renewables, these recommendations apply to a range of sound-producing activities in the marine environment. Much current knowledge of potential effects from OSW draws from studies of pile driving for bridges, wharves, and other structures. While the characteristics of the local environment and species present clearly affect the specifics of how sound may affect aquatic life, there are generalities that can be drawn across sound source type that, with concentrated research and coordination efforts, may further help to improve the knowledge base.

## Conclusions

Several focused, high-priority recommendations were developed by a workgroup in 2021 to improve our understanding of cumulative effects of offshore wind energy-related sound to fishes and aquatic invertebrates. Those recommendations were published in a workgroup report (Popper et al. 2021) and an article in *The Journal of the Acoustical Society of America* (Popper et al. 2022). Since the workgroup's efforts concluded, there has been continued progress on a variety of fronts to further identify research and coordination needs. With several notable exceptions, however, there has been limited progress in actually funding or conducting the necessary research, and so there are still few field studies conducted under real-world conditions that examine behavioral, physiological, and ecosystem effects of sound that may have possible fitness consequences for fishes and aquatic invertebrates. There have been several recent efforts toward standardization in the United States, such as with BOEM's recently released Nationwide Recommendations for Impact Pile Driving Sound Exposure Modeling and Sound Field Measurement for Offshore Wind Construction and Operations Plans (BOEM 2022a). There have also been several recent field studies to improve our understanding of effects from pre-construction surveys, construction, and operation of OSW facilities in Europe (e.g., van der Knaap et al. 2021, 2022).

In the long term, the aim of all such funding and research should be to inform cumulative impact models, thereby substantially enhancing our understanding of possible sound-related impacts of OSW energy development to populations and ecosystems. Effective assessment of potential cumulative impacts of sound and vibration on fishes and aquatic invertebrates is currently hindered by a range of knowledge gaps, including those identified in this paper. Filling such critical gaps in knowledge will improve understanding of possible sound-related impacts of energy development to populations and ecosystems.

**Acknowledgments** Support for the State of the Science Workgroup was provided by New York State Energy Research and Development Authority (Agreement #118972). The authors of this chapter thank the more than 40 people who participated in workgroup discussions. While it is not possible to name all of these people here, they are listed in the appendix to the workgroup report (Popper et al. 2021). Special thanks to Julia Gulka and Kate McClellan Press for their support in managing workgroup discussions and developing the 2021 report.

**Abstract**

The National Offshore Petroleum Safety and Environmental Management Authority (NOPSEMA) is Australia's offshore energy regulator and has a unique perspective on the benefits of adaptive management for addressing underwater noise impacts. This is due to the dual role in assessing the adequacy of proposed management programs for underwater noise-generating activities as well as undertaking compliance inspections to ensure management programs are effectively implemented as intended.

Environmental impact assessment is not a perfect discipline. It relies on a series of systematic impact predictions based on comprehensive considerations of interactions between a proposed activity and the environmental values and application of relevant scientific studies. The predictions of impact then inform the selection of mitigation measures needed to reduce potential impacts to acceptable levels. The effectiveness of mitigation measures and how they will

function and perform within the range of variables presented by a real-world setting is uncertain in many cases. For underwater noise-generating activities, uncertainty in the effectiveness of mitigation measures can be addressed through the application of adaptive management.

NOPSEMA's regular compliance monitoring of noise-generating activities has revealed the importance of adaptive management for responding to unforeseen circumstances and environmental data during the implementation of activities to address key areas of scientific uncertainty.

This chapter highlights the post approval requirements to implement adaptive management programs to address new information, and scientific uncertainties that remain following project approval. Monitoring and adaptive management are critical for ensuring underwater noise impacts can continue to be managed to acceptable levels throughout the full duration of an activity.

Two case studies are explored in the chapter to highlight how changes in the knowledge base that informed impact predictions and changes in the environmental setting should be evaluated to determine the need for adaptive management.

## Introduction

In Australia, the National Offshore Petroleum Safety and Environmental Management Authority (NOPSEMA) is the independent regulator of environmental management, health and safety and structural (well) integrity for all offshore oil and gas operations and greenhouse gas storage activities in Commonwealth waters, and in coastal waters where regulatory powers and functions have been conferred. NOPSEMA regulates these offshore activities under the *Offshore Petroleum Greenhouse Gas Storage Act 2006*, and more recently NOPSEMA's role has expanded to administer the functions of the Offshore Infrastructure Regulator under the *Offshore Electricity Infrastructure Act 2021* which includes the regulation of environmental management, work health and safety, and infrastructure integrity of future offshore renewable energy activities.

Offshore energy activities can introduce significant sources of anthropogenic underwater noise in the Australian marine environment, with the potential to adversely affect marine receptors if not effectively managed. Common examples of significant noise-generating offshore energy activities that NOPSEMA regulates include marine seismic surveys which are undertaken for multiple purposes such as to identify potential oil and gas reservoirs below the seafloor or for site characterization for renewable energy developments, and pile driving which is undertaken to

install foundation piles into the seabed for the construction of offshore oil and gas or renewable energy developments.

NOPSEMA administers an objective-based environmental management regime in accordance with the Offshore Petroleum and Greenhouse Gas Storage (Environment) Regulations 2009 (Environment Regulations) that aims to ensure environmental impacts and risks of offshore energy activities are reduced as to as low as reasonably practicable (ALARP) and an acceptable level and consistent with the principles of ecologically sustainable development (ESD) set out in section 3A of the *Environment Protection and Biodiversity Conservation Act 1999*. This objective-based regime requires proponents of offshore energy activities to submit an environment plan (EP) to NOPSEMA for approval before their activities can commence. An EP must include an assessment of all the environmental impacts and risks of a proposed activity and set out the evidence base that demonstrates how the activity will be managed in a manner that will ensure the impacts and risks are reduced to ALARP and acceptable levels and consistent with the principles of ESD.

An EP must also set out environmental performance outcomes (EPOs) that are equivalent to or better than the acceptable levels of environmental impact or risk, along with environmental performance standards (EPSs) with associated measurement criteria, which collectively outline a framework of measurable benchmarks for environmental performance to be achieved by a proponent during the implementation of their proposed activity. EPs must also include an implementation strategy with arrangements for ensuring that environmental management will continue to be effective during the implementation phase. Once NOPSEMA is reasonably satisfied the EP meets the acceptance criteria set out in the Environment Regulations, an EP will be approved (NOPSEMA 2022a, b, c).

NOPSEMA's objective-based regime means NOPSEMA does not prescribe "one size fits all" control measures or "set and forget" approaches to environmental management. Rather, activity proponents have the flexibility to design their environmental management arrangements during the preparation of an EP to suit the specific activity circumstances and operating environment with arrangements in place to continuously review and adapt their management arrangements in response to potential changes not foreseen during the EP's preparation. The benefit of this adaptive regulatory approach is that it can address scientific uncertainty, provides for continuous improvement in environmental management over time, and allows for offshore energy activities to rapidly adopt advances in technology, consider new science, and respond to any unforeseen changes in an operational environment.

Activity proponents are legally responsible for complying with the commitments in the approved EP. NOPSEMA can and will undertake compliance-monitoring inspections to ensure activity proponents are effectively implementing key environmental management commitments and effectively adapting management arrangements where necessary, so that EPOs and EPSs will continue to be met and environmental impacts and risks remain ALARP and acceptable.

This chapter outlines how NOPSEMA's regulatory framework provides for the effective management of potential impacts and risks from anthropogenic underwater noise generated by offshore energy activities on an ongoing basis. It provides

insights into the challenge faced by NOPSEMA to make defensible decisions in relation to impacts and risks from anthropogenic noise when faced with scientific uncertainty and explains how this challenge can be overcome through the development and implementation of monitoring and adaptive management approaches. Two case studies have been included to illustrate monitoring and adaptive management in practice and demonstrate how this environmental management approach has successfully resulted in the effective management of impacts and risks from underwater noise in response to unexpected changes during activity implementation.

## The Challenge: Making Defensible Regulatory Decisions When Faced with Scientific Uncertainty

Ecologically important species such as whales, sea turtles, and pinnipeds as well as commercially important species of fish and invertebrates are among the major noise-sensitive marine fauna groups in Australia. Potential impacts to these marine fauna groups that could result from underwater noise generated by offshore energy activities may include displacement from important biological habitats, disturbance to important biological behaviors, stress, diminished health, communication masking, impairment to hearing (e.g., temporary or permanent threshold shifts), physical injury, and mortality (CMS 2017). There are also a number of indirect impacts that may occur, including but not limited to impacts on other trophic levels (e.g., prey displacement or depletion) and reduced reproductive success. The extent, severity, and duration of these impacts will depend on the nature of the noise exposure (e.g., intensity, frequency, and duration), the nature of the environmental receptor (e.g., behavior, life stage, ecology, and physiology), and the level of spatial and temporal overlap between the noise-generating activity and the habitat of the noise-sensitive fauna group (NOPSEMA 2023a).

While the scientific knowledge base is rapidly evolving, the population or ecological level consequences of different levels of underwater noise exposure remain uncertain for a wide range of taxa. Some examples of the key areas of scientific uncertainty that reduce confidence in predictions of the consequences of underwater noise on values of the marine environment include (NOPSEMA 2023b):

- Dose-response relationships for relevant noise effects to inform development of suitable effect thresholds for environmental impact assessment
- The effects of underwater noise emissions on listed threatened whales to inform the management necessary to ensure offshore energy activities do not reduce population viability and /or impede species recovery
- Behavioral, physical, and physiological impacts of noise on fish and invertebrates and implications for the fisheries that target them
- The biological and ecological consequences of underwater noise impacts on ecologically and commercially important marine fauna
- The biological and ecological consequences of underwater noise exposure on marine turtles particularly during important life stages and behaviors

- The effectiveness of marine fauna detection technologies or control measures for managing the impacts of noise from offshore energy activities

During the EP assessment process, NOPSEMA scrutinizes the level of scientific uncertainty associated with predictions of underwater noise impacts and the anticipated effectiveness of management measures in reducing these impacts. NOPSEMA applies greater precaution in the decision-making process when there is a higher degree of scientific uncertainty in the effectiveness of the control measures proposed in the EP by the proponent.

## Addressing Scientific Uncertainty

When making a decision regarding whether the EP demonstrates the environmental impacts and risks of an activity will be of an acceptable level, NOPSEMA will assess the case made by the proponent in the submission in accordance with NOPSEMA's policies and guidance (NOPSEMA 2022a, b, c). This includes, but is not limited to, whether areas of uncertainty in predictions of impact and risk are appropriately identified, acknowledged, and addressed.

Where there is uncertainty as to whether acceptable levels of impact will be met, there is a broad range of measures that will need to be considered to account for this uncertainty. Some examples include:

- Approval of the EP with conditions or limitations that exclude the noise-generating aspects of the activity from occurring within sensitive seasons or habitats
- Ensuring measures are in place for the proponent to identify and review relevant new science prior to and during activity implementation and adjust management measures where necessary
- In situ measurement of received sound levels to validate sound level predictions and inform further mitigation needed to account for deviations from predictions made in the EP
- In situ field monitoring to detect the presence, abundance, and behavior of biota to inform management and mitigation
- Implementation of monitoring technologies and protocols to inform real-time mitigation (Douglas and Brandon 2016)
- Employing adaptive management measures in response to exceedances of management triggers such as higher than expected fauna encounters, changes in the sound exposure regime, or lower than expected performance of important control measures

Monitoring and adaptive management measures form part of a proponent's environmental management system (EMS) designed to help manage environmental impacts and continuously improve environmental performance through the adoption of a systematic approach centered on environmental leadership commitment. The

Australian/New Zealand Standard ISO 14001:2016 sets out the requirements for an EMS and promotes the application of a conventional cylindrical improvement cycle centered around four management elements that includes:

1. **Plan** (i.e., establish the necessary environmental objectives and processes to deliver results in accordance with the organization's environmental policy)
2. **Do** (i.e., implement the planned processes)
3. **Check** (i.e., monitor and measure processes against the organization's environmental policy including its commitments, environmental objectives, and operating criteria and report results)
4. **Act** (i.e., where necessary, take actions to continually improve)

An EMS is an important part of the implementation strategy in an EP and must include measures to ensure impacts and risks continue to be identified and managed, control measures are effective, and defined levels of performance for environmental management are achieved. An example of monitoring and adaptive management cycle considerations within the Australian/New Zealand Standard ISO 14001:2016 EMS framework is provided in Fig. 1.

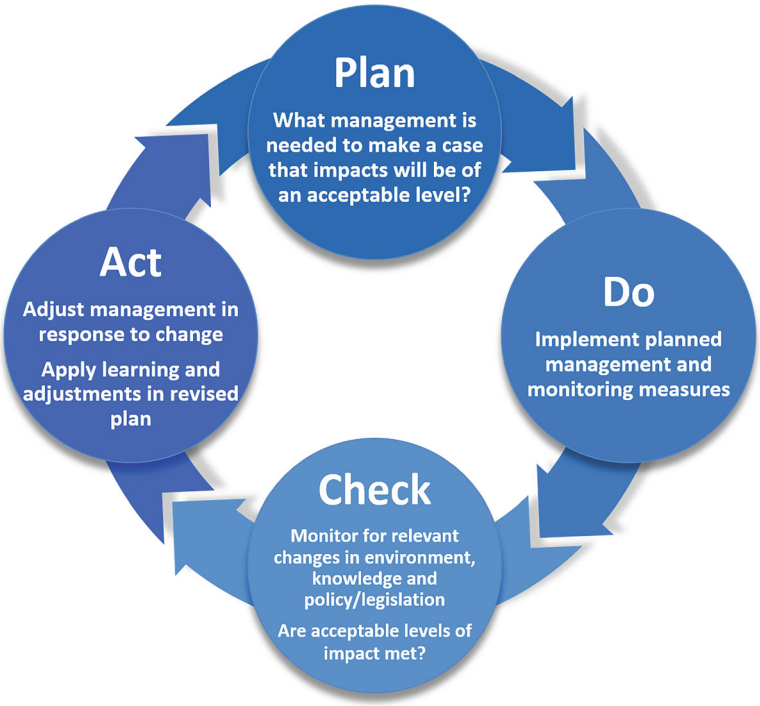

**Fig. 1** Example of the considerations for an effective adaptive monitoring and management process within the Australian/NEW Zealand Standard ISO 14001:2016 environmental management system framework

The benefit of implementing monitoring and adaptive management measures within an EMS is that it not only results in improved environmental outcomes but also allows proponents to have the flexibility to continue to implement their activities within operational schedules and time frames by adapting to changing circumstances. In order to ensure that a monitoring and adaptive management process is effective, the EMS should clearly describe:

- The primary performance indicators of any measures that will be implemented to verify whether impact predictions are accurate (e.g., equipment calibration and/or specifications and competency and/or training of personnel responsible for undertaking verification checks)
- The process for assessing and applying results of monitoring to appropriately inform environmental management
- The criteria to be used to decide if and when a defined action needs to be employed in response to results of monitoring to ensure that impacts to the environment are continually managed to an acceptable level and reduced to ALARP (e.g., implementation of revised or new control measures)

In an underwater noise context, key examples of changes that can trigger adaptive management responses include:

- An unforeseen change in presence, abundance, and behavior of sound-sensitive marine fauna within the area that may be affected by underwater noise.
- The unexpected ineffectiveness of marine fauna detection methods in real-world conditions.
- The ineffectiveness of control measures due to a change in offshore activity or environmental circumstance.
- The received sound levels within important fauna habitat are higher than predicted.

## Monitoring and Adaptive Management Case Studies

Two hypothetical case studies are presented below to illustrate the benefits of an effective monitoring and adaptive management program. The case studies particularly illustrate the efficacy of an effective monitoring and adaptive management program in addressing scientific uncertainty in the extent, severity, and duration of environmental impacts of underwater noise during the implementation of an activity where there are changing circumstances.

Both of these case studies relate to the implementation and environmental management of marine seismic surveys (MSS). MSSs are undertaken for a range of purposes including to identify potential oil and gas reservoirs below the seafloor. During these activities, underwater noise is generated from the use of high-pressure airguns that, when discharged, release highly compressed air that expands and

compresses rapidly to produce a pulse of high intensity and low-frequency impulsive, broadband sound.

## Case Study 1: Adaptive Management in Response to New Science

- MSS activity was proposed to be undertaken within a productive fishing ground for the southern rock lobster (*Jasus edwardsii*), a highly valuable commercial species.
- The EP was approved on the basis that a review of the best available science indicated the expected sound exposure regime would result in impacts deemed acceptable to southern rock lobsters or the commercial fishery. The sound exposure regime was predicted using validated noise-modeling methods tailored to the specific sound source and operating environment. In addition, an EMS was in place that required new information, including newly published science, to be considered in relation to refining the ongoing management of the activity.
- Prior to the commencement of the activity, new scientific evidence was published indicating that noise generated by seismic survey airguns has the potential to result in physiological impacts to southern rock lobsters at noise levels that can be generated by commercial seismic surveys (Day et al. 2016). Given the relevance of this result to the predictions of impact and proposed control measures in the accepted EP, the publication of this scientific paper triggered a formal review as part of the EMS measures.
- New information published in this paper triggered a reevaluation of the impacts of the activity. The formal review undertaken by the proponent resulted in a conclusion that there was a higher potential for the activity to impact southern rock lobsters than was predicted in the approved EP. For example, the paper presented new evidence that noise exposure at levels commensurate to a seismic survey could result in a depressed immune response, impairment of reflex behaviors, and damage to the sensory hairs of the statocyst that may have implications for southern rock lobster ecology such as feeding, predator avoidance, locomotion, and social behaviors.
- In response to the revised assessment indicating that the impacts may be greater than what was initially predicted in the accepted EP, the proponent adapted to the change by designing and implementing an enhanced suite of control measures to ensure the impacts to southern rock lobsters and the commercial fishery continue to be managed to an acceptable level and ALARP. This enhanced suite of control measures included:
  - Utilizing a smaller seismic source to reduce the received noise levels at the seabed
  - Increasing the number of streamers to allow a reduction in survey intensity by increasing acquisition line spacing
  - Establishing exclusion zones to reduce the overlap with southern rock lobster habitat and fishing grounds
  - Designing compensation arrangements for demonstrably affected commercial fishers

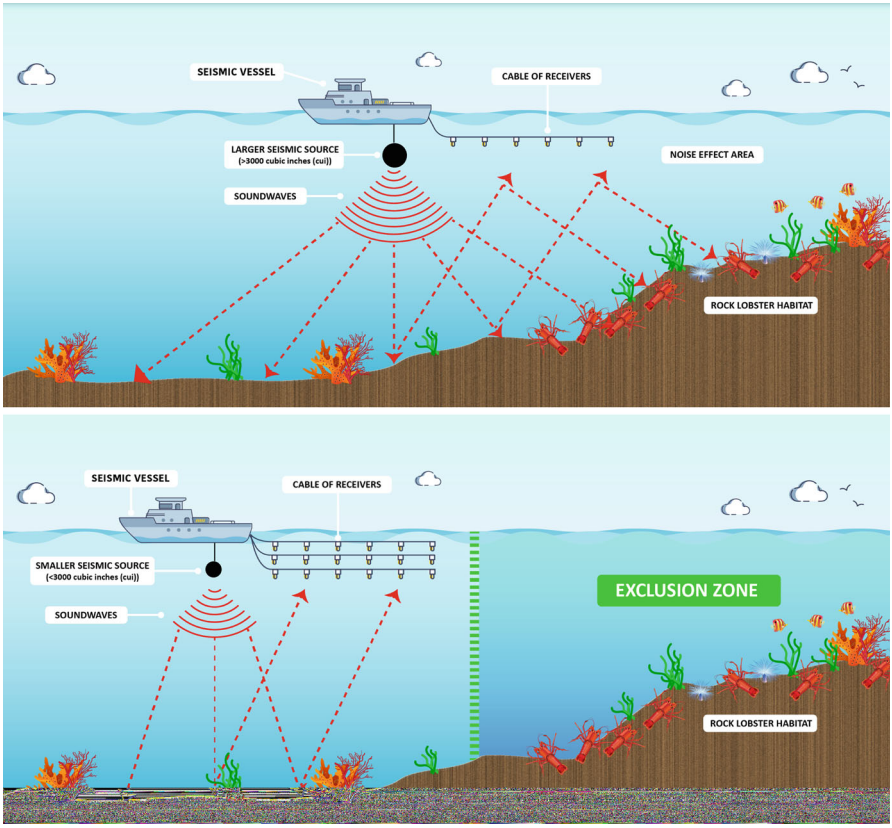

**Fig. 2** Illustration of the approved approach (top) versus post approval adaptive management approach (bottom) in response to new information

- The adaptive management approach implemented provided confidence that underwater noise impacts to a commercially and ecologically important species continued to be managed to acceptable levels and also allowed the proponent to continue with the activity in an environmentally responsible manner (Fig. 2).

## Case Study 2: Adaptive Management in Response to In Situ Fauna Monitoring

- An MSS activity was proposed to be undertaken adjacent to an area of known upwelling that supports elevated primary and secondary productivity formally defined as a biologically important area (BIA) for the pygmy blue whale foraging.

Blue whales are listed as endangered under Australian environmental law, and there is a recovery plan in place to support the recovery of this species (Department of Environment 2015). Anthropogenic noise is identified as a priority threat to recovery that needs to be carefully managed.

- During the assessment process, NOPSEMA required the activity to be restricted spatially so that it did not take place inside the defined blue whale foraging BIA. This was necessary because a case could not be made that impacts to blue whales in this area could be managed to an acceptable level during the foraging season.
- The environmental impact assessment in the EP was based on the prediction that the potential for the activity interact with blue whales was low given that the activity location was outside of the defined BIA boundaries. This assumption was consistent with available data on the distribution of blue whales in the region of the proposed activity.
- However, after the EP was approved and during the implementation of the activity, the proponent observed high numbers of blue whales in the activity area outside the defined BIA. Although the EP anticipated the potential for some blue whales to be present outside the BIA, the observed numbers were higher than what was predicted in the accepted EP, indicating a greater potential for impact to foraging blue whales.
- In response, the proponent was expected to adequately evaluate the change to the operational environment and adapt the management of the activity in accordance with their EMS. In particular, the EMS required the proponent to adopt specific measures to ensure impacts to blue whales continued to be managed to ALARP and acceptable levels.
- The enhanced suite of control measures in this scenario included:
  - Additional observation platforms and enhanced marine fauna detection capability
  - Increasing the size of mitigation zones to account for more effective noise propagation in deeper water
  - The cessation of nighttime operations due to the lack of whale detection capability
- This example of an effective adaptive management approach highlights the importance of having measures in place to allow the proponent's activity to rapidly adapt when the level of marine fauna detection is higher than predicted. The timing and distribution of marine fauna presence and behavior is often highly variable annually and interannually, and incomplete baseline information may mean the expected presence and abundance of noise-sensitive fauna may differ from observations. It is particularly important that management arrangements for activities proposed in sensitive marine fauna habitats include measures to adaptively manage unexpected fauna interactions so that impacts remain acceptable for the life of the activity (Fig. 3).

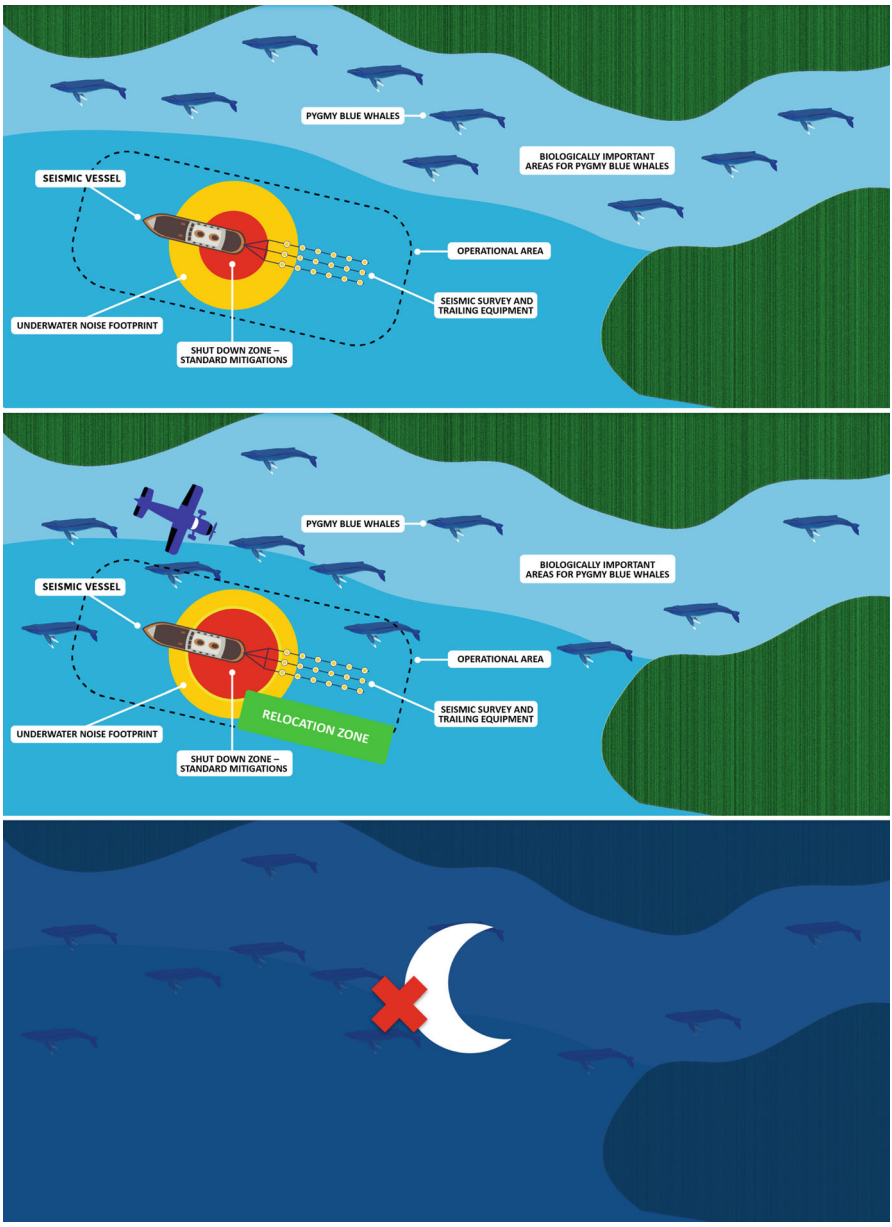

**Fig. 3** Illustration of the approved approach (top) versus post approval adaptive management approach (middle) and further adaptive management in response to a change in the environmental setting – no night-time operations (bottom)

## Conclusion

Industry and the research community need to work together to address research priorities in a timely, cross-disciplinary, collaborative, and integrated way. Varied, balanced, and transparent research outputs with clear pathways to adoption in risk and impact assessment, regulatory decision-making, and activity monitoring and management will reduce uncertainty and improve confidence in the effectiveness of environmental management.

Monitoring and adaptive management will continue to play a vital role in ensuring new science, and new technology, and unanticipated changes in the environment are taken into account by proponents through their EMSs during project implementation. A well-managed and flexible environmental management approach that triggers adaptive management in response to change can be an effective mechanism for addressing some areas of scientific uncertainty and improve confidence that impacts and risks continue to be managed to an acceptable level for the life of the activity.

**Abstract**

The United States National Marine Fisheries Service (NMFS) issues permits for incidental marine mammal harassment under the U.S. Marine Mammal Protection Act. Authorizations may be issued on a project-by-project basis via incidental harassment authorizations (IHAs), or on a programmatic basis using rulemaking to issue an incidental take regulation (ITR) for a period of up to five years, with individual projects receiving letters of authorization (LOAs). In January 2021, NMFS issued the first ITR encompassing the programmatic activities of competitive industry interests for the energy geoscience industry in the Gulf of Mexico. The Rule became effective in April 2021, and under the ITR, LOAs are issued for geophysical activities related to oil and gas exploration and development in the region. The ITR requires LOA holders to "collectively be responsible for compilation and analysis of [protected species monitoring] data for inclusion in subsequent annual synthesis reports." The "Gulf of Mexico Proactive Regulatory and Observational Program" (GOM-PROP) was conceptualized to achieve compliance with this provision. The approach to achieving this comprehensive reporting across dozens of companies with various contractors and subcontractors considered issues such as managing confidential business information while facilitating collaboration; achieving consistency in data collection and management; logistics of compiling and storing data; achieving participation from LOA holders; and enabling industry to lead subsequent ITR development. GOM-PROP works closely with U.S. regulatory agencies to ensure reporting will meet the standards and needs and will appropriately inform compliance and future permit applications.

## Introduction

In recent years, academia, government, industry, and the general public have paid keen attention to the potential effects of anthropogenic underwater sound on marine life, and particularly as pertains to marine mammals. Exposure to underwater sound has the potential to contribute to hearing threshold shifts or elicit behavioral responses (Southall et al. 2019; Southall et al. 2021). The biological significance of sound exposure, both with respect to individuals and the population, is the subject of significant ongoing research, with methods like Population Consequences of Disturbance (PCoD) modeling showing significant promise in appropriately assessing the significance of exposure over time (Keen et al. 2021).

Anthropogenic sound can generally be divided into impulsive or continuous sounds, which are treated separately under existing regulatory schemes. While

definitions vary, impulsive sounds can be characterized by their kurtosis when the signal is detectable above the effective quiet threshold (EQT) (Martin et al. 2020). Both types of signals may also be characterized as tonal or broadband. Tonal signals are those of a specific frequency, whereas broadband signals contain many frequencies. Marine mammal physiological and behavioral responses vary based on the characteristics of the signals to which they are exposed (National Marine Fisheries Service 2018).

In addition to the type of signal, the context in which the sound exposure occurs can influence behavioral responses. These contextual factors may include the individual and group behavioral state; group composition; age and sex of the individual; and age, sex, and group composition of the larger group (Ellison et al. 2011; Southall et al. 2021). Certain species may also be more sensitive to certain sounds, or may dampen hearing in anticipation of sounds (Nachtigall and Supin 2013; Nachtigall et al. 2016; Nachtigall et al. 2018).

Seismic surveys are used for a variety of applications, including hydrocarbon exploration, determination of appropriate carbon capture and sequestration (CCS) sites, and evaluation of locations for offshore infrastructure (e.g., wind farms). Sound from seismic surveys has been a particular focus for the regulatory, academic, and conservation communities. Whereas in most cases anthropogenic sound is incidental to the activity, the production of sound in seismic survey is essential to obtaining geological images of the subsurface. In the marine environment, compressed air sources, colloquially referred to as air guns, are used to produce a broadband, impulsive signal of approximately 0.1 s every 10–20 s as the vessel tows the source(s) at approximately 5 knots (Gisiner 2016). Compressed air sources are typically necessary to image the deep geological features required for hydrocarbon exploration and CCS storage locations. In order to achieve the acoustic output levels necessary for imaging, commercial seismic surveys utilize an array of multiple compressed air sources.

In the United States, marine mammals are protected by the Marine Mammal Protection Act (MMPA). The MMPA prohibits "harassment" of marine mammals, which is defined as, ". . .any act of pursuit, torment, or annoyance which— (i) has the potential to injure a marine mammal or marine mammal stock in the wild; or (ii) has the potential to disturb a marine mammal or marine mammal stock in the wild by causing disruption of behavioral patterns, including, but not limited to, migration, breathing, nursing, breeding, feeding, or sheltering" (16 U.S.C. § 1362). The "take" of marine mammals is defined as attempts to, "harass, hunt, capture, or kill," and divided into two levels: Level A, which indicates significant potential to injure a marine mammal or stock; and Level B, which, ". . .disturbs or is likely to disturb a marine mammal or marine mammal stock in the wild by causing disruption of natural behavioral patterns," (16 U.S.C. § 1362). Take of marine mammals may occur incidentally during the course of anthropogenic activity in the marine environment. Incidental take of marine mammals is allowable provided that the take is of a small number of individuals; has no more than a negligible impact on the species or stock; and has no unmitigable adverse impact on the species or stock for subsistence use.

NMFS' policy associated with assessing harassment that may occur via exposure to sound is based on the concept that exposure to certain levels of underwater sound can constitute a Level A or Level B take of a marine mammal based on the potential resultant hearing threshold shift. Threshold shifts are characterized as either permanent threshold shifts (PTS) or temporary threshold shifts (TTS). Permanent threshold shifts are not fully recoverable, and result in permanent suppression of hearing capabilities around the range of frequencies to which the receiver was exposed. Temporary shifts are recovered within hours to days of the exposure. Only PTS is considered injurious and, therefore, would constitute Level A take.

Whether PTS occurs is dependent upon the hearing capability of the animal receiving the signal. In the United States, marine mammals are divided into five generalized hearing groups to evaluate their hearing ranges, given in Table 1 (National Marine Fisheries Service 2018). The PTS onset thresholds for each hearing group for both impulsive and nonimpulsive sound are estimated in Table 2 based on studies of TTS and general physiological characteristics and hearing studies for species within the hearing group (National Marine Fisheries Service 2018). In the United States, NMFS applies a received level of 160 dB root mean square sound pressure level re 1 μPa as the threshold beyond which behavioral changes that constitute Level B take of marine mammals exposed to impulsive underwater sound would potentially occur. Exposure to this threshold does not necessarily always result in Level B take defined under MMPA (change in behavioral pattern); that is, detection of a sound of a given amplitude does not always elicit a behavioral response. Similarly, exposure to a sound at the Level A take threshold does not necessarily result in PTS for every species or individual in the hearing group. These thresholds should be considered precautionary and intended to be preventative in order to provide sufficient protection to the animals, rather than indications of when a Level A or B take is most likely to occur (Gisiner et al. 2020).

Incidental harassment of marine mammals by underwater sound produced during anthropogenic activities, including seismic surveys, is authorized either via an

**Table 1** Hearing group generalized hearing ranges for marine mammal species. All ranges are given for animals underwater (National Marine Fisheries Service 2018)

| Hearing group | Generalized hearing range |
|---|---|
| Low-frequency (LF) cetaceans (baleen whales) | 7 Hz to 35 kHz |
| Mid-frequency (MF) cetaceans (dolphins, toothed whales, beaked whales, bottlenose whales) | 150 Hz to 160 kHz |
| High-frequency (HF) cetaceans (true porpoises, *Kogia*, river dolphins, cephalorhynchid, *Lagenorhynchus cruciger & L. australis*) | 275 Hz to 160 kHz |
| Phocid pinnipeds (PW) (underwater) (true seals) | 50 Hz to 86 kHz |
| Otariid pinnipeds (OW) (underwater) (sea lions and fur seals) | 60 Hz to 39 kHz |

**Table 2** Onset level of permanent threshold shifts (PTS) for impulsive and nonimpulsive sound by marine mammal hearing group. All thresholds are underwater and therefore referenced to re 1 μPa (National Marine Fisheries Service 2018)

| | PTS onset thresholds (received level) | |
|---|---|---|
| Hearing group | Impulsive | Nonimpulsive |
| Low-frequency (LF) cetaceans | **Cell 1**<br>$L_{p,0\text{-pk,flat}}$: 219 dB<br>$L_{E,p,LF,24h}$: 183 dB | **Cell 2**<br>$L_{E,p,LF,24h}$: 199 dB |
| Mid-frequency (MF) cetaceans | **Cell 3**<br>$L_{p,0\text{-pk,flat}}$: 230 dB<br>$L_{E,p,MF,24h}$: 185 dB | **Cell 4**<br>$L_{E,p,LF,24h}$: 198 dB |
| High-frequency (HF) cetaceans | **Cell 5**<br>$L_{p,0\text{-pk,flat}}$: 202 dB<br>$L_{E,p,HF,24h}$: 155 dB | **Cell 6**<br>$L_{E,p,LF,24h}$: 173 dB |
| Phocid pinnipeds (PW) (underwater) | **Cell 7**<br>$L_{p,0\text{-pk,flat}}$: 218 dB<br>$L_{E,p,PW,24h}$: 185 dB | **Cell 8**<br>$L_{E,p,LF,24h}$: 201 dB |
| Otariid pinnipeds (OW) (underwater) | **Cell 9**<br>$L_{p,0\text{-pk,flat}}$: 232 dB<br>$L_{E,p,OW,24h}$: 203 dB | **Cell 10**<br>$L_{E,p,LF,24h}$: 219 dB |

incidental harassment authorization (IHA), or via a letter of authorization (LOA) under an incidental take regulation (ITR). IHAs allow for authorization of a specific activity for a period of up to one year for activities that meet the MMPA standards: only a small number of individuals affected; no more than a negligible impact on the species or stock; and no unmitigable adverse impact on subsistence use. An ITR allows for the authorization of a given set of activities over a five-year period, where individual activities are authorized via LOAs. Per the National Marine Fisheries Service, the negligible impact standard is applicable across all activities covered under the ITR; the small numbers standard is applied at the LOA level (50 C.F.R. Part 217 §§ 217.180 - 217.188-217.189).

The U.S. Gulf of Mexico is home to a substantial amount of geophysical survey activity to support ongoing hydrocarbon exploration and development in the region. (This activity is expected to continue to increase as the Gulf of Mexico progresses into offshore wind development and carbon capture, sequestration, and storage activities, both of which require geophysical surveys.) Accordingly, in 2002, the U.S. Bureau of Ocean Energy Management (BOEM, then the Minerals Management Service) petitioned NMFS for development of an ITR to govern geophysical activities for hydrocarbon development in the Gulf of Mexico. This petition underwent multiple petitions prior to the filing of a lawsuit challenging the proposed ITR (NRDC v. Jewell 2010). BOEM revised the petition a third time in 2011, and a settlement agreement was implemented in 2013 that allowed for the authorization of geophysical surveys in the Gulf of Mexico provided that these surveys abided by a set of mitigation measures. This agreement was amended in 2016, and extended in 2017, 2018, and 2020 to allow for completion of the ITR. The Final Rule was released in January of 2021, and the final ITR (50 C.F.R. Subpart S – Taking Marine

Mammals Incidental to Geophysical Survey Activities in the Gulf of Mexico, referred to herein as the "Gulf of Mexico ITR") became effective on April 19, 2021, for a period of five years.

Data collection regarding marine mammal detection is conducted by observers aboard survey vessels, and is required under the ITR. Visual monitoring for marine mammals during geophysical surveys under the Gulf of Mexico ITR must be conducted by qualified Protected Species Observers (PSOs). Similarly, acoustic monitoring is conducted by Passive Acoustic Monitoring Operators (PAMOs). LOA holders are required to employ third-party observers, trained via an NMFS-accepted course and who have received NMFS approval, with no responsibilities other than monitoring, data collection, and communication with relevant crewmembers regarding mitigation implementation. The primary purpose and objective of both PSOs and PAMOs is to monitor for marine mammals within a designated proximity to the survey and initiate mitigation measures as necessary. It is imperative to recognize that data collection is a secondary responsibility; observers' primary objective is implementation of required mitigation measures.

Specific mitigation requirements vary based on the operational details of the survey. Compressed air surveys can be subdivided into deep penetration surveys – those using arrays of compressed air elements with a total volume of greater than 1500 cubic inches – and shallow penetration surveys, which use small arrays or a single compressed air source with a volume under 1500 cubic inches, or an electro-mechanical acoustic source (e.g., sparkers). At least 30 min prior to activating a deep penetration acoustic source, an area of 1000 m around the array must be monitored and remain clear of marine mammals (200 m for shallow penetration). For both deep and shallow penetration surveys, seismic survey operators are required to "ramp-up" the acoustic array by slowly increasing the number of active elements over a period of at least 20 min. If, during the course of operations, a marine mammal approaches within 500 m of the acoustic source (100 m for shallow penetration surveys), the source must immediately be shut down. This shut down requirement is waived for small delphinids (genera *Steno*, *Tursiops*, *Stenella*, and *Lagenodelphis*), which are known to approach and bow-ride vessels even during periods when the acoustic source is active.

During operations, PSOs and PAMOs must collect data via an electronic reporting form. However, while the United States requires the collection of certain data, there is currently no standardized reporting format. LOA holders must submit a report to NMFS within 90 days of survey completion or following the expiration of an issued LOA, or annually if the LOA is for a period of more than one year. These individual reports must include operations conducted and marine mammals detected; documentation methods, results, and interpretation; summarize all operations and sightings; provide information regarding where the acoustic source was used; and demonstrate validity of the PAM system. LOA holders must also submit track lines of the specific locations in which the survey was conducted.

A requirement unique to the Gulf of Mexico ITR is development of a comprehensive annual report analyzing all geophysical activity in the Gulf of Mexico during the ITR year. This requirement stipulates that, "LOA-holders must contribute to the

compilation and analysis of data for inclusion in an annual synthesis report addressing all data collected and reported through annual reporting in each calendar year. The synthesis period shall include all annual reports deemed to be final by NMFS in a given one-year reporting period" (50 C.F.R. § 217.185(d)(2)). The annual report is independent of individual reporting requirements described above. The comprehensive annual report is intended to provide a summary of: geophysical survey activity (including type, location, month, and source status); monitoring effort including source status, location, and visibility; mitigation measures implemented by survey type and location; sighting rates of marine mammals during periods with and without source activity including initial sighting distance, closest point of approach, observed behaviors and movements, and analysis of effects of factors influencing detectability; total take across all activities; conclusions from monitoring during the year; and recommendations for adaptive management.

The adaptive management provision of the Gulf of Mexico ITR is intended to allow NMFS to consider new information to determine whether modification of mitigation and/or monitoring measures may be appropriate without undergoing a full rule revision. Adaptive management may consider the annual reports, research on the potential effects of sound on marine mammals, and any information that may indicate take inconsistent with what was authorized by the LOA. The annual adaptive management process includes other applicable regulatory agencies (BOEM and the Bureau of Safety and Environmental Enforcement, BSEE) and industry.

The lack of a standardized reporting format has created challenges for analysis of PSO and PAMO data in the U.S. Detection data varies widely between regions, making comparisons within the United States and abroad difficult (Milne et al. 2019). Even within the U.S. Gulf of Mexico, detection data may not be comparable across the entire PSO dataset (Barkaszi and Kelly 2018). The U.S. Gulf of Mexico is currently home to 28 cetacean species and one species of manatee; three additional species have been sighted nearby, but are not considered endemic in the Gulf region (Würsig et al. 2000). Many of these species are difficult to distinguish, particularly during the typically brief glances afforded to PSOs.

The diversity of species, coupled with the mutable nature in which PSO data have historically been collected, presented a significant challenge for compliance with the annual reporting of the Gulf of Mexico ITR.

## Development of the Gulf of Mexico Proactive Regulatory and Observational Program (GOM-PROP)

Finalization of the Gulf of Mexico ITR highlighted the need for industry to proactively collaborate toward a structure that would facilitate satisfying the requirements associated with producing a comprehensive annual report. This posed a particular challenge, as companies with an operational interest in the region are competitors and therefore are understandably cautious about data sharing. As the global trade association for the energy geoscience industry, the EnerGeo Alliance was

well-positioned to serve as the intermediary through which to centralize the data necessary to achieve reporting goals. GOM-PROP members for year 1 included the following companies (in alphabetical order):

- Beacon Offshore Energy
- BHP
- bp
- CGG
- Chevron
- EnVen
- ExxonMobil
- Hess Corporation
- Houston Energy
- ION
- Kosmos Energy
- LLOG Exploration
- Magseis Fairfield
- Occidental Petroleum Corporation
- PGS
- PXGEO
- Quarter North Energy
- slb
- Shell
- Talos
- TGS

ION withdrew from the program at the end of year 1 due to unrelated business challenges. Equinor joined the program for year 2, maintaining membership at 21 participants as of November 2022.

## Data Collection

Data were collected at sea during operations conducted under an LOA by qualified PSOs and PAMOs, as described above. Data included effort, environmental conditions, operational status of the seismic source, cetacean acoustic detection and sighting events, and sea turtle visual detection. Herein, acoustic events are referred to as "detections" and visual sightings as "observations." Collectively, visual and acoustic events are referred to as "sightings."

For each detection or observation, PSOs recorded the following information: time; vessel position; vessel course; water depth; species; number of animals; group age/sex composition; sighting/detection distance and bearing; animal heading and movement; behavior of animal(s); vessel activity; source status; and environmental data. Not all data could be accurately recorded for each event, and PSOs reported the identification "unknown" if a determination could not be made at the time. Protected

species were identified to the species level if possible, or to the closest identifiable group (e.g., unidentifiable delphinid).

These data were then imported into a bespoke database by syncing the observer forms returned to GOM-PROP members by contractors with the database and importing the data.

## Database Development and Use

The database endeavored to provide more than simply satisfying regulatory objectives and would also provide operational value to GOM-PROP members. Marine Remote Services LLC (MRS) developed and deployed an independently administered, central Protected Species Observer (PSO) database solution to support a comprehensive reporting system across dozens of companies with various contractors and subcontractors. The database was designed to unify PSO sightings collected by multiple PSO service providers, and to consider complex Industry issues such as: (1) managing confidential business information while facilitating collaboration; (2) achieving consistency in data collection and management; (3) logistics of compiling and storing data; (4) ensuring data collection meets analysis requirements; and (5) achieving participation from LOA holders.

The resulting database, firstKnowledge™, is a standalone, fully functional, and independent web-served PSO time-series database which is designed to contain user-submitted protected species detection data in an industry-supported format. In its internet-connected mode, the product is referred to as SaaS or "Software as a Service." In unconnected scenarios, the database defaults to an "on-prem" database instance allowing all sightings and events to be recorded in a file for later uploading to the SaaS portal. In the cloud configuration, the database is hosted on a secure and redundant web server with data integrity, protection, and duplication built-in. The access portal allows for portal sign-in and a specific database access authentication which determines what functionality is available and which dataset details are accessible to different users.

Basic data entry into the firstKnowledge™ database is performed by import widgets that authorized users are assigned. For users that have current data collection systems in place, the system provides for data ingestion with the use of custom widgets programmed to field map those datasets over to firstKnowledge™ data fields and tables from a variety of formats (including the frequently used .xls and .csv) by the batch processing method. For those users without existing systems, the system provides an intuitive input screen that performs content and format validation when populating the collection of data tables, including time stamping and other common database functions on an individual sighting or event record basis. All records were scrutinized for duplication and an audit trail established for all subsequent data manipulation performed.

The database is based on an Elastic Stack and used Elasticsearch which allows for rapid searching for all types of data. Data are stored in Elastic Stack, enabling the system to interactively explore, visualize, and share insights into the data collected.

Elasticsearch stores and indexes data to facilitate searches. A basic set of use cases were created that describe stakeholder data needs. Use cases incorporate the following:

- Multiple authentication levels addressing the basic and advanced stakeholder requirements.
- A secure data collection portal with secured individual contributor access.
- User dashboard serving metrics from user-specific datasets.
- Basic reporting capability.
- Fulfilling the custom needs of industry analysis.
- Managing, integrating, and analyzing spatial information using Elasticsearch as a geographic information system.

The reliability and trustworthiness of the data throughout its lifecycle must be maintained, and therefore, it is essential that any corrections or revisions are validated and traceable. Additionally, data security must be closely monitored to ensure only authorized users are able to access information. To ensure data integrity, data input and validation are continuously monitored, as are data security and backup. Finally, access control is maintained and an audit trail is established.

Finally, firstKnowledge™ is designed so that specific details of data contributions from system users will be maintained in separate tables, ensuring anonymity, while still being able to connect to the relevant record and allow for the use of table and foreign keys during specific data mining and reporting operations.

## Results from Year One

During the first year of GOM-PROP, from April 2021 to April 2022, more than 95% of LOA activity days authorized under the ITR were issued to GOM-PROP members. The limited number of LOAs issued to nonmembers was largely small-scale activities (i.e., single source or small array over few days). The extensive participation by industry allowed for a particularly comprehensive review of protected species detections and observations during the first year of ITR implementation. The completeness of this dataset will allow for valuable comparisons during subsequent program years.

### Summary of Geophysical Activity

Effort data were analyzed across the seven geographic management zones identified in the GOM ITR (Fig. 1). These zones were defined for management purposes. Sightings were assigned to zones based on the geographic coordinates. Next, activities were sorted based on source activity (Table 3). Survey effort when the source was not active (excluding transit) represented 20.2% of all survey time. For all vessel activities recorded in the database and representing total time on the water,

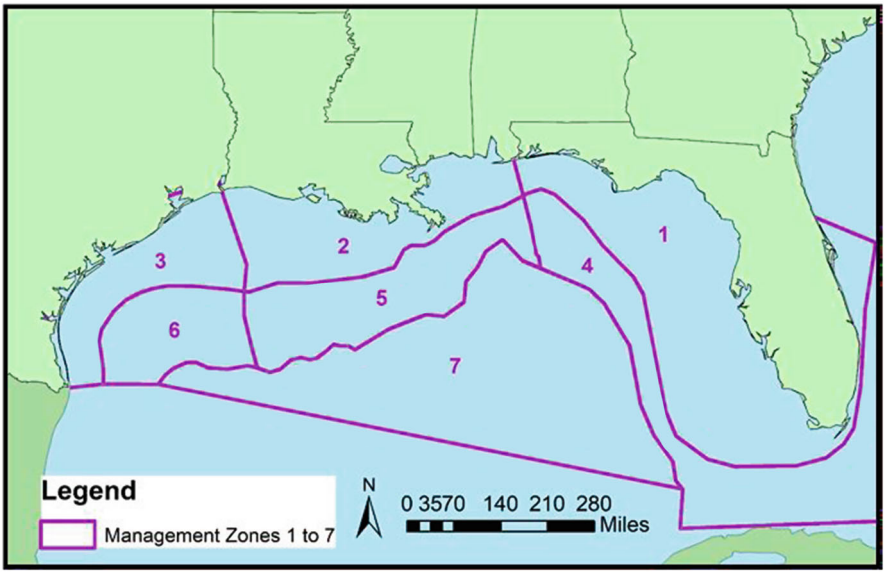

**Fig. 1** The U.S. Gulf of Mexico with the seven management zones used in the ITR highlighted with purple lines

**Table 3** Vessel activity codes reported in effort data sorted by source activity category

| Vessel activity code | Category |
|---|---|
| Data acquisition | Active source |
| Deploying/retrieving equipment | Inactive source |
| Line change[a] | Active source |
| Standby | Inactive source |
| Testing[a] | Inactive source |
| Transit | Transit; inactive source |
| Other[a] | Active source |
| No data[a] | Active source |

[a]Indicates that the source activity status is uncertain based on code. The source was assumed to be active unless otherwise indicated

transit represented 5.4% of the total time on water; source active codes represented 75.5%; and source off represented 19.1% of the total time on water.

PSO effort data were collected from July 2021 to February 2022. While the ITR year extended from April 2021 through April 2022, the first survey undertaken under the ITR did not begin until July, and surveys in progress at the conclusion of the ITR year were not included in the analysis at the request of NMFS. Data were collected in zones 2, 3, 5, 6, and 7 (Fig. 1), with acquisition occurring in all of these areas except zone 2. Coordinates for ten observations placed the sightings as outside the Gulf of Mexico. Because operations were only authorized within the GOM, these coordinates are most likely erroneous, and therefore, the effort was categorized as "unknown zone." Hours of effort by source status are show in Table 4.

**Table 4** Effort data from July 2021 to February 2022 divided by zone. Geospatial coordinates for ten sightings erroneously placed the observations outside the Gulf of Mexico; these are listed as "unknown zone"

| Zone | Total active effort (hours) | Total transit effort (hours) | Total deploying/standby/other/no data (hours) |
|---|---|---|---|
| 2 | 0 | 8.8 | 0 |
| 3 | 7.8 | 31.3 | 20.6 |
| 5 | 404.1 | 16.0 | 44.5 |
| 6 | 251.4 | 34.8 | 194.2 |
| 7 | 606.6 | 0 | 60.6 |
| Unknown | 4.2 | 0 | 1.7 |
| Total | 1274.1 | 91.0 | 321.5 |

The distance at which animals can be detected is affected by visibility. Visibility conditions were documented during daylight operational hours. For both active and inactive survey time, visibility exceeded 5 km for 91.1% of the recorded time; was between 2 and 5 km 5.3% of the time; between 0.5 and 2 km 1.8% of the time; and less than 500 m 1.8% of the time. For effort during the time that the source was active, passive acoustic monitoring (PAM) was used 99.9% of the time (day and night). When visibility was recorded while the source was active, visibility exceeded 5 km 95.0% of the time; was between 2 and 5 km 2.6% of the time; between 0.5 and 2 km 1.2% of the time; and less than 500 m 1.2% of the time. The use of PAM allowed for continued operation during nighttime hours and when visibility was limited to distances smaller than the exclusion zone required to be monitored for mitigation.

Beaufort (BF) sea state also affects the ability of PSOs to detect marine life and was recorded during visual monitoring effort. Sea state is measured on a scale of 1 to 8, and the ability to detect certain species (e.g., beaked whales) decreases with an increase in sea state, particularly above Beaufort 5 (Barlow 2013, 2015). BF sea state ranged from BF1 to BF7 during periods of visual monitoring. Visual monitoring includes both active source time, as well as inactive time (e.g., during transit and preclearance watch). The most frequently reported sea states were BF2, BF3, and BF4, which represented 26.5%, 24.6%, and 27.2% of recordings, respectively, for a total of 78.3% of reported sea states. The remaining 21.7% of observations were divided between BF1 and BF5–BF7.

## Mitigation Measures

Mitigation measures, specifically shutdown of the seismic source or delay of ramp-up, were implemented in compliance with each survey's LOA. There were 26 instances of marine mammal visual observations recorded, and an estimated 106 individuals. Four observations of sperm whales (eight individuals), one obser-

vation of unidentified dolphins (two individuals), and one observation (two individuals) of unidentified cetaceans. Ten acoustic detections of an estimated 25 individuals were recorded, all of which were unidentified dolphins. (Total effort is reported in Table 4.)

When animals were sighted within the exclusion zone while the source was powered, the source was shut down until the animal(s) were observed moving outside the exclusion zone or were not sighted for 30 min. Soft start was similarly delayed when animals were sighted in the exclusion zone.

Three of the four sperm whale observations occurred while the source was powered, resulting in shutdowns ranging from 12 to 36 min for a total mitigation time of 1 h and 28 min. For context, total effort was 1686.6 h, with the source active or deploying/standing by for 1595.6 h. The remaining sperm whale observation was outside the exclusion zone and mitigation was not required. A single unidentified cetacean observation resulted in a shutdown of 12 min. Sperm whales require an exclusion zone of 1500 m, compared with 500 m for other species sighted. All visual observations, including those that occurred while the source was inactive or the vessel was in transit, are shown in Table 5.

**Table 5** Summary of all marine mammal detections by source or vessel activity

| Species | Active source (Groups/ individuals) | Inactive source (Groups/ individuals) | Transit (Groups/ individuals) | Total (Groups/ individuals) |
|---|---|---|---|---|
| Atlantic spotted dolphin | 0/0 | 0/0 | 1/6 | 1/6 |
| Clymene dolphin | 0/0 | 1/3 | 0/0 | 1/3 |
| Common bottlenose dolphin | 0/0 | 1/3 | 2/10 | 3/13 |
| Gervais' beaked whale | 0/0 | 1/2 | 0/0 | 1/2 |
| Pantropical spotted dolphin | 0/0 | 1/7 | 1/23 | 2/30 |
| Risso's dolphin | 0/0 | 2/20 | 0/0 | 2/20 |
| Sperm whale | 4/8 | 4/5 | 0/0 | 8/13 |
| Unidentifiable cetacean | 1/2 | 0/0 | 0/0 | 1/2 |
| Unidentifiable dolphin | 1/2 | 4/11 | 1/2 | 6/15 |
| Unidentifiable whale | 0/0 | 1/2 | 0/0 | 1/2 |
| Total | 6/12 | 15/53 | 5/41 | 26/106 |

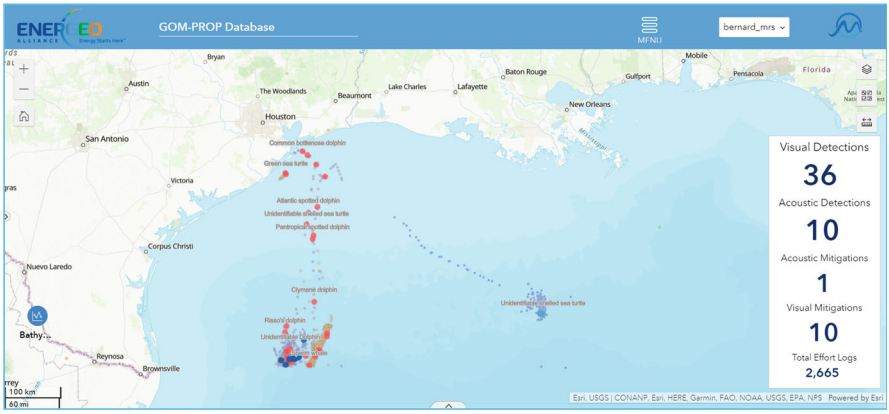

**Fig. 2** First-year GOM-PROP detections of protected species groups recorded in the firstKnowledge™ database, detailing effort logs (small dots), acoustic detections (blue dots), and visual detections (red dots)

One acoustic detection resulted in a 38-min delay to soft start. The remaining acoustic detections occurred while the source was powered and did not result in shutdowns, as small delphinid detections do not require shutdown of the source.

Visual and acoustic detections, along with effort logs, were recorded in the firstKnowledge™ database (Fig. 2).

## Detection Rate

Visual detections were evaluated for frequency over both time and space. Common bottlenose dolphins were the most frequently sighted species in Zone 3 at a rate of 0.22 individuals per hour or 0.02 individuals per kilometer. In Zone 6, Risso's and Pantropical Spotted Dolphins were the most commonly sighted delphinids at 0.042 and 0.048 individuals per hour respectively. Sperm whales were the most commonly sighted whale and were visually detected in Zones 6 and 7 at approximately 0.01 individuals per for both zones. Detection rates by zone are reported per hour (Table 6) and distance surveyed (Table 7).

Due to the low number of detections during the first year of the program, it was not possible to examine whether environmental factors influenced detection rate.

## Summary

The majority of the monitoring effort (75.5%) during the first year of the program occurred while the source was active. Inactive source time while the vessel was in transit or the source was deactivated (for maintenance, preclearance watch, etc.)

represented only about a quarter of monitoring effort, and not all surveys engaged in off-duty monitoring except where required such as during preclearance.

Effort was concentrated predominately in Zones 5, 6, and 7. Given the areas under development and the areas under consideration for future development, it is likely that hydrocarbon exploration will be concentrated in these areas for the remaining years of the current ITR and potentially in future years as well.

GOM-PROP aims to evaluate behavioral responsiveness, or lack thereof, of various species and marine mammal hearing groups to geophysical surveys, as well as quantify the effectiveness of the mitigation measures employed, which are largely aligned with international industry best practices. However, due to the limited number of activities in the first program year, it was not possible to make inferences regarding these objectives.

In four instances, a shutdown of the source was required due to sightings of animals within the regulatory shutdown radius. One shutdown was documented as an "unidentified cetacean," while the other three were sperm whale groups. Given that source shutdown is required for sperm whales at 1500 m rather than the 500 m

required for most species, the prevalence of sperm whale shutdowns may be related to the larger mitigation zone and the frequency with which the species was detected. The frequency of observation may be due to the greater total effort in Zones 5, 6, and 8, which represent the continental shelf and abyssal area (see Fig. 1). In three of the instances where a shutdown was required, the first observation of the animal occurred within the exclusion zone. In the fourth instance, a group of sperm whales was observed outside the exclusion zone for 69 min before an animal entered the exclusion zone and a shutdown was required. This observation suggests that particular group was not actively avoiding the survey area. While this behavior cannot be extrapolated beyond this anecdotal instance, GOM-PROP presents a unique opportunity to aggregate data over an extended period to consider questions about avoidance and approach as activities authorized under the Gulf of Mexico ITR progress.

Although the number of observations were insufficient to draw substantive conclusions regarding animal responses to seismic surveys, the data collected illuminated a number of areas for potential improvement in the collection of PSO

data. First, widely used source codes for vessel activity do not always clearly indicate whether the source was active, whether certain individual elements were active, or if the source was shutdown (see Table 3). Project proponents may consider adding clarity via metadata definitions for activity codes or adding a "source status" column to more clearly delineate whether the source was engaged. Next, as recommended by RPS (2019), it would be beneficial to include the time and/or distance of infill due to mitigation for protected species. This information would be useful in evaluating whether mitigation measures may increase the number of encounters with protected species, as well as assessing the additional operational costs that may be incurred in certain areas based on historical protected species sightings. Finally, unidentified cetacean sightings be should be refined for use within the Gulf of Mexico. For example, adding an "Unidentified cetacean – not large whale" category would help to definitively rule out sightings of baleen or sperm whales when evaluating unidentifiable observations. PSOs may consider adding further categories as appropriate in order to define unidentifiable observations as clearly as possible and reduce ambiguity in the PSO dataset during analysis without the necessity of reviewing the "notes" section for each encounter.

NMFS is encouraged to consider implementation of a standardized set of columns, including specified units, for PSO data collection. This would not preclude the inclusion of additional data as PSO providers deem relevant and important but would standardize the most essential information (such as time, geographic coordinates, source status, etc.) to facilitate broad-scale analysis of PSO data.

## Future Directions

While only a small number of surveys occurred during the first year of GOM-PROP, the program nonetheless represents an important step forward in conservation efforts in the Gulf of Mexico. Twenty-one member companies, ranging from regional operators to international energy corporations, partnered to ensure the continued safe, sustainable implementation of geophysical surveys in the region. This significant investment demonstrates the Industry's desire to lead the science on important conservation questions.

GOM-PROP was developed with a long-term focus in mind; not only for the current five-year ITR, but for many subsequent ITRs to come. As operations continue, this program will support the development of a robust PSO dataset that has been thoroughly vetted and quality controlled, and, through use of the database, been preprepared for comprehensive analyses and review by scientists and regulators. The use of independent PSOs, and analysis by an independent group of scientists for this report, further demonstrate the industry's commitment to ensuring that operations are rigorously evaluated to ensure compliance with required monitoring and mitigation, as well as critically assessing the potential impacts of operations on marine mammals.

The database also presents a new tool for project proponents to use in planning, allowing for the evaluation of historical protected species sightings within a given

geography. As the dataset grows over time, the GOM-PROP database will represent a unique opportunity to quickly review sightings and plan for potential downtime based on prior sightings. This will assist project proponents in evaluating the likely duration of surveys and inform future ITRs.

The first year of data collection via GOM-PROP successfully developed a bespoke database with necessary data standards and management, and analyzed the first year of data to address questions associated with ITR goals and beyond. This program has established a first-of-its-kind, industry-led effort to ensure that mitigation during operation is implemented and documented and that data collected during operations are reviewed on an annual ongoing basis.

**Acknowledgments** Thank you, first and foremost, to the members of the Gulf of Mexico Proactive Regulatory and Observational Program. Without their support and trust, this program simply would not exist. Thank you particularly to EnerGeo's allied trade associations the American Petroleum Institute, the Offshore Operators Committee, and the National Ocean Industries Association and their staff who vigorously advocated for the value of the program during development and continue to be valued partners both in the Gulf of Mexico and throughout the United States. Thank you to the staff at RPS, who provided valuable insight throughout database collection and refinement. Finally, thank you to the staff at Advisian, Kathryn White, Claudette Cloutier, and Jose-Manuel Serrano; and at Marine Remote Services, Bernard Padovani Eric Kubera; and the staff at the EnerGeo alliance for their efforts and support on behalf of the program.

**Abstract**

Commercial ships are the most common anthropogenic sound sources in the ocean today. Only a few monitoring stations exist where opportunistic measurements and estimations of ships' underwater radiated noise (URN) can be performed. This chapter describes the development and operation of a cabled real-time hydrophone station, located outside a major port on the west coast of Sweden. The station was designed to record the local ambient noise and obtain opportunistic measurements of large numbers of commercial ships passages in relatively shallow, 46 m, waters. The propagation loss was measured twice to reduce the uncertainty in the SL estimations. During the measurement period, the source level (SL) for 254 opportunistic commercial ship passages was estimated. One particular cargo ship passed the station 23 times, resulting in multiple URN estimations and the possibility to investigate the effect of different propagation loss conditions on the calculated SL. Finally, the calculated SL was compared to SL models commonly used in the production of soundscape maps.

## Introduction

To get a good estimation of anthropogenic sound sources in the ocean, their source characteristics need to be described. In many oceans, radiated noise from commercial ships is the most common, and often dominating, anthropogenic sound source of ambient noise, and there are international standards and class notations that describe how to measure it (ANSI 2009; ISO 17208-1:2016; Bureau Veritas 2018; ISO 17208-2:2019). The method used to calculate the radiated noise level (RNL) or source level (SL) differs, and the accuracy varies between the standards due to their different requirements regarding, e.g., the measurement setup and estimation of the propagation loss (PL). Additionally, most of them are not designed to work in shallow water (Ainslie et al. 2022). However, the Bureau Veritas (2018) notation covers both shallow and deep waters. It is likely that future international regulations will require knowledge of the radiated noise from commercial ships (IMO 2014), and both the shipping industry and authorities foresee a need for a simple and cost-effective estimation of the SL from commercial ships. One way forward is to have monitoring stations close to ports and shipping lanes, relying on opportunistic measurement as the ships pass by (Hannay et al. 2016). However, it should be noted that a simplified method to estimate the SL with ship passages of opportunity would include uncertainties, typically related to the estimations of PL (Ainslie et al. 2022). The PL depends on environmental parameters, such as the bottom type(s), topography, and sound speed profile, and show a large variation over time but can be measured or modelled. Depending on the purpose of the SL estimations, estimates

based on opportunistic ship passages could still be adequate and answer many questions for industries, scientists, and managers.

Multiple SL estimations from ships can be used to develop and evaluate SL models of various ship categories such as cargo, tankers, and containerships (MacGillivray and de Jong 2021). One of the main usages of such SL models for different ship categories is to make soundscape maps (Farcas et al. 2016; Jalkanen et al. 2018; MacGillivray and de Jong 2021). Soundscape maps are an important tool for regulators to evaluate the environmental impact of noise over large regions. To improve the source models and maintain accuracy of the models as ships are modernized, a large number of ship URNs needs to be estimated each year. To date, however, very few attempts have been made to estimate the SL from a large number of ships, but see Hannay et al. (2016), Karasalo et al. (2017), and Wladichuk et al. (2019).

The aim of this work was to design and deploy a real-time monitoring station close to the inlet to the Port of Gothenburg in Sweden for recording the ambient noise as well as SL estimations from opportunistic passing commercial ships. Further, the aim was also to develop a systematic method for estimating the SL from commercial ships passages in near real-time inspired by Hannay et al. (2016). The Bureau Veritas (2018) measurement and analysis guidance were used when possible. Data on ship movements was recorded locally.

This work was conducted within the EU INTERREG North Sea project Joint Monitoring Programme for Ambient Noise North Sea (JOMOPANS). The project was also funded by the Swedish Agency for Marine and Water Management and the Swedish Transport Administration.

## Design and Operation of the Hydrophone Station

### Technical Description the Hydrophone Station

The hydrophone station was developed by the Swedish Defence Research Agency (FOI) and consists of three main parts. First, a sea unit located at the sea floor, at 46 m depth, consisting of two hydrophones and a transmitter, a data collection system, and a network switch that sends the recorded data to shore. Second, a hybrid fiber optic cable that connects the sea unit with the third part, a land unit that supplies power to the sea unit and receives data and stores it on a hard drive (Fig. 1). The system described here was in operation from November 2021 to March 2022. An AIS antenna and a receiver were also connected to the computer in the land unit, storing the AIS data locally. The land unit was remotely controlled through a 3G modem and included the possibility to reprogram the data collection at the sea unit. A first version of the station was in operation at the study site from May 2019 to February 2020.

The sea unit consisted of a waterproof Delrin plastic housing mounted on a 125 kg concrete foundation. Two hydrophones (Neptune D70h) and one transmitter

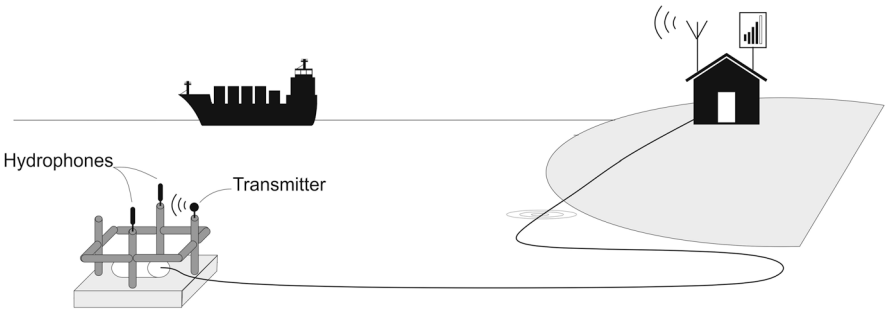

**Fig. 1** A schematic drawing of the three parts of the Vinga station. To the left, the sea unit with the white cylindrical Delrin housing on a 125 kg concrete foundation (light gray) and the hydrophones and transmitter in a PVC structure (gray) is shown. A hybrid fiber optic cable connects the sea unit to the shore where a land unit, located in a house, received and processed the data

(Neptune D45) were mounted in a PVC structure 1.5 m above the seabed with a 0.75 m separation (Fig. 1).

The sea unit contained a programmable real-time unit from National Instruments, NI cRIO 9063. A NI 9250 data acquisition card and a NI 9263 signal generation card was connected to the real-time unit. The main purpose of the real-time unit was to redirect the data to the output of the tcp/ip network for data transmission to the land unit. The Neptune D70h hydrophones were connected to the inputs of the NI 9250 card. The card had a user selectable sampling frequency of up to 102.4 kHz. The signal resolution was 24-bits. The hydrophones, having built in 40 dB preamplifiers, had a sensitivity of −153 dB re 1 V/μPa below 10 kHz. From 10 kHz up to 25 kHz, the sensitivity dropped monotonically to −157 dB re 1 V/μPa. The 2σ of the sensitivity was approximately +/−1 dB. The hydrophones were wired to separate amplifier units with 0 dB gain settings for optimal impedance matching with the data acquisition unit.

The 2-kilometre hybrid cable had 12 fiber optical wires for signal transmission and 2 AWG16 copper wires supplying the sea unit with power. Only two of the fiber optical wires were used. The communication between the land part and the sea part takes place with the help of "Network stream" technology provided by NI LabVIEW software package.

In the Delrin housing, temperature and humidity sensors were added to monitor the climate within the sea unit to warn if the temperature gets too high or if there is any leakage.

A Neptune D45 transducer was connected through a cable to the NI 9263 signal generation card in the sea unit. It was used to function test the hydrophones regularly in situ when it was located on the sea floor. At set times (daily at 05:05 local time), fifteen 1 ms long calibration pulses in the frequency range 2–20 kHz were transmitted with the transducer and captured with the hydrophones. The purpose was to investigate if there were any measurement variations (short or long term) giving indications of fouling or other more sudden disturbances or damage to the hydrophones.

The land unit was controlled by a computer through a LabVIEW generated program. Incoming data was stored on an external hard drive which disk capacity limits the maximum sample rate. The system was programmed to collect data with a 51.2 kHz frequency. The selected sample rate allows for analysis up to approximately 20 kHz, including radiated noise from most ships, sound from wind and waves, as well as biological sound from fish, seals, and some whales.

A system calibration was done in FOI's water tank in Kista, Sweden. Sequent, the system was evaluated in a marine environment at FOI's test site in the Stockholm archipelago before it was deployed at the study site.

At the end of the measurement period, the sea unit malfunctioned due to water leakage in one of the cable connectors resulting in a short circuit. An autonomous logger, a DSG LS1 from Loggerhead Instruments with an HTI hydrophone (−165 re 1 V/µPa), was deployed to finalize the measurements from April to June 2022.

The hydrophone station was deployed 2 km outside the island of Vinga where many ships pass within 1 km on their way to or from the Port of Gothenburg on the Swedish west coast (Fig. 2). The number of possible opportunistic passages of commercial ships with an active AIS transponder was about 30 ships every day within 5 km from the station. There are also smaller vessels without AIS transponders, which will add noise to the area. The seafloor in the area consists mainly of mud with patches of hard rock.

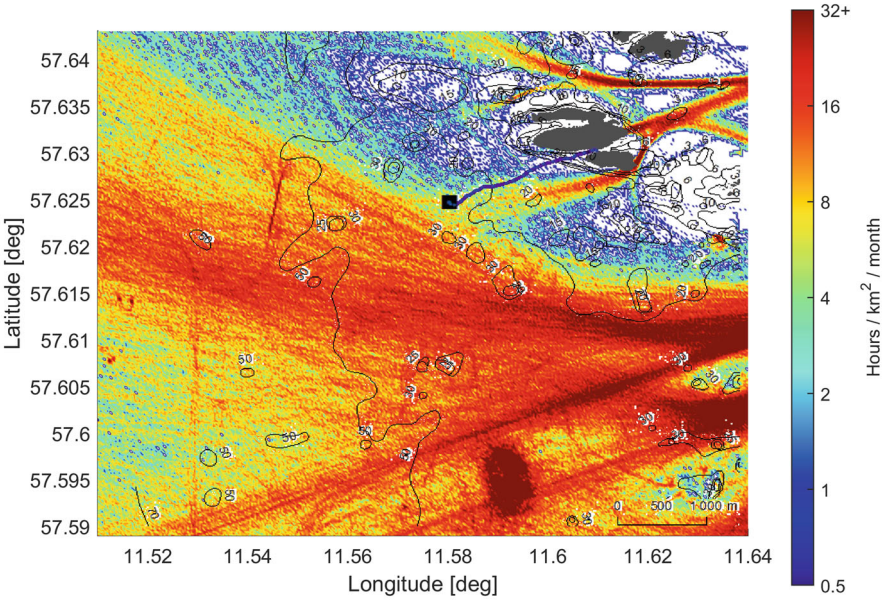

**Fig. 2** Monthly averaged ship density from November 2021 to June 2022. The position of the Vinga station is marked with a black square with a connecting dark line showing the fiber optic cable path to the island of Vinga

### Propagation Loss Measurements

Propagation loss (PL) measurements were conducted in March and June 2022 by towing an underwater acoustic transducer (Lubell Labs 1424HP) at a depth of approximately 5 m from the position of the hydrophone station and 4 km towards south west. Seven tones ranging from 160 Hz to 1060 Hz were continuously played throughout the measurement. As the hydrophone station was online during the March measurement, the decay of the signals could be monitored in real time and the measurements were conducted until the signals decreased to background levels. The received levels were compared to the received levels from a reference hydrophone located on the ship about 7 m from the transducer.

The sound speed profile was measured with a Swift Sound Velocity Profiler (SVP) from Valeport Instruments, both in March and June 2022.

## Ambient Noise, PL and SL Analysis

Opportunistic SL estimates of commercial ships were based on detecting individual ship passages close to the hydrophone station. Ship passages were detected using automatic identification system (AIS) data recorded locally, and suitable time periods in the recorded acoustical data were selected based on the closest approach distance as well as the distance to other ships. This section describes the way the recorded data was analyzed to achieve as accurate an estimation of the SL as possible.

### Ambient Noise

Hydrophone data from the station was processed using the regional standards developed by the EU project JOMOPANS (Ward et al. 2021) in 1/3 octave bands for frequencies ranging from 20 Hz to 20 kHz. Monthly and weekly statistics were thereafter calculated for three different frequency bands 126, 501, and 5012 Hz. This allows for a broader understanding of the soundscape of the study area. The ambient noise will affect the SL estimation and how this is handled can be found in section "Source Level Calculation Based on AIS Data," point 5.

### Propagation Loss

The PL was estimated for each frequency individually. A simple $A \cdot \log_{10} R$ formula was used for fitting the data, where $A$ is the PL coefficient to be estimated and $R$ is the total distance between the underwater acoustic transducer and the hydrophone station.

## AIS-Based Detection of Single Ship Passages at a Hydrophone Station

The subsequent steps were followed to extract time periods suitable for opportunistic SL estimates. This method has been used previously in Lalander et al. (2021).

1. Decode AIS data within a suitable area and time period.
2. For each ship with a unique identification number (MMSI) within the area, detect time periods where the distance from the ship to the hydrophone station is below 1000 m and the ship speed is larger than 1 m/s.
3. Keep only passages with time periods longer than 30 s.
4. Keep only time periods where all other moving ships (ship speed $>0.2$ m/s) are at least 1200 m away from the hydrophone station.
5. Keep only time periods where the closest point of approach (CPA) is below 650 m.
6. Keep only time periods where the longest duration between AIS messages is less than 20 s.

## Source Level Calculation Based on AIS Data

The described approach is based on the guidelines of the classification society Bureau Veritas (2018). It is recognized that the methods themselves and the meaning of some key terms (for example, source level, propagation loss, and radiated noise level) may differ from those adopted by recent ISO standards such as ISO 18405, and ISO 17208 parts 1 and 2. However, in the absence of an ISO standard on measuring ship noise in shallow water (ISO 17208-3 being at only Committee Draft stage) and for consistency with the approaches in the classification society guidance, the terminology and basic methodology used in this chapter and indicated in the text where adaptations have been made.

Data from the hydrophones were processed in several sequential steps to calculate the SL of a passing ship, based on the guidelines from Bureau Veritas (2018). In accordance with the guideline, the SPLs measured in different directions from a ship are treated equally and averaged to form the final SL from the ship. The signal processing steps are given in detail in Svedendahl et al. (2021) and are summarized below:

1. From AIS data, the GPS position of the ship were extracted and the distance, $R$, and angle, $\alpha$, between the hydrophones and the assumed acoustic center of the ship were calculated. The acoustic center was assumed to be $L/3$ in front of the stern of the ship and 2/3 of the draught, where $L$ is the length of the ship. This data was combined with the data from the hydrophone to synchronize acoustic data and ship position.
2. Each passage was divided into 19 time segments, all of which centered around a given set of $\alpha$. The set was given in steps of 5°, ranging from $\pm 45°$ to $\pm 135°$, where the sign depends on if the starboard or port side was facing the hydrophone. In order for the time segments to contain a certain amount of data, they correspond to 100 m long distances or the ship length, whichever is greater.

3. Subsequently, for each time segment, the power spectral density (PSD) was calculated using Welch method (1 s segments with 50% overlap and a Hanning window function).
4. For 1/3 octave band analysis, the narrow band spectrum was converted into 1/3 octave bands by taking the total narrow band energy in the respective band and normalizing with the 1/3 octave bandwidth. Thus, the bands do not correspond to the traditional 1/3 octave band metric, instead they correspond to the frequency averaged spectral density level in each band.
5. The calculated spectrum was compared to the background noise spectrum. If the signal-to-background ratio (SBR) was larger than 10 dB, the spectrum was used directly without any modifications. For a SBR of 3–10 dB, the background was subtracted from the signal spectrum. Lastly, if the SBR was less than 3 dB, this data was removed from further analysis.
6. The PL was corrected for in each time segment, by taking into account the distance from the hydrophones to the location of the acoustic center at the midpoint of each time segment. A simple formula was used in this case: PL = Alog(R). $A$ can be a frequency dependent variable or a constant value and was either estimated from PL measurements or fixed to 17, a value that often yields relatively good agreement with measurements in the study area, based on previous FOI experiences (Bergström et al. 2013; Andersson et al. 2015). Nevertheless, the estimation of PL is the largest source of uncertainty when calculating the SL. The environmental parameters are known to effect the estimation of a ships SL and are not included in this model. However, measurements or more refined modelling of the PL was not feasible.
7. If several hydrophone channels were used, the power spectrum densities calculated from each channel were averaged in all time segments.
8. After the PL correction, all source spectrum density levels were averaged to create a single spectrum for the run.

## Factors That Influence URN Estimation

The international standards and class notations highlight the importance of knowledge of the ambient noise, calibrated equipment, and the estimation of PL. If these are not known, the SL estimation can have large uncertainties. In this chapter, the projects efforts to reduce these uncertainties are described.

### Ambient Noise

The highest SPL over time was recorded in the 1/3-octave band 126 Hz (Fig. 3). The ambient noise showed a large variation in short timescales, minutes to hours. This is caused by the high number of ships passing within a few kilometers from of the station and appears as peaks in the time series (light gray lines in Fig. 3). Both the weekly median and the weekly arithmetic mean (AM), i.e., the mean value calculated in the linear scale and not in the decibel scale, are more stable over time

(Fig. 3). The AM shows more variation and is significantly higher than the monthly median value for all three frequency bands, suggesting that the sound sources that pass the station have a very high sound level, even if they only occur a small part of the time. In May to June, a reduction in SPL is noticed in the lower frequency bands, most likely caused by the change in the PL rather than changed ship density.

## In Situ Function Test

The transmitted calibration pulses were most of the time picked up by the hydrophones. The weekly averages of the calibration ping show a stable result above

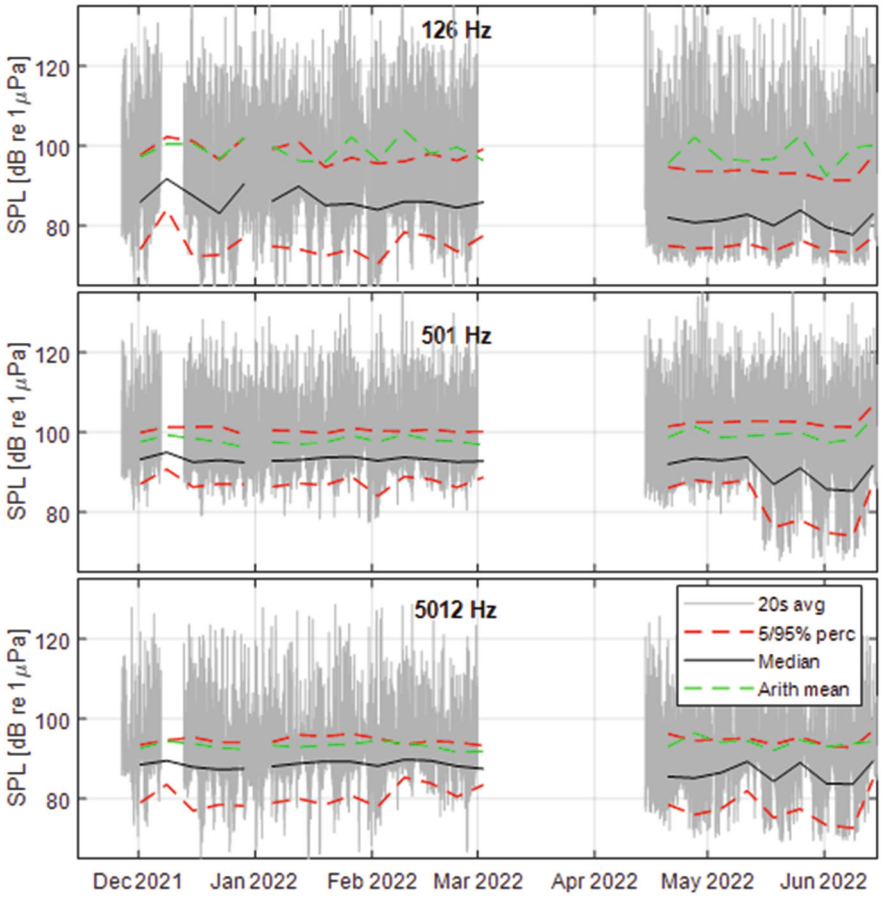

**Fig. 3** Sound pressure level (SPL) at Vinga 2021–2022 over time for different 1/3-octave bands. Light gray lines show 20-s averages. The median, 5%/95% percentile, and arithmetic mean are calculated per week. The statistics are calculated on weeks that have at least 3 days of audio recordings. Gaps in the data series was due to technical failure

6 kHz (Fig. 4), while below the measured pressure, variation is high. This is due to a low signal-to-noise ratio of the transmitted sound waves and variable ambient noise.

## Propagation Loss Estimations

By fitting the received levels in the hydrophone station to a simple PL = Alog(R) formula, and using the reference hydrophone located approximately 7 m from the underwater acoustic transducer to estimate the source levels, the PL coefficient, *A*, could be estimated for all frequencies. Figure 5a shows the results for a single frequency (660 Hz). The measurement data have clear fluctuations that likely stem from interference effects originating from multiple acoustic pathways from the source to the hydrophone station.

In March, the sound speed was lower close to the surface (around 1445 m/s) compared to the sea floor (around 1475 m/s), while the sound speed profile varied much less with depth in June (1485–1495 m/s). The sound speed profile likely affected the PL estimates, seen in Fig. 5b. The PL coefficient was found to vary less with frequency in March, compared to June.

## Estimated SL from Opportunistic Ship Passages

During the measurement period, 254 opportunistic commercial ship passages were recorded from 100 individual ships that passed the Vinga station under the right circumstances to pass the quality check for a SL calculation. The SL estimations were largely done automatically, but the data was also reviewed manually.

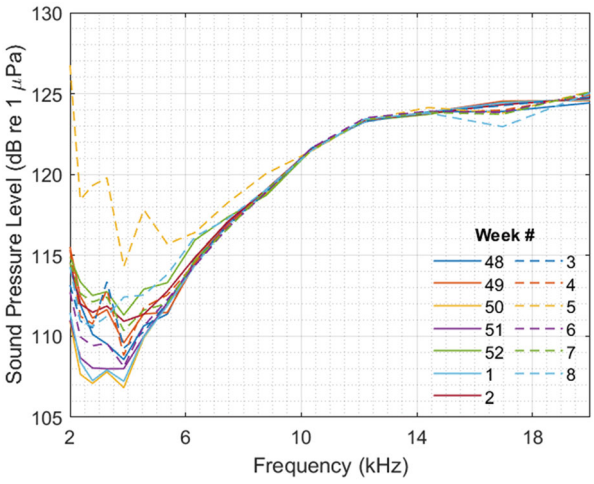

**Fig. 4** Weekly averages of received calibration pings in one of the two hydrophones on the sea unit in the frequency range of 2–20 kHz for November 29th (week nr. 48) 2021 to February 21st (week 8) 2022)

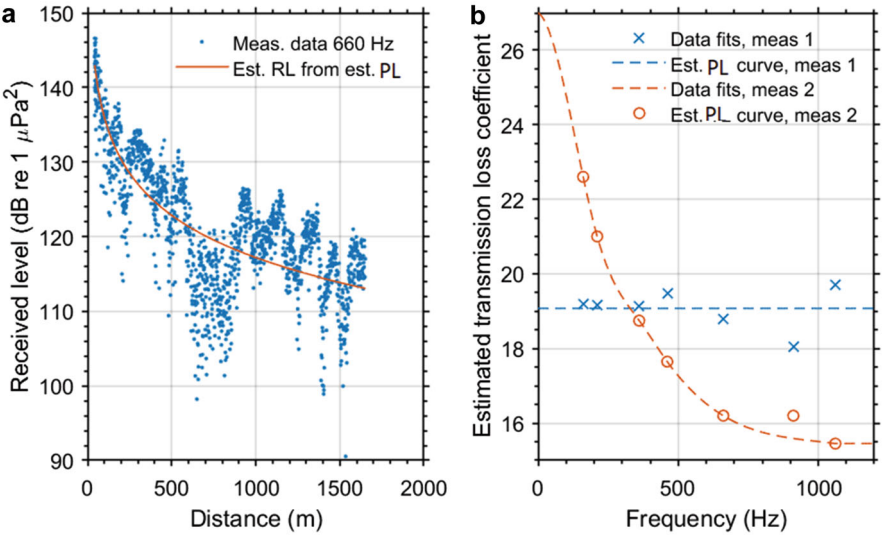

**Fig. 5** Results of the propagation loss (PL) measurements in March 2022 (measurement 1) and June 2022 (measurement 2). (**a**) Received level (RL) from measurement 1 at 660 Hz including a best-fit curve based on a PL-coefficient, the estimated source level, and the distance between the source and the hydrophone station. (**b**) Calculated PL-coefficient as a function of frequency and an estimated PL-coefficient curve based on these calculations for measurement 1 (blue) and 2 (red)

A 238 m long Ro-Ro ship (roll-on/roll-off ships are cargo ships designed to carry wheeled cargo) passed the station 23 times at distances ranging from 310 to 480 m during the measurement period. It mostly travelled at speeds of 17–23 knots, once passing at 10 knots. The PL estimation has a substantial effect on the calculated SL of the ship. For a passage of the ship at 20.4 knots, there is a 5 dB difference in the frequency range 10 Hz–25 kHz depending on the PL estimation used (Fig. 6, left). The uncertainty that the assumed simple model for sound propagation attenuation leads to is estimated to be a couple of decibels.

The measurements show that the ship makes the most noise below 100 Hz with two peaks around 18 and 40 Hz for the speed presented here. For speeds between 19 and 21 knots, the estimated SLs are very similar (Fig. 6, right). The calculated SL for this Ro-Ro ship was also compared with the SL for a similar ship and for the speed of 20 knots, which was produced according to the JOMOPANS-ECHO model for the AIS code vehicle carrier (MacGillivray and de Jong 2021) (Fig. 6, right). The model fits relatively well down to 20 Hz where the measured values increase.

As mentioned, about 100 individual ships SL were calculated from several different ship categories, taken the AIS data. Since the URN estimations are from almost an 8-month period, the PL will have changed during this period. In order to reach as good estimation as possible, the data of PL from the two measurement in March and June 2022 was used, with a cut-off date on the 14th of April. Specifically, the PL measurement from March was used for ship passages before the cut-off and

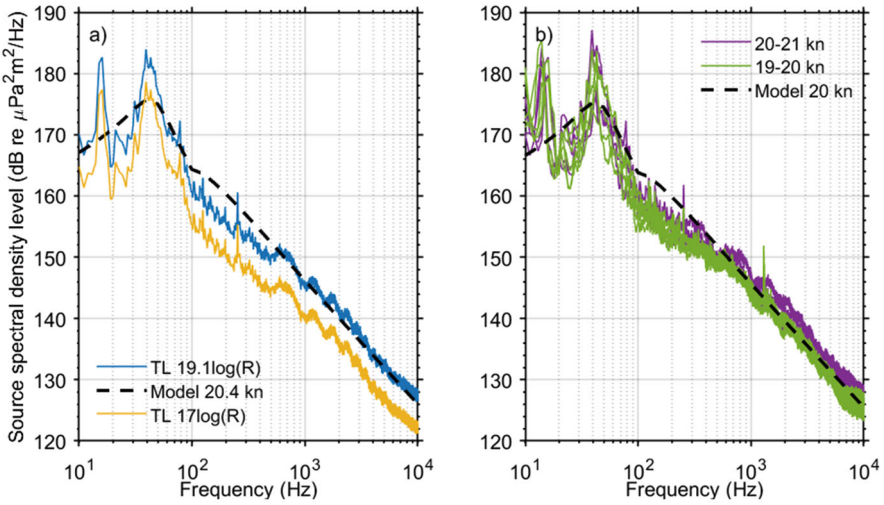

**Fig. 6** Estimated source level (SL) at 1 m from a 238 m long Ro-Ro vessel passing the Vinga station compared to the JOMOPANS-ECHO model for a vehicle carrier (black) (MacGillivray and de Jong, 2021) for a ship of equivalent category, size and speed. (**a**) SL at 20.4 knots with two different propagation loss (PL) – coefficient estimations. (**b**) Calculated SL at 1 m for various speeds compared the model

the one from June was used for ship passages after the cut-off. The cut-off date was chosen naturally due to the two different hydrophone stations used in the project and noticed change in the sound speed profile.

The ship category cargo was the category that made the most noise (ship length over 200 m, Fig. 7). These ships were also the fastest. The top right ship in Fig. 7, with a length of 238 m, is the same ship presented in Fig. 6. Smaller and slower ships make less noise. However, there were a number of passages of small fast pilot boats, which were some of the quietest vessels recorded (Pilot vessel, Fig. 7). The bandwidth of the broadband SPL presented in Fig. 7 was chosen to relate to the article by McKenna et al. (2012).

## Summary and Recommendation

The development and operation of a cabled real-time hydrophone station on the Swedish west coast were successful and generated high-quality data on both ambient noise and SL estimations of over 254 opportunistic commercial ship passages. However, several were from the same ship.

The in situ function test worked well throughout the measurement period and did not indicate any damage to the hydrophones. Damage to the hydrophone elements would indicate variation in the higher frequencies, which was not seen in the data. The high variation below 6 kHz is caused by low signal-to-noise ratio, which is a

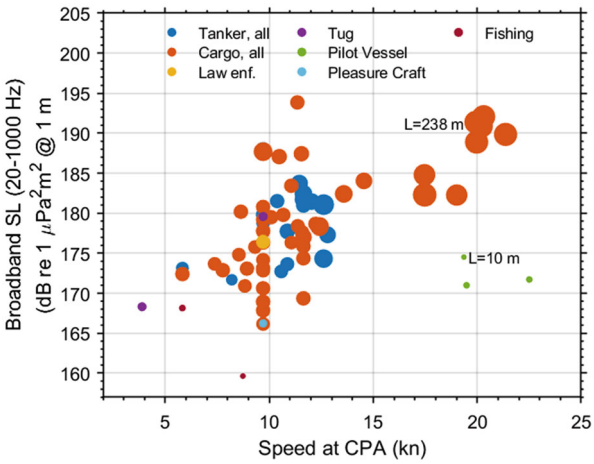

**Fig. 7** Estimated broadband (20–1000 Hz) sound pressure level (SPL) of the SL for unique ship passages near the Vinga station. The ship classifications were based on AIS data. The marker sizes indicate the length of the ship, with the longest (238 m) and shortest (10 m) ships indicated in the figure

consequence of the low signal output by the transducer and higher ambient noise. Having a transducer that can produce high enough output energy at lower frequencies could not be used in this station design due to the size and power requirement of such transducer. By having this function test running, unnecessary and costly retrievals of the station can be avoided.

The ambient noise level measured showed a high variation in the short time scale of minutes to hours. This is to be expected from a location close to the entrance of a busy port. In addition, the highest SPL was noticed in the 1/3-octave band 126 Hz compared to the other two bands (501 and 5012 Hz). This is to be excepted since ship noise has most of the energy below 500 Hz (McKenna et al. 2012; Karasalo et al. 2017; Wladichuk et al. 2019). More results from the ambient noise measurements can be found in Putland et al. (2022).

The PL measurements include relatively large uncertainties that are not completely covered by this chapter. Both the acoustic transducer and the reference hydrophone were located on the same ship, but on different rigs, thereby naturally varying in depth and relative distance between each other throughout the measurement. A more detailed knowledge of the time-varying distance and depth data, possibly by additional sensors, mounting the reference hydrophone and acoustic transducer to a single, more rigid, construction, or using a calibrated source could decrease some uncertainties in the propagation loss coefficient estimates. Moreover, the acoustic transducer transmit voltage response (TVR) and the electrical power available on ship were limited, which lead to a compromise regarding the number of tones that were projected into the water and the amplitude of each tone. The TVR of the acoustic transducer was significantly weaker for lower frequencies, for which the ambient noise is larger, which limited the feasible frequency range of the measurement. Otherwise, it would certainly have been of interest to measure frequencies below 160 Hz as well. In this case, a single tone per 1/3 octave band was chosen,

while also avoiding multiples of other tone frequencies and multiples of 50 Hz. Furthermore, an oversimplified model for the PL was used here, which did not take into account multipath or similar effects from the environment. If detailed knowledge of the measurement site is available, a more complex model could be used.

With the above comments in mind, it may be of interest to work towards a PL measurement standard, which could indicate not only how to conduct such measurements but also what frequency ranges that should be included. This is of particular importance for shallow water measurements. Some URN guidelines promote PL measurements but do not specify how to conduct them nor the frequency range(s) that need to be covered.

As a possible outlook, it would be interesting to study if an individual ship could be used to track changes in the PL. As the site was near a pilot station, and the same pilot vessels pass by the station relatively often, it may be possible to adjust for some environmental changes without the need to invest in the large time consuming effort of making PL measurements. By tracking the changes in the estimated SL of the ship, given certain ranges in spatial location, heading, and speed, it may be that PL measurements can be done less frequently.

The Ro-Ro ship with multiple passages showed similar SLs for 19–21 knots during the measurement, no matter the time of passage period. Disregarding any possible difference in cargo load and drive mode, the PL correction works well even though the closets point of approach is different for most passages. The estimated SL fits well with the JOMOPANS-ECHO SL model for vehicle carrier (MacGillivray and de Jong 2021) for a ship with the same length and at the same speed. Local PL effects are most likely the cause of the discrepancy between the model and the SL estimation data below 100 Hz.

The calculated broadband levels are in the same range as previously published (McKenna et al. 2012; Karasalo et al. 2017; Wladichuk et al. 2019). The AIS category cargo, which is a broad category of ships, was the most common, the largest and the most noisy ship category. The second most common and noisy category was tankers, which in general travel a bit slower. A more in-depth analysis of each subcategory of cargo can be done but was out of the scope in this chapter.

When choosing a measurement position for opportunistic ship passages, there is a trade-off between having enough passages to get good data and too many passages that could disturb the SL measurement of each individual ship. The position chosen proved to be a good compromise.

In conclusion, having a hydrophone station at the entrance of a major port, as described in this chapter and in Hannay et al. (2016), the SL of specific ships can be obtained in a cost-effective manner. The radiated noise information are useful for shipping companies and managers if noise levels for individual ships are regulated in the future, and silent class notification becomes more common. Although the economic gains are low for this particular benefit at the moment, silent ships has been proven to increase fuel efficiency due to good maintenance and/or technical solutions (Gassmann et al. 2017), which in turn results in lower running cost.

**Abstract**

Mobile offshore drilling units (MODUs) are used to drill oil and gas wells in the ocean. For deeper water operations, there are two common forms of MODUs: semisubmersible rigs and drillships. Over the past several years, JASCO Applied Sciences measured MODU drilling operations by semisubmersibles and drillships, including platforms that were moored with anchors or that held position using dynamic positioning (DP) thrusters. The MODUs were accompanied by support vessels on standby, with additional vessels conducting resupply operations during the drilling campaigns. The measurements were performed in response to regulators requesting verification of the vessel source levels and the distances where the sounds were expected to either injure or disturb marine life.

Overall, drillships had higher source levels than semisubmersibles. Moored platform sound levels decreased with drilling depth and hole diameter. The signatures of moored platforms featured tones from different types of rotating machinery. When platforms or nearby support vessels were holding station using DP, the tonal signatures were obscured by DP thruster sounds. All measurements of underwater radiated noise from platforms using DP contained sounds from ultrashort baseline (USBL) beacons at 25–27 kHz.

## Introduction

Nearly 45% of global gas reserves and 15% of global oil supplies are found in the offshore environment (IEA 2018). To access these resources, mobile offshore drilling units (MODUs) are used to drill gas and oil wells in the seafloor. The most common types of MODUs for offshore operations are semisubmersible rigs and drillships. Both can hold position over offshore wells using dynamic positioning (DP) thrusters or can be moored using anchors. Characterizing the underwater sounds emitted by these MODUs is important for understanding the potential underwater noise impacts that these offshore drilling activities can have on marine fauna, including the distances over which these sounds have the potential to injure (via permanent or temporary hearing threshold shifts) or disturb marine fauna. To this end and in fulfillment of local regulatory requirements, JASCO Applied Sciences (JASCO) has measured underwater sounds of MODU operations for several semisubmersibles and drillships (Table 1) at locations around the globe. This chapter provides a high-level overview of the results of these measurements, with respect to the nature and levels of underwater noise associated with MODU activities.

This chapter considers underwater noise measurements of the semisubmersible *West Aquarius* while on DP as well as the moored semisubmersibles *Ocean Onyx* and *Polar Pioneer*. Underwater noise measurements of four drillships are also considered: *Stena Forth* and *Stena IceMax* while on DP as well as the moored drillships *Noble Discoverer* and *Kulluk* (Austin et al. 2018).

Measurements were recorded at locations in the Alaskan Chukchi and Beaufort Seas, in the Atlantic Ocean off the east coast of Canada, and in the Otway Basin off Southeastern Australia (Table 1). These locations span different environmental regimes for water depths and seafloor types. In the Chukchi and Beaufort Seas, the water depths are shallow (35–45 m) and the seabed is relatively flat with a sandy silt bottom. The sites on the Scotian slope of the Atlantic are deep (2000–3000 m) with a clay seabed. At the site in the Otway Basin, the water depth is 70 m with a relatively flat seabed consisting of well-cemented carbonate caprock, overlying semicemented carbonate rock.

## Background

Drillships are large vessels equipped with a drilling derrick and drilling equipment such as pumps, mixers, shakers, pipe racking, and pipe movement equipment. A drill-string generally passes through a moonpool in the ship's hull. In addition to the drilling equipment, as with other large ships, the list of sound-generating equipment also includes the vessel's engines, generators, propulsion systems, and hydraulics for cranes and winches. Noise is transmitted to the ship's hull through mechanical coupling of the machinery with the ship's structure, as well as through coupling of airborne noise. All the mechanical equipment and machinery is housed on or below the ship decks and mechanical vibrations are well coupled to the ship's hull. The vibrations are then transmitted from the hull into the surrounding water and radiated throughout the water column.

Drillships float and are self-propelled so they have the advantage of ready mobility. They are well suited to deepwater drill sites where mooring can be a challenge. Because they are mobile platforms that float on the sea surface, they require advanced dynamic positioning capabilities or sophisticated moorings to maintain their positions in the presence of waves and currents.

Semisubmersible MODUs consist of a main platform above columnar legs attached to pontoons. The pontoons float at the water surface while the unit is towed to a well site. Once at the drilling location, the pontoons are flooded to ballast the structure and lower its center of gravity. The main platform remains elevated above the sea surface and away from waves, which provides increased operational stability compared to a drillship. Pathways for sound coupling for a semisubmersible include vibration transmissions through the drill-string and from the columns and pontoons below the water.

Each MODU employs similar types of equipment and machinery, so their acoustic footprints differ principally in the mechanisms by which the sound couples from the structures to the surrounding water. It is generally assumed that drillships emit higher underwater sound levels than semisubmersibles, given the greater surface area that is coupled with the water.

The drilling programs JASCO measured took between 1 and 4 months per well. The duration varied based on the well type (exploration or development), the depth, and operational complexity. MODUs are typically accompanied by support vessels on standby. These vessels include supply vessels, fuel tankers, anchor handlers, spill response vessels, ice management vessels, etc. In remote locations where there are no nearby ports, these vessels remain on standby for extended periods, typically within a few kilometres of the MODU. They use operationally relevant power levels, ranging from idle to underway, and may use DP to hold station. During the measured programs, stationary vessels within 500 m of the MODUs were always under DP for navigational safety. DP thrusters, similar to ship propellers, cause cavitation noise, i.e., the noise created through vibration and creation of low-pressure points and bubbles, and their signatures differ for the various thruster types and power levels.

## Results

### Otway Basin, Australia

In the Otway Basin, JASCO measured underwater sound levels of the moored semisubmersible *Ocean Onyx*, while it was undertaking an exploration drilling program for Beach Energy Limited. Measurements were collected to validate JASCO's modeling predictions used in the Beach Energy Otway Environmental Plans for exploration and development drilling activities. The model validation is not discussed in this chapter.

Sound levels were measured at 0.3, 1, 5, and 25 km ranges (Fig. 1). Continuous recordings at 24-bit resolution and 64 kHz sample rate were collected using seafloor-mounted Autonomous Multichannel Acoustic Recorders (AMARs; JASCO). The AMAR at the furthest recording distance was configured with three hydrophones such that the originating direction of the received sounds could be computed; a single hydrophone was used at the other recording locations. The most prominent feature in Fig. 1 is the decrease in sound level with distance from the drill rig. Across all frequencies, recordings at the two nearest stations indicate that the mean and all data above the median exceed the upper limit of expected ambient sound levels, based on the Wenz curve, owing to noise from the MODU. At the 5 and 25 km stations, the sound levels are much reduced, with sound from the MODU not notable at the 25 km station. The soundscapes at the farthest two stations exhibit frequency distributions characteristic of noise from vessel traffic originating from commercial shipping. Operational details for the variable activities of the MODU and support vessels were obtained from the MODU operator's activity logs. The recordings were

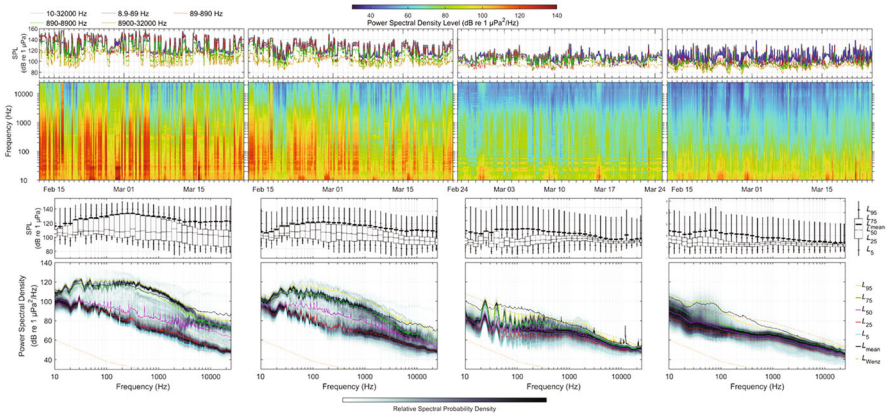

**Fig. 1** (Top row) In-band sound pressure level (SPL) and spectrogram (or long-term spectral average; LTSA) of underwater sound, (bottom row) percentiles and mean of decidecade SPL and percentiles and probability density (grayscale) of 1-min power spectral density levels, by station, compared to the Wenz curve limits (colored lines) of prevailing noise (Wenz 1962). Stations (left to right) were located 0.3, 1, 5, and 25 km from the semisubmersible

also influenced by weather conditions and merchant shipping unrelated to the MODU program.

The operational activity logs were referenced to identify periods when specific drilling activities occurred. The spectrogram on the left in Fig. 2 was generated from acoustic data collected at 300 m range during drilling. Several distinct tones are present in the data, and broadband sound levels are around 120 dB. The spectrogram on the right in Fig. 2 is from a period during drilling when there was a resupply vessel alongside. Vessels used DP whenever they were within 500 m of the *Ocean Onyx*, and vessels in DP mode were the dominant source of noise in this example. Here the received broadband SPL is much higher, reaching nearly 160 dB at the loudest time, and the tones evident in the spectrogram on the left are obscured by the more broadband noise from the DP thrusters on the support vessel.

It is worth noting that to characterize sounds from an MODU operating in isolation, it is crucial to be able to select time periods not contaminated by noise from ancillary support vessels. AIS records or navigational logs for the vessels can be cross-referenced with the time stamped acoustic recordings for this purpose. Acoustic recordings should also be collected over long durations (days to months) because there are often only short periods of time when no vessels are alongside the MODU. Activities associated with mooring operations, cementing, installing the blowout preventer (BOP), or running casing were not considered. Twenty time periods for drilling were identified, and seventy 10-minute periods out of the 6-week drilling operation were considered suitable for characterizing noise from the *Ocean Onyx* while drilling. Source level measurements were matched with drill logs and the source levels were grouped by the drilling activities.

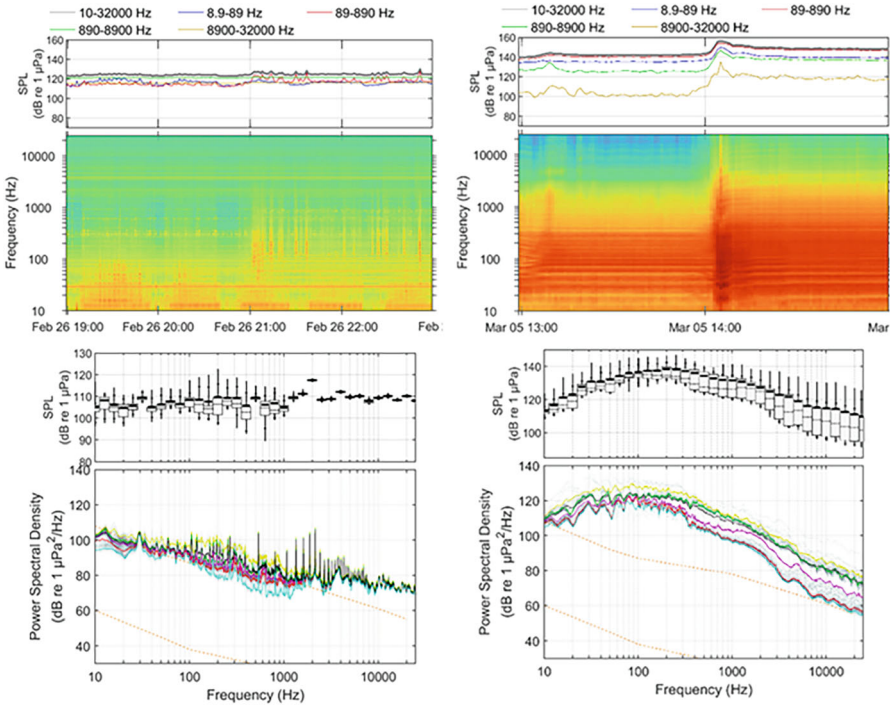

**Fig. 2** (Top row) In-band sound pressure level (SPL) and spectrogram (or long-term spectral average; LTSA) of underwater sound, (bottom row) percentiles and mean of decidecade SPL and percentiles and probability density (grayscale) of 1-min power spectral density levels, by station, for a (left) drilling period on 26 Feb 2021 with no support vessels nearby and (right) drilling period on 5 Mar 2021 which included resupply and support vessels, compared to the Wenz curve limits (colored lines) of prevailing noise (Wenz 1962)

Detailed examination of periods during drilling with no vessel noise indicated the presence of tones associated with machinery with variable rotation rates, diesel generators and pumps with variable loads, and a consistent high-pressure pump. The monopole source level (MSL; dB re 1 µPa m) for each drilling period sample was calculated using JASCO's ShipSound software. The mean MSL for the *Ocean Onyx* was determined for three drilling depth ranges (Fig. 3). The mean MSL was 175.2, 169.3, and 162.7 dB re 1 µPa while drilling at depths between 95–172, 365–621, and up to 1851 m, where the hole diameter was 26″, 17.5″, and 12.25″, respectively.

## Alaskan Beaufort and Chukchi Seas, USA

Measurements of drillships in the Alaskan Chukchi and Beaufort Seas (obtained for Shell Offshore Inc.) were more readily obtained without contamination from sounds of ancillary support vessels. For these drilling programs, support vessels were

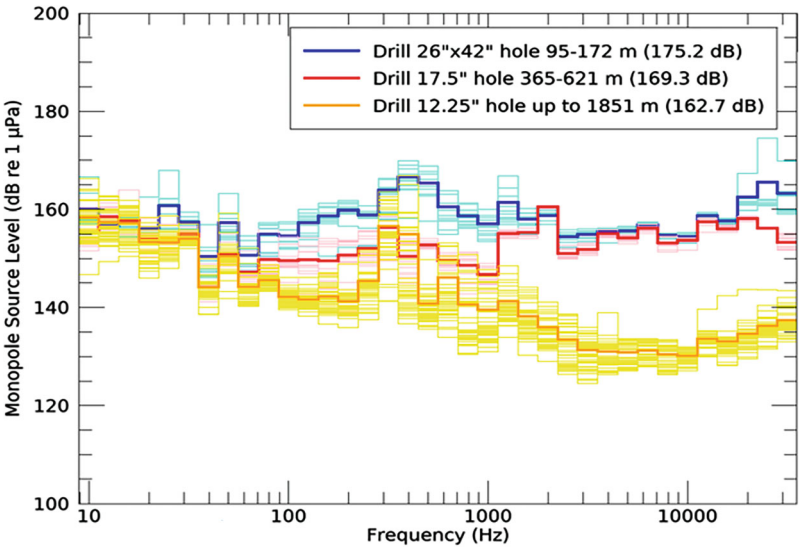

**Fig. 3** Monopole source level (MSL; dB re 1 µPa m) and spectra for the moored semisubmersible *Ocean Onyx* drilling in the Otway Basin, Australia, from ShipSound processing of data measured at 300 m range, averaged over measurements for three drilling depths

required to be farther than 25 nmi from the drillship unless the vessels were actively engaged in an activity that required them to be closer. This provided long recording periods of drilling noise without vessels present. The image on the left in Fig. 4 shows drilling noise measured while three support vessels were within 5 km of *Discoverer* while it drilled a pilot hole at the top of a well in the Chukchi Sea. These data were measured 1 km from the drillship with a seafloor-mounted AMAR recording at a 64 kHz sample rate. The period with drilling is not easily discernible from the vessel noise in the panel on the left. In this case, an ice management vessel and a spill response vessel were both between 0.5 and 1 km from the drillship, and an anchor handler was within 4 km. The spectrogram on the right was recorded when there were no vessels within 10 km of the drillship. Low-amplitude tonal noise is evident in these data, caused by the machinery on the drillship when it is not actively drilling. A period while the drillship drilled a 26″ hole is annotated on this figure.

The left panel of Fig. 5 shows the power spectral density levels for sounds recorded during the period of drilling the 26″ hole as measured at 1, 2, 4, and 8 km from the drillship. Many discrete tones are evident. The right panel in Fig. 5 is a similar plot, for the drillship *Kulluk* drilling in the Beaufort Sea.

There was one activity during these drilling programs that was notably louder, and that was the drilling of the mudline cellar (MLC); a large pit excavated from the seafloor, 12 m deep by 6 m wide, to house the blowout preventer at the top of the well. This was dug using a 6 m diameter drill bit, consisting of multiple rotating disks angled to displace the excavated sediment. During this activity, the sound levels jumped up by approximately 20 dB, as can be seen in the spectrogram and

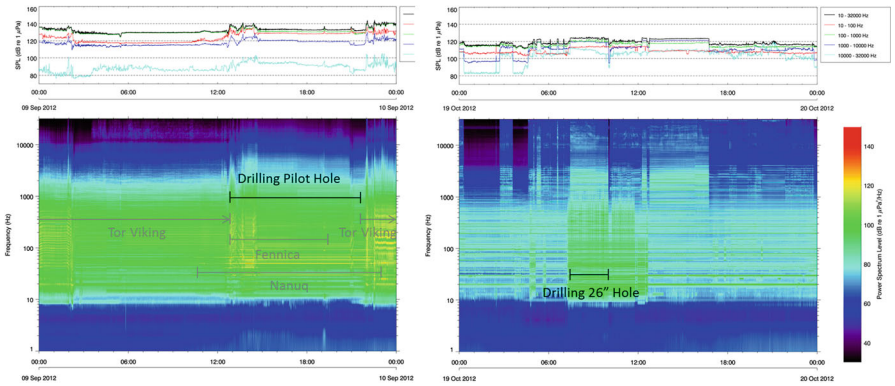

**Fig. 4** In-band sound pressure level (SPL) and spectrogram (or long-term spectral average; LTSA) of underwater sound measured while the *Discoverer* was (left) drilling a top hole with three support vessels nearby and (right) drilling a 26″ hole with no vessels within 10 km

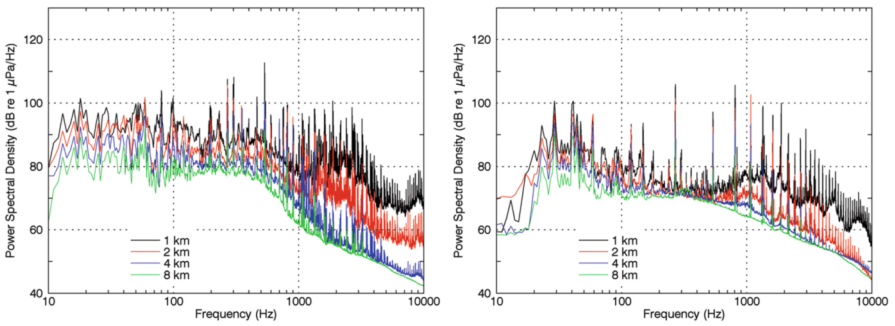

**Fig. 5** Power spectral density for (left) the *Discoverer* drilling a 26″ hole in the Chukchi Sea and (right) the *Kulluk* drilling in the Beaufort Sea as received at seafloor acoustic recorders at four ranges

band level plots in Fig. 6. JASCO measured this activity in the Chukchi Sea in 2 years, once the activity was carried out from a drillship and once from the semisubmersible platform the *Polar Pioneer*. Figure 7 shows a plot of the power spectral density for drilling and for mudline cellar excavating in these 2 years; the left panel is the drillship and the right is the semisubmersible. In both cases, the MLC excavation (which is the upper black curve) is not only louder than the drilling, but in both cases many of the tones in the spectrum were obscured and the noise was more broadband in nature. Source levels were estimated by back-propagating received levels measured at a range of 1 km. Mean broadband source levels were calculated as 168.6 dB re 1 µPa·m for the *Kulluk* drilling in the Beaufort Sea, 174.9 dB re 1 µPa m for the drillship *Discoverer* drilling in the Chukchi Sea, and 170.1 dB re 1 µPa m for the semisubmersible *Polar Pioneer* drilling in the Chukchi Sea. Source level

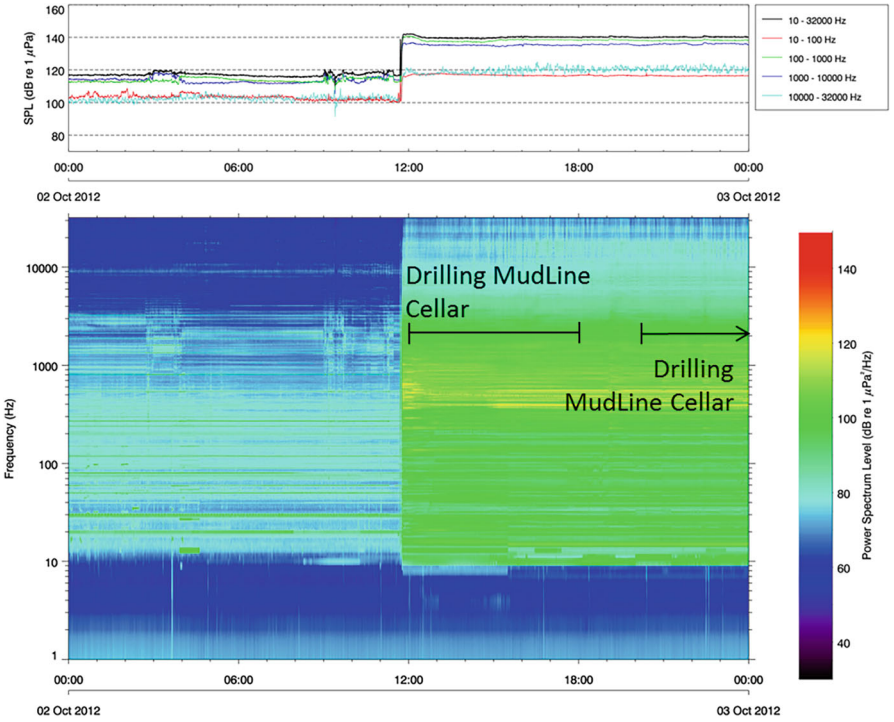

**Fig. 6** In-band sound pressure level (SPL) and spectrogram (or long-term spectral average; LTSA) of underwater sound measured while the drillship *Discoverer* was drilling a mudline cellar with no vessels within 10 km

estimates for MLC excavation were more consistent among the sources: 191.8, 193.0, and 193.3 dB re 1 µPa for the *Discoverer*, *Kulluk*, and *Polar Pioneer*, respectively. These measurements are all detailed in Austin et al. (2018).

## Scotian Slope, Canada

JASCO measured two drillships (the *Stena IceMAX* at the Shelburne Basin Venture Exploration Project for Shell Canada Limited, and the *Stena Forth* at the Pelles A-71 Exploration Well in the Flemish Pass for the Chinese National Offshore Oil Corporation [Kowarski et al. 2021]) and one semisubmersible (the *West Aquarius* at an exploratory drilling well in the Flemish Pass for Exxon Mobil Canada [Delarue et al. 2021]) and during an exploratory drilling campaign off the coast of Nova Scotia for BP Canada Energy Group ULC (Martin et al. 2019) at four drilling locations off the Canadian east coast. All measurements were collected using AMARs, with (project-dependent) samples rates of 16, 32, 64, or 128 kHz. All these MODUs were operating on DP during the drilling programs.

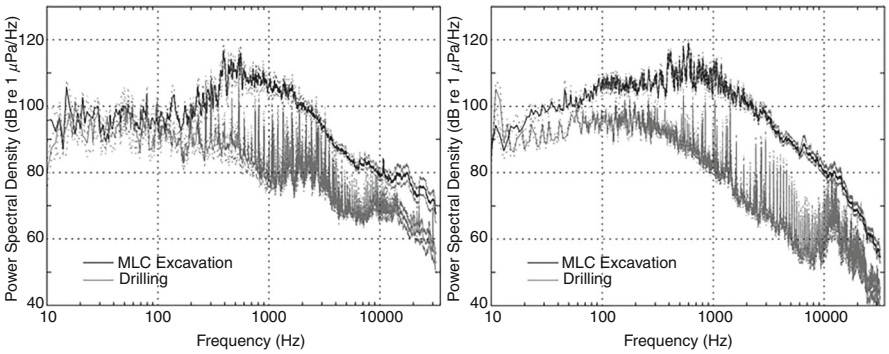

**Fig. 7** Power spectral density for drilling and mudline cellar (MLC) excavation in the Chukchi Sea by (left) the drillship *Discoverer* and (right) the semisubmersible *Polar Pioneer*, as received at seafloor acoustic recorders at 1 km range

Figure 8 is an example of the data collected at (left) 2 km and (right) 20 km during drilling by the semisubmersible *West Aquarius* on DP in the Scotia Basin. There are fewer discrete tones discernible in the data then was observed for the moored semisubmersibles measured in Alaska and Australia. In this case, the dominant sources of noise were the DP thrusters constantly engaged to maintain position over the well, nearby vessels, and wind. There was no obvious trend in overall sound levels relative to the operational drilling activities. This was also the case for data measured at 2 km range from this semisubmersible while drilling in the Flemish Pass (Fig. 9).

Similarly, measurements of drillships on DP on the Scotian Slope were dominated by noise from the platform's DP thrusters. Fig. 10 is an example of this from measurements made at 2 km range while the *Stena IceMAX* was drilling in the Shelburne Basin and using DP. Fifty-two hours of data were collected during this measurement program, and approximately 33 h of drilling activity occurred in this period. Throughout all 52 h, the *IceMAX* and four support vessels were operating in dynamic positioning (DP) mode. The full period spectrograms and band-level data in Fig. 10 do not show changes in measured sound levels that correlate with changes in the drilling state. This suggests that DP system noise and mechanical noise from the *IceMAX* and OSVs were larger contributors to the sound field than the actual sound generated from drilling equipment. Over the entire measurement period, the 100–1000 Hz band had the highest SPL on both static recorders. This band is where most sound from large vessels occurs. The spectrogram shows lines varying in frequency, forming many "V" shapes. This effect normally indicates vessels transiting past a recorder, but a vessel using DP in changing current or wind could also generate this pattern as the power output of the thruster increases and decreases. In the case of the fixed-pitch propellors on all thrusters on the platforms measured, this varied in association with the variation in revolutions per minute (RPM) of the thruster.

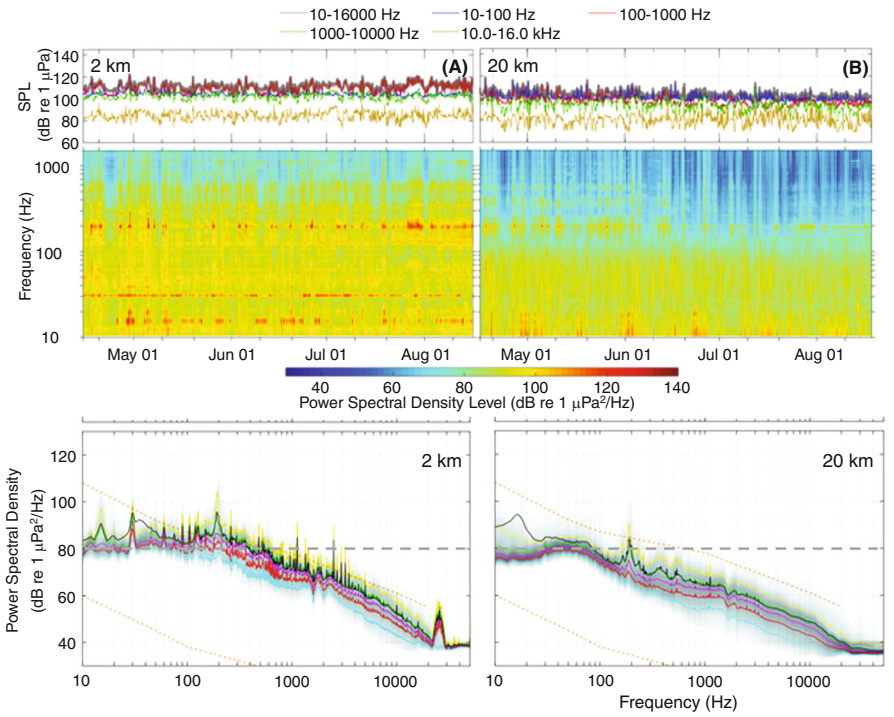

**Fig. 8** (Top row) In-band sound pressure level (SPL) and spectrogram (or long-term spectral average; LTSA) of underwater sound, (bottom row) percentiles and probability density (grayscale) of 1-min power spectral density levels recorded at (left) 2 km and (right) 20 km from a semisubmersible rig drilling while under dynamic positioning in the Scotia Basin, offshore Eastern Canada

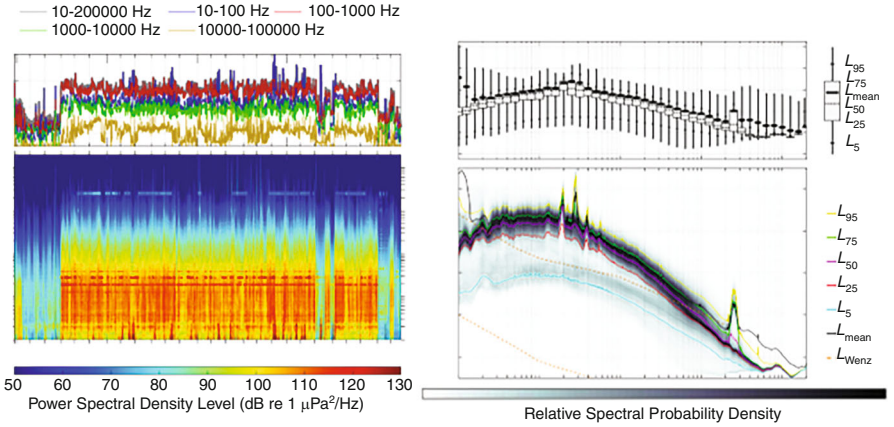

**Fig. 9** (left) In-band sound pressure level (SPL) and spectrogram (or long-term spectral average; LTSA) of underwater sound, (right) percentiles and probability density (grayscale) of 1-min power spectral density levels recorded at 2 km from a semisubmersible rig drilling while under dynamic positioning in the Flemish Pass, offshore Eastern Canada

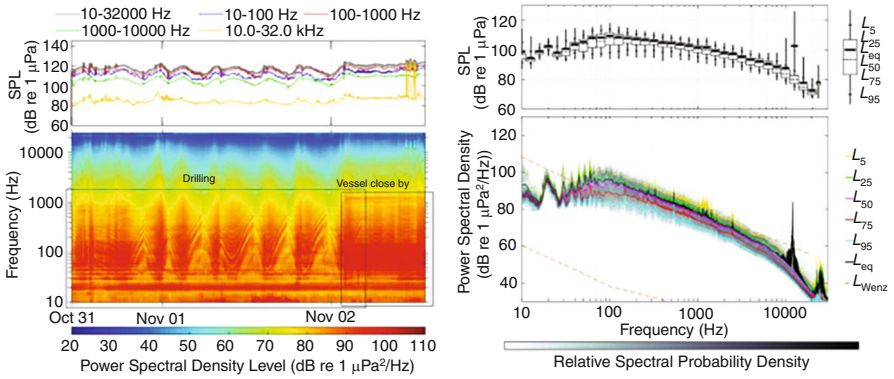

**Fig. 10** (left) In-band sound pressure level (SPL) and spectrogram (or long-term spectral average; LTSA) of underwater sound, (right) percentiles and probability density (grayscale) of 1-min power spectral density levels recorded at 2 km from a semisubmersible rig drilling while under dynamic positioning in Shelburne Basin, offshore Eastern Canada

All recordings of drillships and semisubmersibles consistently contained a notable high-frequency tone around 25 kHz. This was determined to be associated with the high-precision acoustic positioning system associated with the DP system and an echosounder used to monitor the drillship distance from the seafloor. Estimated mean MSLs for each MODU measured while using DP varied between 183 and 187 dB re 1 µPa m. It is worth noting that faint tones were recorded by JASCO in the Orphan Basin offshore Newfoundland, Canada, at times corresponding to when the semisubmersible *West Hercules* was operating while on DP at a 209 km range from the recorder. This suggests that in some environments, these DP sounds can extend over long distances.

## Summary

The measurement campaigns that characterized the MODU drilling operations presented here were often logistically challenging, with significant effort expended for, in most cases, relatively limited periods of usable data once attending vessels were removed from the datasets. The loudest part of MODU operations, considering the platforms themselves and the attending vessels, is the operation of the dynamic positioning thrusters. The summary of the mean MSLs in Table 2 demonstrates that the quietest estimate for the mean MSL for a DP MODU is approximately 8 dB greater than the loudest mean measured MSL for moored MODUs. If there is a regulatory or best practice requirement to minimize underwater noise emissions from a drilling operation, the first consideration should be whether the MODU can be moored rather than using DP. Similar logic applies to support vessels, which can minimize underwater noise emissions by maintaining slow transit speeds rather than

**Table 2** Summary of mean monopole source levels for the measured mobile offshore drilling units (MODUs)

| MODU type | Vessel | Location | Mean monopole source level (dB re 1 µPa m) |
|---|---|---|---|
| Moored semisubmersible | *Ocean Onyx* | Otway Basin | 162.7–175.2 |
| | *Polar Pioneer* | Alaska | 170.1 |
| Semisubmersible on DP | *West Aquarius* | Scotian Slope | 183–187 |
| | *Stena Forth* | | |
| Drillship on DP | *Stena IceMax* | | |
| Moored drillship | *Noble Discoverer* | Alaska | 174.9 |
| | *Kulluk* | | 168.6 |

holding station under DP. The reported measurements likely do not represent the full range of potential emissions by DP vessels and thrusters, and certain thrusters and operational conditions may result in both lower and higher MSLs. For context, JASCO has characterized Anchor Handler Tug Support vessels, which were supporting the *Ocean Onyx*, as having mean MSLs of 193.9 dB re 1 µPa (McPherson et al. 2021). Additionally, all measurements of noise from platforms using DP contained sounds from ultrashort baseline (USBL) beacons at 25–27 kHz. The possible impacts of the beacons on the presence of odontocetes near the MODUs is considered in a separate chapter.

The measurement studies in this chapter did not consider the emissions during other stages of a drilling operation, such as mooring, cementing, installing the blowout preventer (BOP), or running casing. While the underwater noise emissions from the platforms using DP varied depending on the speed of the fixed-pitch thrusters, no engine data were available to complete an analysis of this relationship. The speed, which depends on operational requirements and weather conditions, predominantly masks any tonal signatures of rotating machinery. For the moored platforms, sound levels decreased with drilling depth (and hole diameter), and the sound levels were primarily determined by the tones from different types of rotating machinery.

**Abstract**

The Southern North Sea Special Area of Conservation (SAC) is the largest of a suite of sites designated to protect harbor porpoise (*Phocoena phocoena*) and its habitats in UK waters. It was identified as having high persistent densities of porpoise despite the area being highly industrialized and therefore noisy. Activities in and around the site include geophysical surveys, clearance of unexploded ordnance, and construction activities involving pile driving.

Given the potential conflict between maintaining a favorable habitat status and continuing noisy activities, in 2020 the UK nature conservation agencies published guidance on how to assess and manage operations that could cause significant noise disturbance in porpoise SACs. The approach provides an equitable way of managing noise across industries, by defining area/time noise limits. The limits are used as references in impact assessments when planning activities, and measures such as noise abatement and scheduling are agreed between industry and regulators to ensure limits are not exceeded. At the core of this approach is the UK Marine Noise Registry, a database recording when and where impulsive noise occurs, for both past and future activities. This not only helps with planning but also allows for retrospective monitoring and has already provided useful insights for management.

## Introduction

A suite of Special Areas of Conservation (SACs) for harbor porpoise were designated in the United Kingdom in 2019, due to the persistent high densities of the species found in those areas. The SACs have been identified based on elevated densities of harbor porpoise in either summer (April–September) or winter (October–March) (Heinänen and Skov 2015), or year-round. The sites are assumed to provide good foraging opportunities, and it is therefore important that porpoise can access and utilize the habitats within the SACs.

Some of these areas were identified despite a certain level of local disturbance by underwater noise. This is particularly so for the Southern North Sea (SNS) SAC, the largest of the SACs, spanning 36,951 $km^2$, having both summer and winter areas and a small year-round area. The SNS SAC is a particularly industrialized and therefore noisy site. There is considerable oil and gas exploration and associated seismic surveys. There is also a need for clearing of unexploded ordnance (UXO) to make the seabed safe for placing infrastructure. Also, the installation of offshore wind and cables has continued to increase in the area (JNCC 2022). There is an emerging conflict between trying to maintain a favorable habitat for the species and persistent and increasing industrial activities. The site is protected for a species sensitive to noise, and therefore the bar must be set higher in these areas.

In 2020, after several years of stakeholder discussion and trial, the UK nature conservation agencies published guidance (JNCC 2020) on how to assess and manage operations that could cause significant noise disturbance in porpoise SACs. The guidance applies to all regulated activities that result in impulsive noise and therefore have the potential to disturb or injure harbor porpoise. It introduces spatial and temporal limits to disturbance from noise within the sites to protect those important habitats for porpoise: (1) a daily limit, where no more than 20% of the site (or seasonal area) is subjected to disturbance in any given day, and (2) a seasonal limit where no more than an average of 10% of the relevant seasonal area of the site is disturbed over a season. The approach provides an equitable way of managing noise across industries and incentivizes less noisy operations and that those be undertaken in the times of the year with lower densities of porpoise. For the purposes of impact assessment and monitoring, the guidance also advises the use of operation-specific disturbance ranges where it is assumed most of the disturbance will occur. In the absence of dose-response curves for each operation and site-specific environmental conditions, an alternative, semiempirical approach is advised based on published evidence of disturbance of harbor porpoise. The largest of those ranges is 26 km for monopile driving noise (without noise abatement) and high-order

**Table 1** Recommended effective deterrence ranges (EDRs) (JNCC 2020)

| Activity | EDR (km) | References in which EDRs were based |
|---|---|---|
| Mono-pile | 26 | Tougaard et al. 2013; Dähne et al. 2013 |
| Mono-pile with noise abatement | 15 | Dahne et al. 2017; Rose et al. 2019 |

| Other geophysical surveys | 5 | Crocker and Fratantonio 2016; Crocker et al. 2019 |

UXO clearance, and the smaller one 5 km is for geophysical surveys involving sub-bottom profilers (Table 1).

The purpose of this chapter is to introduce a noise management approach that is being adopted in a protected area for marine mammals in the UK, and provide examples of its application, both when planning operations inside the SAC and also in terms of retrospective monitoring providing useful insights for management.

## The UK Marine Noise Registry (MNR)

To assist with the management of noise and assess the effectiveness of the spatio-temporal approach, it is essential to monitor the occurrence of noisy events and understand their distribution, patterns, and potential for disturbance. The MNR (https://jncc.gov.uk/our-work/marine-noise-registry/), established in 2015, is a custom-built database where data is collected on activities in UK waters resulting in impulsive noise (frequency 10 Hz–10 kHz) such as seismic surveys, some sub-bottom profiling equipment, impact pile driving, and explosives/ordnance clearance. Data for planned activities is submitted at the time of license applications, and once the activity has taken place, closeout data is submitted within 3 months or less of the activity takes place. For some sub-bottom profiler surveys exempt from the need for a license, this information is reported on a voluntary basis. The data collected refer to the type of activity, and the day it occurred and where, with parameters such as sound levels and frequencies being optional. The MNR's main purpose is to monitor the distribution and intensity of impulsive noise events retrospectively, but from its inception it was also intended that it could be used in the management of noise. The MNR is currently being developed to be able to provide a planning and management tool using the elements in the SAC noise management guidance to help industry and regulators plan and coordinate to not exceed the noise limits advised.

## Planning Noisy Activities Inside a Protected Area

Projects planned within or in the vicinity of an SAC need particularly stringent environmental impact assessments (habitats regulations assessment, HRA) in order to ascertain beyond reasonable doubt whether the planned activities could have an impact on the integrity of the site considering its conservation objectives (https://www.gov.uk/guidance/habitats-regulations-assessments-protecting-a-european-site). One of objectives for harbor porpoise SACs is to avoid significant disturbance of the species within the site. By using the guidance's two elements (the 10/20% limits and the disturbance ranges) in assessments for both projects alone and in combination, developers and regulators can identify "crunch" seasons where those noise limits could be exceeded.

In the SNS SAC, HRAs have identified seasons where limits could be exceeded, for example, when two wind farms were due to construct in the summer of 2021 in the high-density summer seasonal area (https://assets.publishing.service.gov.uk/government/uploads/system/uploads/attachment_data/file/753026/RoC_SNS_cSAC_HRA_5.0.pdf). Both would be using monopiles, and therefore the 26 km buffer was used in the assessment which concluded that the 10% seasonal limit could be exceeded. In this case, rescheduling construction or using noise abatement systems with pile driving would bring the impact to within limits. Another example was in the summer of 2019, when another HRA (https://assets.publishing.service.gov.uk/government/uploads/system/uploads/attachment_data/file/799521/Spectrum_Seismic_Survey_HRA_Rev_1.3.pdf) concluded that both the 20% daily and 10% seasonal limits would be likely exceeded through several operations planned to occur simultaneously. Regulators and industry agreed on a series of measures to avoid that, including that UXO clearance in a single day had to be within 5 km of a central point to contain the noise footprint, also limiting the number of UXOs detonated each day, and delaying part of a seismic survey to the winter, when lower densities of porpoise were to be expected. This ensured that neither limit was exceeded (daily: 7.27%, seasonal average: 1.42%) (JNCC 2022). Since noisy activities are planned to increase in the site in the short to medium term, it will be imperative to use not just scheduling but also less noisy alternatives and noise abatement systems to keep within the limits.

The upgraded UK MNR, currently in development, will help with HRAs, planning, and management by providing a series of functions that will help with exploring disturbance scenarios by calculating activity "noise disturbance footprints" in areas of interest such as SACs, and providing in-combination totals to compare with advised noise limits. In addition, it will provide a coordination hub for industry to upload, share, and see the work programs of others, allowing live communication for scheduling work to avoid exceeding limits. As of 2022, oil and gas and windfarm operators have new license conditions which require them to cooperate and coordinate their activities so as to not occur on the same day, or if they do operate simultaneously, they must evidence that the noise disturbance limits will not be breached.

## Retrospective Monitoring of Noise

The MNR data has been used to retrospectively investigate the prevalence of impulsive noise events in the SNS SAC, to determine impulsive noise distribution in time and space and the contribution of the different activities to the overall disturbance footprint as well as whether advised limits have been exceeded. Data from 2015 to 2020 were extracted from the MNR and imported into GIS for further analyses. Only data from within the SNS SAC and from within a 50 km radius around the SAC (to capture noise events outside the SAC that could potentially cause disturbance inside it) were used. The data stored in the MNR can include geographic information in points (latitude/longitude) or polygons (the oil and gas licensing blocks). The points mostly show the locations where piling or explosives took place and the blocks where geophysical surveys (seismic and sub-bottom profilers) took place. To estimate the area around the noise source potentially affected by noise disturbance, buffers were added according to the activity type and respective Effective Deterrence Range (EDR) as provided in the noise guidance (Fig. 1). The buffer areas were used to calculate:

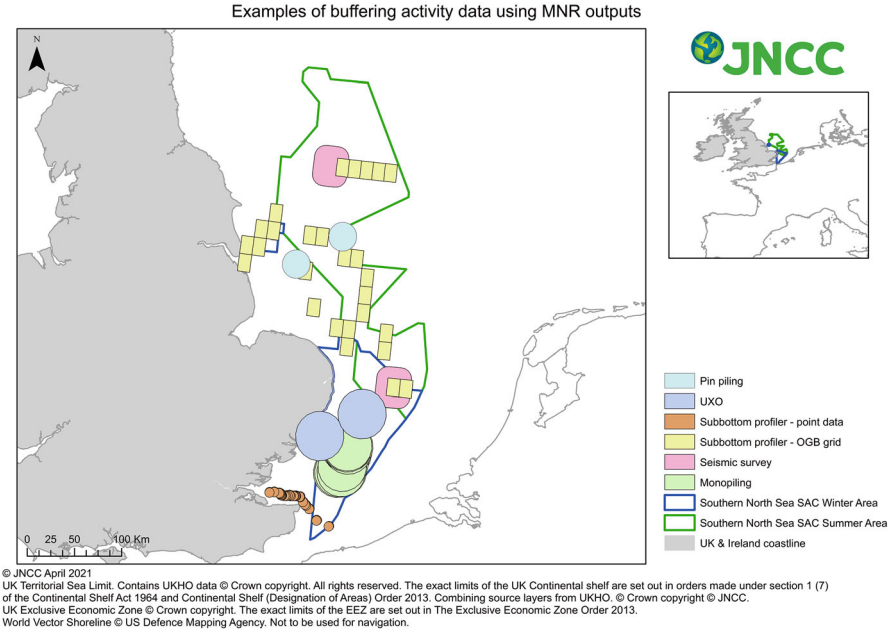

**Fig. 1** Illustration of spatial disturbance footprints for different activities according to EDRs in JNCC (2020). For UXO and mono-piling point locations, the buffer has a 26 km radius. For pin-piling point locations, the buffer has a 15 km radius. For seismic surveys, a 12 km radius buffer was applied around the oil and gas blocks. For sub-bottom profilers, with locations given in oil and gas blocks this was used unbuffered as a proxy for the disturbed area. For sub-bottom profilers' locations given in latitude and longitude, a 5 km radius buffer around the point was used

- Daily disturbed area from all activities combined for each day of each season/year for the relevant seasonal area.
- Seasonal average disturbed area from all activities combined for the relevant seasonal area. For example, a daily footprint of 19% for 95 days would result in an average of 19 × 95/183 days (summer) = 9.86%.

The areas of each buffer overlapping the SAC's summer and winter areas were calculated for activities that occurred in each relevant season (i.e., only winter activities are accounted for in the winter area and the same for the summer area). Plans or projects potentially resulting in noise disturbance in the SAC but operating outside of the season for which the area was identified as having elevated harbor porpoise densities are unlikely to result in significant effects to the site. Since during the "off season" the area is no different in terms of average densities than the rest of the population range, the noise management approach does not apply outside the relevant season (JNCC 2020).

The number of days with impulsive noise events in each season/year period ranged from 2 (winter 2014–2015) to 107 (summer 2018) (Table 2). Seven out of the twelve periods had impulsive noise events in less than 40 days (i.e., less than a quarter of days in a season). Two of the top four periods with the most days with noise were in winter, and two were in summer. The four periods with the lowest number of days were in the winter.

The daily 20% threshold was exceeded on 1 day only, in summer of 2015 (21.01% of the relevant seasonal area). On this day, three geophysical companies were undertaking seismic surveys in the north of the summer area, resulting in a large area potentially disturbed. The second highest daily maximum was recorded on 1 day in winter of 2016–2017 with 19.08%, because of two adjacent mono-piling

**Table 2** Total days with noise and estimated area disturbed for each of the 12 periods (summers and winters from 2015 to 2020) in the respective seasonal SAC area

| Period | Days with noise out of 182 days/winter and 183 days/summer | Maximum daily area disturbed (%) | Seasonal average area disturbed (%) |
|---|---|---|---|
| Winter 2014–2015 | 2 | 9.25 | 0.09 |
| Summer 2015 | 45 | 21.02 | 1.34 |
| Winter 2015–2016 | 0 | 0 | 0 |
| Summer 2016 | 16 | 0.67 | 0.05 |
| Winter 2016–2017 | 83 | 19.08 | 7.38 |
| Summer 2017 | 11 | 5.33 | 0.16 |
| Winter 2017–2018 | 9 | 3.82 | 0.09 |
| Summer 2018[a] | 107 | 10.23 | 1.08 |
| Winter 2018–2019 | 93 | 16.47 | 1.73 |
| Summer 2019 | 93 | 7.27 | 1.42 |
| Winter 2019–2020 | 5 | 10.09 | 0.22 |
| Summer 2020 | 26 | 8.00 | 0.55 |

[a]The figures for Summer 2018 are an underestimate as at the time of this analysis the MNR did not have data on the installation of mono-piles for a large wind farm installed during that summer.

events. This was the season/year period with the highest seasonal percentage, 7.38%, so the seasonal limit of 10% was never exceeded between 2015 and 2020. In both the summer and winter seasons, the maximum daily footprint was due to single activities, mono-piling, and seismic surveys, which due to their large EDRs (26 km and 12 km, respectively) resulted in a large percentage area affected. This shows that on days where mono-piling or seismic activities occur without any noise abatement in place, there is little buffer for other activities to be able to occur without exceeding noise limits, particularly in the winter area which is smaller than the summer area.

Figure 2 shows the contribution of different activities to the estimated area disturbed by noise within the SNS SAC, together with the total number of days in which the activities took place for the relevant season/area for all years combined (2015–2020). It shows that in the summer (summer area), seismic surveys contributed the most to the noise footprint (65.6%, 99 days), with sub-bottom profiler surveys occurring in more days but due to the estimated smaller potential disturbed area contributed less to the total footprint (14.7%, 167 days). UXO clearance using explosives accounted for 19.5% of the total area and occurred in 57 days over the 6 years. As mentioned before, there are several wind farms due to be installed in the SNS SAC's summer area in the next 10 years. If piling campaigns take place in the summer, they will likely account for much of the future disturbance in this area. Scheduling piling, geophysical surveys, and explosives in the "winter" (October to March) in this area will avoid the elevated harbor porpoise densities during the "summer" months and limit disturbance within the SAC. In the winter (winter area), mono-piling contributed the most to the noise footprint (50.8%, 53 days), followed

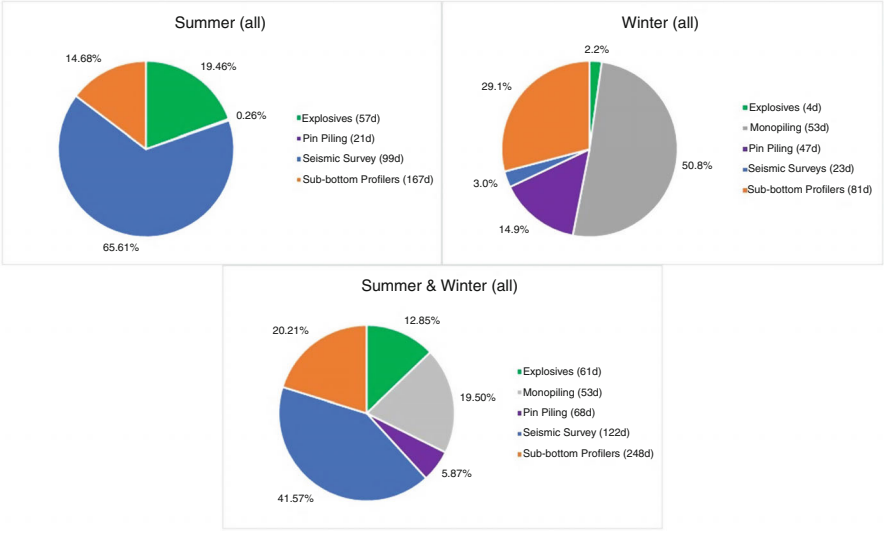

**Fig. 2** The contribution of different activities to the estimated area disturbed by noise within the Southern North Sea SAC (2015–2020). All summers, all winters, and all data combined. Total days of noise per activity also given in brackets

by sub-bottom profilers (29.1%, 81 days) and pin-piling (14.9%, 47 days). It is likely there will be further wind farms being installed in the winter area in the next 10 years, and scheduling piling in the "summer" months (April to September) will avoid the elevated harbor porpoise densities during the "winter" and limit disturbance within the SAC.

While seismic accounted for the largest spatial footprint overall, this is likely an overestimation due to the way the noise is reported in oil and gas blocks rather than survey lines. Sub-bottom profilers had the largest temporal footprint (248 days over the 6 years). This is an underestimate given that many such surveys are not yet licensed and therefore do not necessarily report to the MNR.

## Discussion

For highly industrialized marine areas that contain important habitats for species sensitive to noise, it is a challenge for regulators to keep noise to levels low enough to avoid significant disturbance to species in these areas. In the UK, a new approach advised by nature conservation agencies has been adopted for managing noise inside harbor porpoise SACs. The approach is based on the setting of spatial and temporal limits to regulated activities that result in impulsive noise. The appeal of the approach has been that it applies equally to all industries and helps to standardize cumulative assessments. It is also pragmatic recognizing that porpoise habitats within these sites need to continue to provide those important functions for which they were designated but are also able to cope with a certain level of noise disturbance. The approach is relatively straightforward to interpret and apply, but it relies on good environmental impact assessments, on good regulation and communication, on good reporting, and on monitoring of both noise and harbor porpoise distribution. Initially, there was some resistance by regulators and industry in adopting it since they could see issues in implementation, the potential restrictions to operations, and the incomplete evidence base. But by keeping the approach under scrutiny, monitoring its application, and through good communication between regulators and industry, the approach has kept noise footprints contained in the area. In the UK, different industries are regulated by different departments so for the approach to work, it has also been essential for regulators to communicate with each other, which they have done through a working group that meets regularly (https://assets.publishing.service.gov.uk/government/uploads/system/uploads/attachment_data/file/1114313/SAC_Noise_Management_Regulators_Working_Group_Terms_of_Reference_2022.pdf).

It has been possible to undertake retrospective monitoring of noise inside the SNS SAC, through the data collected via the UK MNR. This has helped to identify spatial and temporal patterns of past activities, and also identify persistent hotspots of noise, information that can help predict future noise scenarios and better plan and regulate future activities. For example, the data showed that seismic surveys account for most of the spatial footprint on the site since they occur mainly in the summer area in the summer, but it is sub-bottom profilers that have the highest temporal footprint. It is

clear also that when there is either monopiling, UXOs, or seismic surveys, the daily noise quota is rapidly reached.

While the advised limits have only been exceeded on 1 day in the 6-year period looked at, it is increasingly likely in the future that the daily or seasonal thresholds could be exceeded in the SNS SAC, with at least ten winds farms, planned in or around the SAC, likely requiring pile-driving and underwater explosive clearance campaigns. This highlights the need for careful planning. In the future, it is likely that in addition to scheduling to avoid large periods of concurrent operations, the use of noise abatement systems such as bubble curtains (Bellmann et al. 2020), alternative methods of turbine installation, and low-order UXO clearance will be needed to ensure that limits are not exceeded and that disturbance in the protected site is kept low.

Data that is routinely reported to the UK MNR on planned activities can be used in disturbance risk assessments, and the new functions currently being implemented in the upgraded MNR will enable the exploration of future disturbance scenarios, which can be used to support assessment, planning, and management.

It is hoped that this noise management approach for use in marine mammal protected areas will, alongside other measures, incentivize industry to employ less noisy alternative operations and technologies and find other ways to reduce their disturbance footprint in time and space. The approach will be reviewed regularly to see if it is working at reducing noise in the sites and if it continues to be based on the best available evidence.

**Abstract**

Injury to marine mammals due to sound from impact piling of the foundations for offshore wind farms has become a significant concern in the UK and worldwide. With increasing pile sizes and hammer energies being proposed for future developments, this concern remains a significant consenting risk.

The use of soft-start (where the initial hammer energy is reduced for a period at the start of piling) and the use of slow-start (where the hammer strike rate is reduced) are common mitigation strategies for reducing the potential for injury to marine mammals in the UK. More recently, the use of Acoustic Deterrent Devices (ADDs) has become commonplace as an additional mitigation strategy for deterring marine mammals from the area where piling will take place.

The range at which injury can occur depends upon numerous different factors, including the source level of sound radiated by the pile into the water column, hammer energy, strike rate, swim-away speed, timings for each phase, and propagation of sound away from the pile. For the mitigation strategy to be most

effective, any near-by animal needs to swim some distance from the pile before full-power piling occurs. However, at present there is no definitive methodology for determining the most effective combination of ADD, soft-start, and slow-start in order to reduce the risk of injury to as low as practicable.

This chapter examines the various factors that affect the efficacy of a combined ADD, slow-start, and soft-start piling mitigation protocols, and makes recommendations as to how to design the most effective mitigation strategy.

Sound · Impact · Injury · Pile driving · Mitigation · ADD · Soft-start

## Introduction

Installation of offshore wind turbine foundations using percussive piling can lead to temporary or permanent threshold shift (TTS/PTS) in marine mammals (NMFS 2018; Southall et al. 2019).

During offshore impulsive pile driving, the early stages of the construction operations are managed to give near-by marine mammals the opportunity to move away from the pile and reduce the potential for injury. This may be via a combination of:

- Acoustic Deterrent Devices (ADDs)
- Slow-Start (low hammer strike rate)
- Soft-Start (operational speed, low hammer energy)

An ADD can be employed to promote flight away from the foundation before potentially harmful peak-sound levels are experienced. Given that animals will experience the greatest proportion of the energy when closest to the pile, hammer strikes early in the pile sequence are designed to be quieter and have a lower contribution to the cumulative effects of sound energy (slow- and soft-starts). The intended combined effect of these mitigation protocols is that any near-by marine mammals could move away from the sound source at a rate such that the increasing transmission loss offsets the increasing hammer energy, reducing the potential for injury.

The dual injury thresholds set out in Southall et al. (2019) include both unweighted peak-sound pressure level and cumulative (marine mammal hearing weighted) sound exposure level (SEL) metrics. Mitigation strategies therefore need to account for both instantaneous injury (as reflected by the peak threshold) and cumulative SEL over the entire pile installation period. While it is relatively straightforward to determine the required mitigation for instantaneous injury (by estimating the radius over which the peak threshold is exceeded), the specification of mitigation using cumulative SEL is more complex.

The effects of the ADD duration, and the strike rate/blow-count of the slow- and soft-start periods can be chosen to minimize the impact region. This can then assist with suggestions for an effective mitigation strategy.

## Outline of Methodology

There are numerous factors which can affect the calculated injury range for a marine mammal including:

- source sound level and frequency spectrum;
- site-specific propagation losses;
- hammer strike rate (in each phase of piling);
- slow- and soft-start durations;
- hammer energy reductions during soft- and slow-start;
- species group hearing weighting;
- swim speed and direction.

In order to focus on the objective of investigating the mitigation strategy, it has been necessary to focus on those parameters which are of most interest to this study. Because low-frequency (LF) cetaceans are often predicted to experience the largest PTS zones in recent noise modelling studies for piling (based on cumulative SEL), compared to high-frequency (HF) cetaceans which typically experience the largest instantaneous peak-sound pressure threshold, the LF-cetacean hearing group was chosen as a focus for the noise modelling. Likewise, since the swim speed and direction of travel of a marine mammal is not within the control of the developer, the study has removed the swim-away speed from the parameters investigated, although it is worth noting that the value chosen will have a significant effect on the calculated PTS range. Likewise, the starting range (prior to ADD activation) is also an important parameter on the cumulative exposure but is outside the control of the developer.

The range at which the Southall et al.'s (2019) PTS threshold for LF cetaceans was estimated based on simple, empirical propagation modelling. The various input parameters were then varied as described in Section 55 in order to provide a large dataset of predicted PTS ranges. This dataset was then used as an input to a statistical analysis model to determine the relationship and significance of the various input parameters to the PTS range.

Numerous simplifications were made in the study, and it is important to understand that the real-world piling scenarios will be much more complex. Examples of simplifications made include a constant hammer energy during each phase of piling, no ramp up of energy, marine mammals swimming directly away from piling for the entire duration, and simplified propagation modelling.

## Definition of Parameters

Sets of parameters for swim speeds and pile-driving schedules were taken as pseudo-random combinations of timing (e.g., ADD duration) and piling properties (e.g., strike rate). Each set of parameters, or *experiment*, was then passed to a simple exposure model to give a PTS range for LF cetaceans. The input parameters and their distributions across 125,000 of these experiments are shown in Fig. 1. Note that some of the parameter configurations were removed from the analysis, such as when the total piling duration was shorter than the combined slow-start and soft-start durations. Also, the strike rate and energy were set to zero when there was no soft-/slow-start duration, hence the deviation from the uniform distribution in the below histograms.

The full list of input parameters investigated is as follows:

- ADD activation duration;
- Total piling duration;
- Hammer strike rate at full-power piling;
- Duration of slow- and soft-start periods;
- Hammer strike rate and hammer energy during slow- and soft-start periods; and
- Percentage of the full-power hammer energy used for slow- and soft-start.

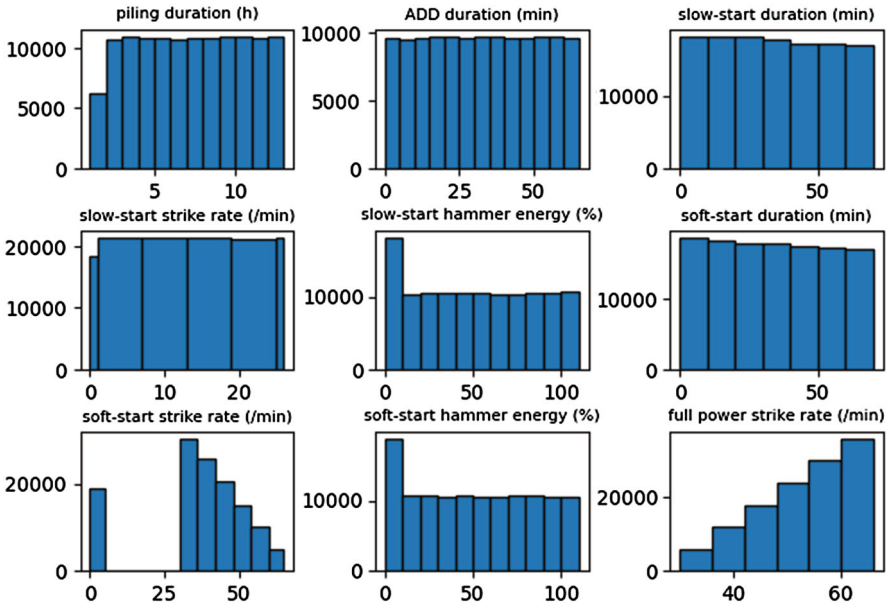

**Fig. 1** Parameter spread of model inputs used in the analysis (125,000 experiments)

The experiment parameters were used to form a complete hammer schedule for each experiment: a series of strike times (in seconds after the first strike or, if used, ADD); and pile-driving source levels (increasing after the slow- and soft- start).

The cumulative sound exposure level was calculated for a moving marine mammal starting at a given distance by finding the distance travelled at the time of each strike (accounting for an assumed LF-cetacean swim-away speed of 2.3 m/s) and taking the sum of all the received single strike SELs based on the equivalent monopole source level and an estimated propagation loss. The sound propagation loss is taken from a simple empirical logarithmic-loss equation

$$RL = SL - A\,\log(r) - \alpha\, r - B,$$

where $r$ is the range from the piling foundation in meters, and the constants $A$ , $B$, and $\alpha$ are taken from representative results of sound propagation modelling of pile driving accounting for LF-cetacean hearing sensitivities, taken here as $A = 16.0$, $B = 3.0$, $\alpha = 0.00012$. In the equation, $SL$ denotes the source level and $RL$ the received level.

In order to model the period of ADD usage, the starting distance of the marine mammal from the pile includes a distance equivalent to the ADD duration multiplied by the swim speed. Sound from the ADD is assumed not to have a significant contribution to the sound exposure, based on the findings of Boisseau et al. (2021).

The above steps describe the process of taking a starting distance and calculating the sound exposure level (for a given set of model experiment parameters). It is relatively simple to use a root-finding algorithm on this process to find the starting distance which corresponds to a specific sound exposure level; in particular, the threshold range for and permanent threshold shift (PTS) in LF cetaceans can be derived using the PTS onset metric from Southall et al. (2019).

## Analysis

For each selected source level, approximately 125,000 different hammer schedules were produced. These were analyzed using the R package *relaimpo*, which calculates the relative importance of each metric toward a total $R^2$ value, which represents the proportion of variance that is explained by the model. The fit to the model was overall strong and increased with source level up to 227.5 dB re 1 $\mu Pa^2s$ re 1 m and then reduces (Table 1).

Because the relative importance of the combined mitigation time is so much greater than the other variables, and since they represent the same unit, these were totaled and a single regression for each source level was plotted. The linear regression model for each sound exposure level was used to estimate the overall mitigation time required. Using the rearranged equations from the regression plots (example can be seen in Fig. 2), the total mitigation time is calculated to maintain an impact radii of 500 m. This distance was chosen since the Joint Nature Conservation

**Table 1** Relative importance of controllable variables to the impact ranges of low-frequency cetaceans

| | Source sound exposure level (dB re 1μPa$^2$s re 1 m) | | | | | |
|---|---|---|---|---|---|---|
| | 220 | 222.5 | 225 | 227.5 | 230 | 235 |
| **Overall model fit ($R^2$)** | 94.1% | 96.1% | 97.3% | 99.5% | 99.3% | 98.6% |
| | **Relative importance ($R^2$)** | | | | | |
| **Piling Duration** | 0.01% | 0.02% | 0.04% | 0.1% | 0.3% | 1.5% |
| **ADD Duration** | 29.4% | 32.6% | 33.6% | 33.0% | 32.4% | 31.7% |
| **Slow-Start Duration** | 30.8% | 30.1% | 30.7% | 31.7% | 31.5% | 30.6% |
| **Slow-Start Strike Rate** | 2.0% | 1.8% | 1.1% | 1.1% | 1.1% | 1.1% |
| **Slow-Start Hammer Energy** | 3.0% | 2.6% | 1.8% | 1.7% | 1.7% | 1.7% |
| **Soft-Start Duration** | 22.2% | 23.4% | 24.8% | 26.6% | 26.8% | 26.4% |
| **Soft-Start Strike Rate** | 4.4% | 3.8% | 3.9% | 3.7% | 3.6% | 3.5% |
| **Soft-Start Hammer Energy** | 2.0% | 1.6% | 1.2% | 1.2% | 1.2% | 1.2% |
| **Full-Power Strike Rate** | 0.2% | 0.3% | 0.3% | 0.5% | 0.6% | 1.0% |

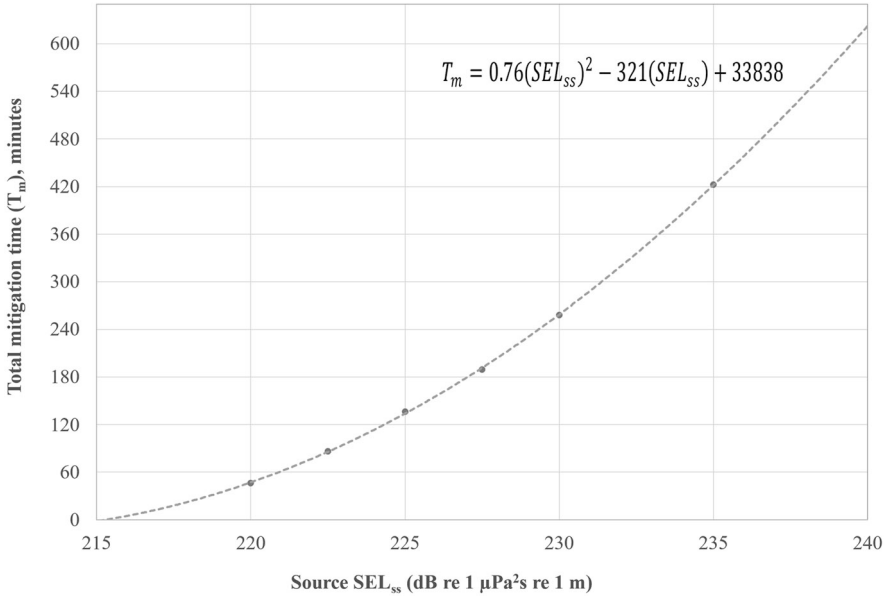

**Fig. 2** Modelled mitigation time for different source $SEL_{ss}$ levels, with polynomial regression applied

Committee (JNCC) will stipulate that the area within 500 m of the sound source must be clear of marine mammals prior to the commencement of activity (JNCC 2010). The area will be monitored by dedicated marine mammal observers (MMOs) and often complimented with passive acoustic monitoring (PAM) prior to commencement of piling. The analysis shown in Table 2 shows that there is an increase in overall delay as the source $SEL_{ss}$ is increased to maintain a mitigation zone of 500 m.

**Table 2** Modelled delay duration to restrict marine mammal PTS due to cumulative effect to 500 m

| Source SEL, dB re 1μPa$^2$s re 1 m | Total mitigation time, Minutes[a] |
|---|---|
| 220.0 | 46 |
| 222.5 | 86 |
| 225.0 | 136 |
| 230.0 | 258 |
| 227.5 | 190 |
| 235.0 | 422 |

[a]These mitigation times are examples for this specific modelling case and input parameters

When the total mitigation time is plotted against the unweighted source $SEL_{ss}$ it is possible to fit a polynomial model very closely to the data ($R^2 \sim 99.99\%$). The model predicts that if source sound level reaches 240 dB re 1 μPa$^2$s re 1 m or more, the total mitigation time required to maintain a 500 m radius PTS zone would be greater than 10 h. Such a mitigation time would be an impractical and expensive burden on the developer. In any case, these mitigation measures assume a behavioral response of a marine mammal which, if the animal is assumed to be swimming at 2.3 m/s for 10 h, by this point would be 83 km from the source (and therefore may not continue to flee from the sound source). Consequently, it is concluded that it is unlikely that use of ADD, soft-start, and slow-start combined can practically mitigate sound from these high sound levels sufficiently to avoid PTS to LF cetaceans outside the 500-m mitigation zone.

## Conclusions

The majority of piling in the UK to date has utilized mitigations such as ADDs, soft-, and slow-start methodologies, combined with a mitigation zone monitored by MMOs and PAM, as the primary means of minimizing the potential for PTS to marine mammals.

Based on the results of the modelling and data analysis, the total length of the mitigation sequence (i.e., the total time of ADD activation, soft-start and slow-start combined) is the most important factor with all three mitigation measures being of similar effectiveness. The analysis shows that the exact parameters used for each phase of mitigation are less important than the total mitigation time, although by fine-tuning these parameters the PTS zone can be further reduced once the total mitigation time has been defined. It should be noted that some variables are closely tied, and despite the apparent low $R^2$ value, should not be ignored (e.g., soft-start hammer energy).

It can be seen in Table 1 that the strike rates during the slow- and soft-start periods are higher contributors to the total importance than, for example, the energy reductions. However, the strike rates show greater contributions to the total for the lower full-power hammer energies than the higher, with the percentages steadily reducing as the energy is increased. It is therefore evident that although the strike rate is an

important factor to consider during the slow- and soft-start periods, it is more useful for reducing the impact to marine mammals for hammers with lower maximum sound levels.

For pile driving with a higher source level, the analysis shows that the required total mitigation time may make the use of ADD, soft-start, and slow-start alone impracticable. Therefore, the trend for larger piles and higher energy hammers means that it is more likely that physical sound reduction methods will be required instead of, or in addition to, these other measures.

Finally, it is worth reiterating that the analysis presented in this chapter is based on a simplistic spreading model and simplified input assumptions. Consequently, while the general findings might be useful in informing an approach to mitigation, the precise relationships in the chapter will not be directly transferable to specific projects.

(Enhancing Cetacean Habitat and Observation) Program that has initiated voluntary, seasonal vessel slowdowns since 2017. ECHO's goal is to reduce the acoustic disturbance of commercial shipping on endangered whales, whose critical habitat coincides with major shipping routes. This initiative requires the cooperation of many stakeholders, and it is therefore imperative that acoustic monitoring along shipping routes suitably evaluates the effectiveness of such mitigation measures. However, doing so is not straightforward, as levels of ambient noise fluctuate not just in response to vessel slowdowns but also with confounding noise sources of environmental, biological, or anthropogenic origin (e.g., noise from currents, wind, marine mammals, small boats, etc.). Here, methods are presented for how to appropriately compare noise levels during baseline and mitigation periods, using data from one acoustic monitoring station as an example. Factors to consider when evaluating the effectiveness of mitigation measures are highlighted, including investigating suitable covariates and thresholds of these, both of which may vary between sites and seasonally at the same site. Useful ways of communicating results to a variety of stakeholders are also presented.

## Introduction

The acoustic signature of shipping significantly contributes to ambient noise levels in the ocean (Hildebrand 2009). Shipping noise is broadband, can extend to echolocation frequencies (Veirs et al. 2016), and can be of high level (with broadband-radiated noise levels sometimes exceeding 200 dB re 1 μPa at 1 m; MacGillivray et al. 2019). Such noise pollution impacts marine life (such as marine mammals, fish, and invertebrates) by masking communication, disrupting foraging and traveling behaviors, causing habitat displacement, and increasing physiological stress (e.g., Nowacek et al. 2007; Duarte et al. 2021). As such, there is interest in mitigation measures to reduce levels of underwater-radiated noise from vessels. Such levels are positively correlated with vessel speed, leading to proposals that noise may be mitigated by lowering vessel speed (McKenna et al. 2012; Veirs et al. 2016). Indeed, initial vessel slowdown initiatives near Vancouver, Canada (e.g., MacGillivray et al. 2019; Grooms et al. 2022), and in the Santa Barbara Channel off California, USA (ZoBell et al. 2021), have demonstrated just this. Modeling explorations into other regions, such as the Canadian Arctic, have also demonstrated the soundscape benefits of vessel slowdowns (Pine et al. 2018). As reducing source levels reduces the spatial extent of affected habitat (Risch et al. 2021), not only do vessel speed reductions reduce the extent to which acoustic space is affected by marine traffic (MacGillivray et al. 2021) and decrease acoustic masking space (Putland et al. 2018), but they also compliment other conservation issues via the co-benefits of

reducing the risk of vessel strikes on whales and lowering greenhouse gas emissions (Ebdon et al. 2020; Leaper 2019; Rockwood et al. 2020).

An example implementation of a vessel speed reduction initiative, led by the Vancouver Fraser Port Authority, is the ECHO (Enhancing Cetacean Habitat and Observation) Program in British Columbia, Canada. This program has encouraged voluntary, seasonal vessel slowdowns since 2017, into and out of Canada's largest port. ECHO's goal is to reduce threats to at-risk whales from commercial shipping, notably the acoustic disturbance on the endangered Southern Resident killer whale (*Orcinus orca*; SRKW), whose critical habitat coincides with major shipping routes (Cominelli et al. 2018). SRKWs are listed as endangered and protected under Canada's Species at Risk Act (SARA) and the United States' Endangered Species Act (ESA). Both Canadian and American governments recognize vessel noise as a threat to the survival of the of SRKW population of only ~73 individuals (Centre for Whale Research 2022; Fisheries and Oceans Canada 2018; National Marine Fisheries Service 2008), alongside chemical pollution (e.g., Desforges et al. 2018) and shortages in prey availability (e.g., Williams et al. 2021). However, unlike mitigating contaminant loads or efforts to manage prey resources, mitigating underwater noise levels and disturbance is an immediate way to facilitate the recovery of the SRKW (Lacy et al. 2017; Burnham et al. 2021).

Previous studies specific to the SRKW have shown that vessel traffic disrupts foraging behavior (Lusseau et al. 2009), that the probability of successful prey capture decreases with increasing vessel speed (Holt et al. 2021), and that high noise levels reduce their probability of foraging in the first place (Williams et al. 2021). Modeling work connecting the ECHO slowdown with SRKW bioenergetics predicted that the voluntary slowdown led to a 22% reduction in "potential lost foraging time" (Joy et al. 2019); this value changed to a 40% reduction in potential lost foraging time when the model was set to a 100% participation rate of vessels travelling under 11 knots. Even though slower vessel speeds mean that vessel transits are of greater duration and vessels are in critical habitat for longer, underwater noise levels are still lower, leading to vessel slowdowns being discussed as an effective way to improve SRKW habitat quality (Joy et al. 2019).

During seasonal ECHO slowdowns, vessels are encouraged to travel at either $<$11 knots (bulkers, tankers) or $<$14.5 knots (containers, cruise ships, car carriers). Slowdown behavior is encouraged in Haro Strait and Boundary Pass (Fig. 1), which vessels pass through as they enter and exit the Port of Vancouver, and has, in recent years, extended to include a slowdown at Swiftsure Bank (Burnham et al. 2021). A related incentive is that vessels that hold a quiet ship notation from an international ship classification society are rewarded with reduced harbor dues at the Port of Vancouver (Vancouver Fraser Port Authority 2022a). The 90% participation rate of the ECHO slowdown period in 2021 in Haro Strait and Boundary Pass (Vancouver Fraser Port Authority 2022b) is aided by cooperation with the British Columbia Coast Pilots Ltd. and the Pacific Pilotage Authority – a similar combination also increased vessel slowdown participation in the Saguenay-St. Lawrence Marine Park (Parrott et al. 2016).

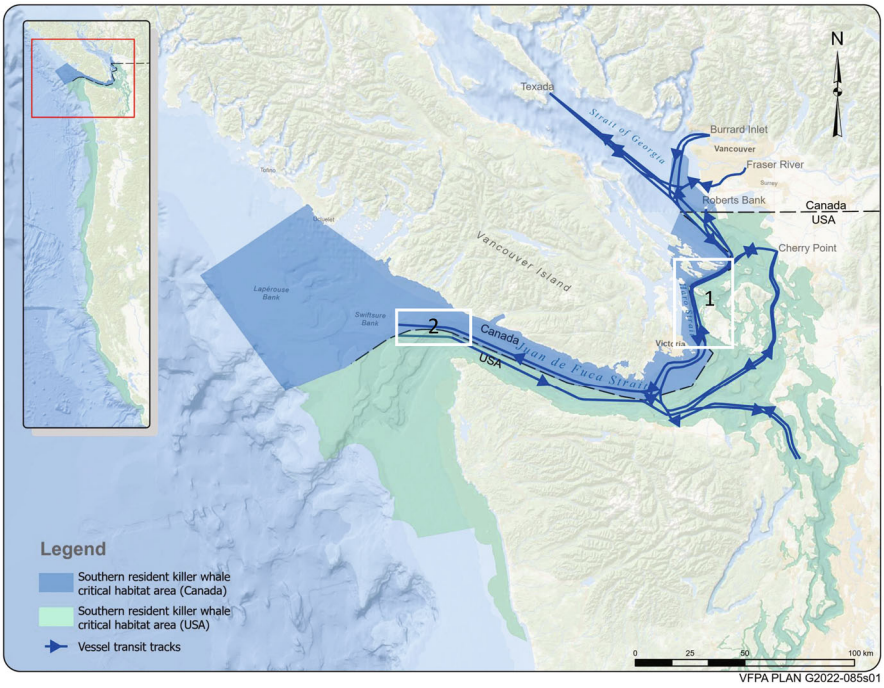

**Fig. 1** Map of shipping lanes into Vancouver and Seattle, alongside the ECHO Program slowdown areas in Haro Strait and Boundary Pass (area 1 in box) and Swiftsure Bank (area 2 box). The dark blue area denotes SRKW critical habitat in Canadian waters, and the green denotes SRKW critical habitat in US waters. (Map modified from Vancouver Fraser Port Authority Plan G2022-085s01, with permission from the Vancouver Fraser Port Authority)

As the ECHO Program is a collaborative effort that requires the cooperation of many stakeholders, from vessel owners and operators to pilotage and port authorities, it is imperative that acoustic monitoring along shipping routes appropriately evaluates the effectiveness of such mitigation measures (MacGillivray et al. 2019). In this chapter, the acoustic data from the 2021 ECHO Program slowdown season (Grooms et al. 2022; VFPA 2022b) are used as a case study with which to explore and evaluate how noise mitigation efforts are evaluated. Annual reports detailing acoustic findings for each ECHO slowdown season are freely available online (https://www.portvancouver.com/echo) and consistently show that broadband (10 Hz–100 kHz) noise levels are reduced by ~3 dB when slowdowns are in place. In other words, a ~ 50% reduction in underwater sound intensity has been consistently achieved through the ECHO Program's seasonal underwater noise reduction initiative. The focus here is not to present these results again but instead to explore how sensitive our approach to evaluating noise mitigation is to natural soundscape variation and different noise filtration criteria metrics. Below, results from several scenarios are presented for how the acoustic data are handled and how this impacts the interpretation of noise mitigation effectiveness.

## Methods

The seasonal ECHO slowdown aligns with historical peak SRKW presence, and the slowdown dates vary annually as they are initiated by the first SRKW sighting on or after June 1, and running until (usually) Oct 31. The ECHO 2021 season consisted of a 2-month baseline (May–Jun 2021) leading up to the start of the slowdown, followed by a 4-month slowdown period (Jul–Oct 2021). Due to animal presence, there was an extension of the slowdown effort into November 2021 (see Grooms et al. 2022); however the extension period was evaluated separately and is not included in this chapter.

Ambient noise was measured at cabled underwater acoustic listening stations along the slowdown route. SMRU Consulting monitors acoustics from Lime Kiln, on San Juan Island, on the east side of Haro Strait, and JASCO Applied Sciences monitors acoustics from Boundary Pass. For details on the locations, depths, acoustic recording settings, etc., refer to Grooms et al. (2022). The ECHO 2021 baseline and slowdown data from Lime Kiln are here used as an example dataset with which to explore various noise filtration metrics used to exclude periods with confounding noise.

## Thresholds and Filtering for Acoustic Data Inclusion

To robustly measure the probability of noise exceeding a given level in baseline versus slowdown conditions, periods of confounding noise need to be excluded from the analyses. This is to ensure that any differences in the noise levels of baseline and slowdown periods arise from the slowdown behavior of participating vessels. In other words, periods with elevated noise levels due to factors external to the vessel slowdown (e.g., nearby speedboats, strong winds, etc.) need to be excluded from acoustic analyses evaluating the effectiveness of the noise mitigation measure. Similarly, periods with low noise levels due to factors external to the vessel slowdown (e.g., when there are no vessels nearby) also need to be excluded.

To identify periods with confounding noise, thresholds were set for measured variables that had correlations to noise levels. Specifically, criteria for inclusion of data collected at Lime Kiln are detailed below.

### Excluding Periods When Participant Vessels Are Absent

Acoustic data were included in analyses when potential vessel slowdown participants were within 6 km of the hydrophone at Lime Kiln. This criterion excluded periods that were quiet, but where this quietness was unrelated to vessels participating in the slowdown. The effect of a slowdown on ambient sound levels can only be measured when the vessels that are potentially slowing down are present, otherwise the data could be skewed by differing amounts of low-amplitude noise levels. Six kilometers was selected as the typical range at which potential slowdown vessels can be heard by human analysists and at which acoustic vessel detectors are triggered.

### Only Including Periods when Potential Participant Vessel Is the Closest AIS Vessel

Acoustic data were included in analyses when potential vessel slowdown participants were the nearest of all automatic identification system (AIS)-broadcasting vessels to the hydrophone and therefore dominating the received noise field. In other words, data were included only when the closest AIS-broadcasting vessel was the potential participant. This was to ensure that noise measurements at Lime Kiln were driven by a potentially participating vessel and not another vessel type, such as recreational boats.

### Excluding Periods with Noise Unrelated to Slowdown Behavior

Acoustic data were included in analyses when an automated acoustic detector did not flag the presence of a small, non-AIS-broadcasting boat. (For details of this acoustic detector, including thresholds at different frequency bands, see Grooms et al. (2022)). This criterion excluded periods that were noisy, but whereby this noise was unrelated to the slowdown behavior of potentially participating vessels.

Acoustic data were included in analyses when wind speed measurements from a weather station located near the underwater acoustic recording station was $<|5$ m/s|. This criterion excluded periods where elevated noise levels were independent of slowdown participation.

Finally, acoustic data were included in analyses when water current speed readings from a near-seafloor current meter co-located with the underwater acoustic recording station were $<|25$ cm/s|. Again, this criterion excluded periods where elevated noise levels were independent of slowdown participation.

Both the wind speed and current speed threshold levels were set by exploring correlations between 1-min SPLs (dB re 1 μPa) in a lower decadal frequency band (10–100 Hz) as a function of current speed, as in Eickmeier et al. (2021). Sound pressure levels (SPLs) tend to have an obvious positive correlation after a particular current/wind speed is reached, and it is this value which Eickmeier et al. (2021) suggest choosing as a threshold level, beyond which data are excluded from noise analyses evaluating noise mitigation measures. Below, SPLs are plotted as a function of both wind speed and current speed, demonstrating how thresholds were selected for acoustic analyses at Lime Kiln (Figs. 2 and 3).

Note that particular thresholds for environmental covariates are site-specific and varied even between nearby Lime Kiln (current speed threshold at 0.25 m/s) and Boundary Pass (current speed threshold at 0.5 m/s) along the ECHO slowdown route (Grooms et al. 2022). Exploring these correlations is encouraged to be site-specific if possible, as soundscapes can vary on small spatial scales.

It is worth noting that the majority of acoustic data is excluded from evaluating the noise mitigation effectiveness. This is because not all the inclusion criteria are being met, whereby thresholds or criteria detailed above are exceeded. In the ECHO 2021 slowdown season, only 7.4% of the available acoustic data were retained for assessing the baseline period, and 10.8% of available acoustic data were retained for assessing the slowdown period (Grooms et al. 2022). It is worth noting that the

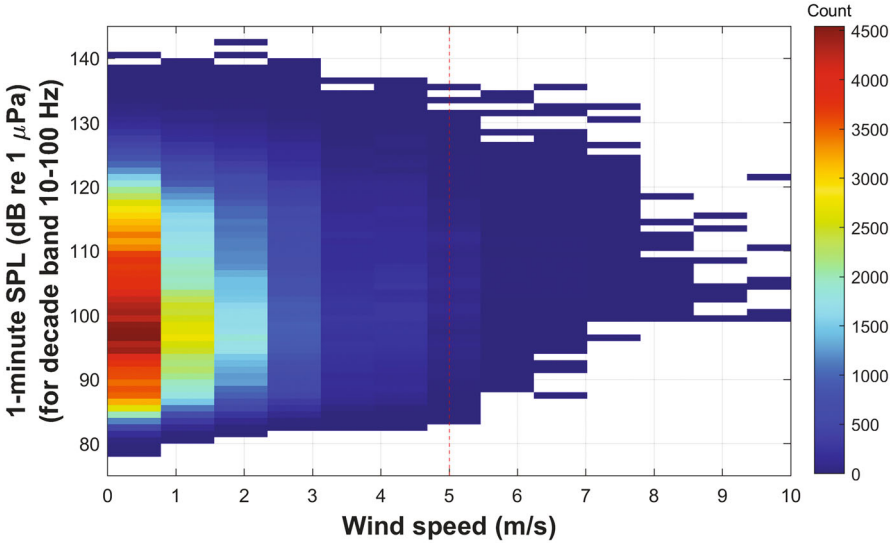

**Fig. 2** Sound pressure levels (1-min averaged SPLs in decade band 10–100 Hz, in dB re 1 μPa) as a function of wind speed (m/s) at Lime Kiln. A threshold value of |5 m/s| was used, beneath which acoustic data were included in noise mitigation analyses. (Data shown cover acoustic and wind data collected for the entire duration of the 2021 baseline and slowdown periods)

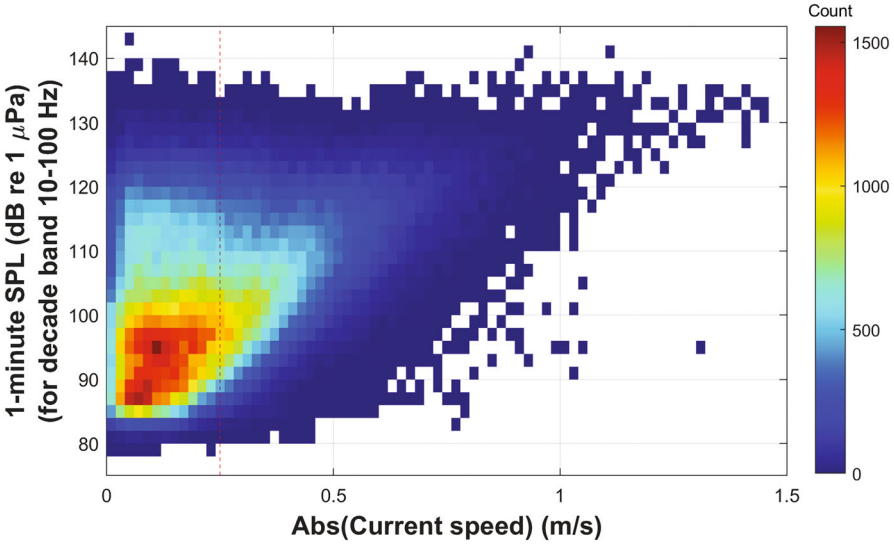

**Fig. 3** Sound pressure levels (1-min averaged SPLs in decade band 10–100 Hz, in dB re 1 μPa) as a function of current speed (m/s) at Lime Kiln. A threshold value of |0.25 m/s| was used, beneath which acoustic data were included in noise mitigation analyses. (Data shown cover acoustic and current data collected for the entire duration of the 2021 baseline and slowdown periods)

majority of data exclusion is due to quiet times between passes of large commercial vessels (slowdown participants). It is from these sub-selections of data – where periods with confounding noise or quiet have been removed – that the noise mitigation evaluation is based on.

## Example Dissemination

In the past years of ECHO reporting (e.g., Grooms et al. 2022), overall results have been presented in the form of cumulative distribution function (CDF) plots. Here, the curves show the probability that a 1-minute averaged sound pressure level is exceeded, in the specified frequency range. CDF plots were created for each decadal frequency band (10–100 Hz, 100–1000 Hz, 1–10 kHz, and 10–100 kHz), broadband (10 Hz–100 kHz), as well as in frequency bands relevant for SRKW communication (500 Hz–15 kHz) and echolocation (15–100 kHz) (Heise et al. 2017). Here, the focus is on a CDF plot for the broadband frequency range, as included in the final ECHO 2021 slowdown evaluation report (Fig. 4).

CDF plots provide a helpful way of simply disseminating slowdown evaluation results, making them more readily interpretable by a wider audience. In particular, such a plot allows for the evaluation of noise mitigation to be relayed as one number,

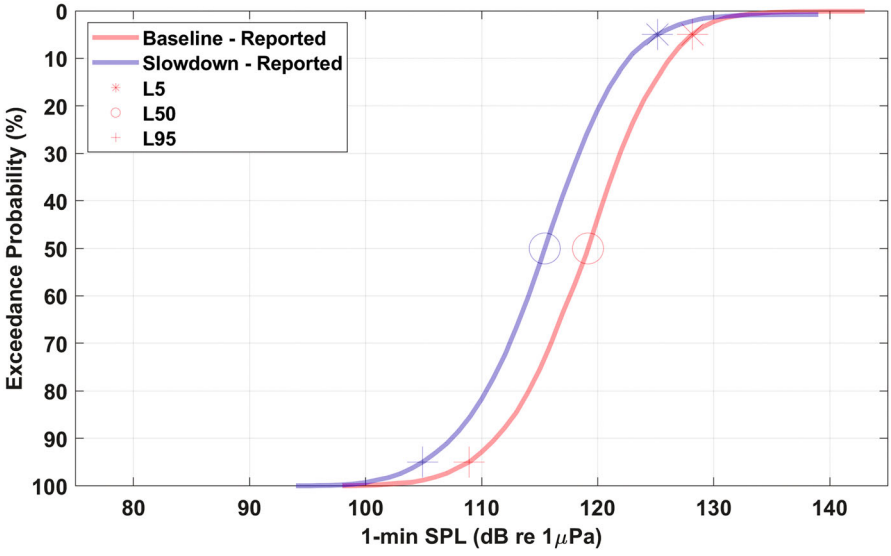

**Fig. 4** Example CDF plot, as reported for ECHO 2021 data, showing the cumulative distribution function for broadband acoustic data (10 Hz–100 kHz) at Lime Kiln, calculated using ECHO 2021 baseline and slowdown data. The baseline $L_{50}$ was 119.2 dB re 1 µPa, and the slowdown $L_{50}$ was 115.5 dB re 1 µPa, leading to a broadband $\Delta L_{50}$ of 3.7 dB. $L_{50}$ values are circled, $L_5$ values are denoted with an asterisk, and $L_{95}$ values are shown with a plus sign

while allowing concurrent graphical evaluation of other metrics. One can focus on the $L_{50}$ value, for example, which here is the median broadband SPL. In other words, the SPL value corresponding to the $L_{50}$ indicates that this value would be exceeded 50% of the time. Similarly, the $L_{95}$ value indicates where broadband ambient noise levels are exceeded 95% of the time, and the $L_5$ value indicates where broadband ambient noise levels are exceeded 5% of the time. The $L_{50}$ exceedance level is commonly used when comparing noise levels (e.g., Merchant et al. 2012). Here, the $L_{50}$ during baseline conditions was 119.2 dB re 1 μPa, and during the slowdown, the $L_{50}$ decreased to 115.5 dB re 1 μPa (Fig. 4). This visualization readily shows how median broadband SPLs were lower during seasonal slowdowns. The "one number" useful for dissemination is the difference between the $L_{50}$ values during periods where vessels acted as normal and periods where vessels were encouraged to slow down, leading to a $\Delta L_{50}$ of 3.7 dB and a concluding remark that median broadband noise levels had a reduction in underwater sound intensity by ~50% when vessels were encouraged to slow down.

## Modifying Filtration Metrics

To examine how appropriate and/or necessary the thresholds and metrics for acoustic data to be included in noise mitigation evaluations, variations on these thresholds were explored using the dataset from Lime Kiln. These included asking the following:

1. What if no data were excluded, and instead, all available acoustic data were used to compare noise levels during baseline and slowdown periods (i.e., including all data)?
2. What if only times with confounding quiet periods were excluded from noise mitigation evaluations (i.e., including all data, except data where AIS >6 km)?
3. What if, instead, only times with confounding quiet and confounding noisy periods from noise mitigation evaluations were removed? In other words, acoustic data can remain in the analysis regardless of current speed or wind speed (i.e., including all data, except data where AIS >6 km and data with acoustic detections of small boat presence).
4. What if the durations of baseline and slowdown periods become more equal (i.e., using only data that pass all inclusion criteria and drawing from a slowdown period that is reduced so that it is the same duration as the baseline period)?
5. How much data are needed for comparisons between baseline and slowdown periods to be robust (i.e., using only data that pass all inclusion criteria and drawing from smaller and smaller slowdown and baseline durations)?

The results of these variations are presented below, in terms of the effect on median $L_{50}$ differences, with the question numbers above corresponding to the subsections in section "Results."

## Results

### Findings If No Data Are Filtered

Using all available data in the CDF analysis meant that the acoustic analyses used to evaluate whether the noise mitigation was effective included all possible confounding covariates, and this skewed the results derived from the CDF plots. This skew is evident in Fig. 5, where the curves for baseline and slowdown periods have shifted to the left (relative to the final reported values shown for broadband noise in Fig. 4 and shown in Fig. 5 in muted tones) because several instances of confounding quiet times have been purposefully included (for the sake of example). While several instances of confounding noisy times are also included, the shift of the curves to the left indicates that it is the inclusion of the confounding quiet times that has a more predominant effect on the overall result due to there being more total minutes where potential participants were >6 km of the hydrophone at Lime Kiln than ≤6 km of Lime Kiln. The crossing pattern of the unfiltered baseline and slowdown CDF curves hints that this strategy of no filtration is too unstable to draw conclusions from. Nevertheless, the $\Delta L_{50}$ of 0.7 dB under this scenario leads to the conclusion that unfiltered slowdown is slightly quieter than the unfiltered baseline.

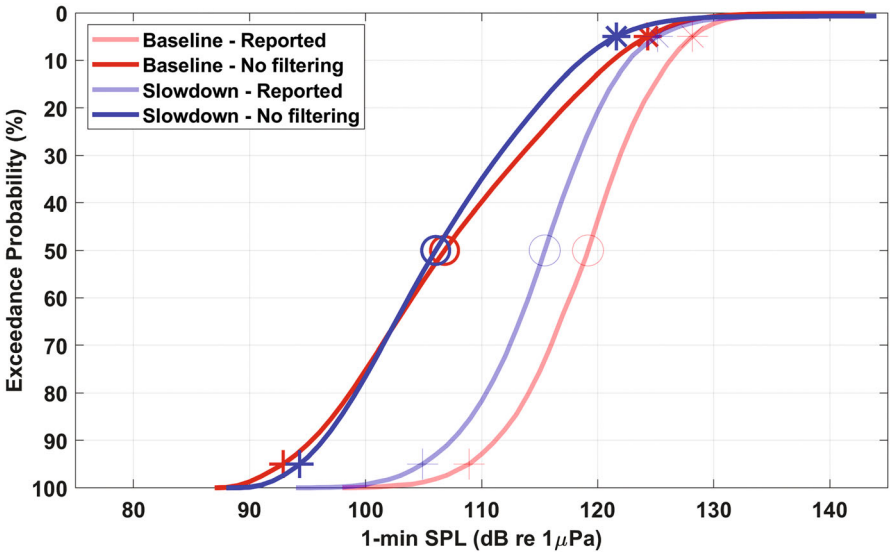

**Fig. 5** CDF plot on all available acoustic data (i.e., no data have been excluded for the noise mitigation evaluation), showing the cumulative distribution function for broadband acoustic data (10 Hz–100 kHz) at Lime Kiln, calculated using ECHO 2021 baseline and slowdown data (bright lines). The original CDF curves presented in Fig. 4 (as reported by the ECHO Program) are shown in muted tones. $L_{50}$ values are circled, $L_5$ values are denoted with an asterisk, and $L_{95}$ values are shown with a plus sign

## Findings If Only Confounding Quiet Times Are Removed

Following on from the finding that including all acoustic data from Lime Kiln in the noise mitigation evaluation skewed the cumulative distribution functions to the left, the results were then explored for a scenario where only the exclusion of confounding quiet periods was applied (Fig. 6). In other words, all periods with confounding noise (from small boats, from high current speeds and high wind speeds) were still included in the analysis. Here, the resulting $\Delta L_{50}$ of 3.4 dB in this scenario leads to the conclusion that partially filtered slowdown is quieter than the partially filtered baseline, though this result is not far from the final reported $\Delta L_{50}$ of 3.7 dB (Fig. 4).

## Findings If Only Confounding Quiet and Confounding Noisy Times Are Removed

Following on from the finding that excluding only confounding quiet periods from the noise mitigation evaluation at Lime Kiln yielded a $\Delta L_{50}$ of 3.4 dB (Fig. 6), the results were then explored for when the exclusion of periods with confounding noisy periods due to the presence of small boats was also applied (Fig. 7). In other words, periods where the automated small boat noise detector flagged the presence of a

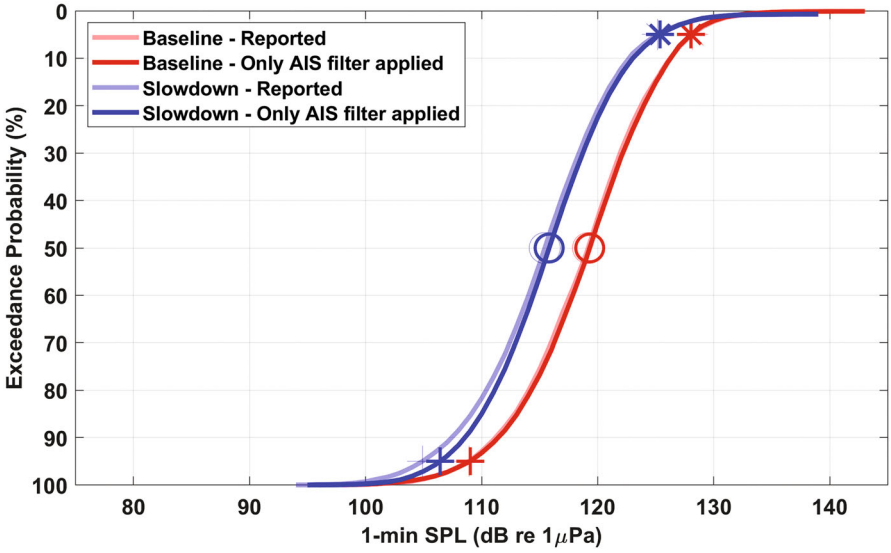

**Fig. 6** CDF plot when the only exclusion criteria was to remove confounding quiet periods, showing the cumulative distribution function for broadband acoustic data (10 Hz–100 kHz) at Lime Kiln, calculated using ECHO 2021 baseline and slowdown data (bright lines). The original CDF curves presented in Fig. 4 (as reported by the ECHO Program) are shown in muted tones. $L_{50}$ values are circled, $L_5$ values are denoted with an asterisk, and $L_{95}$ values are shown with a plus sign

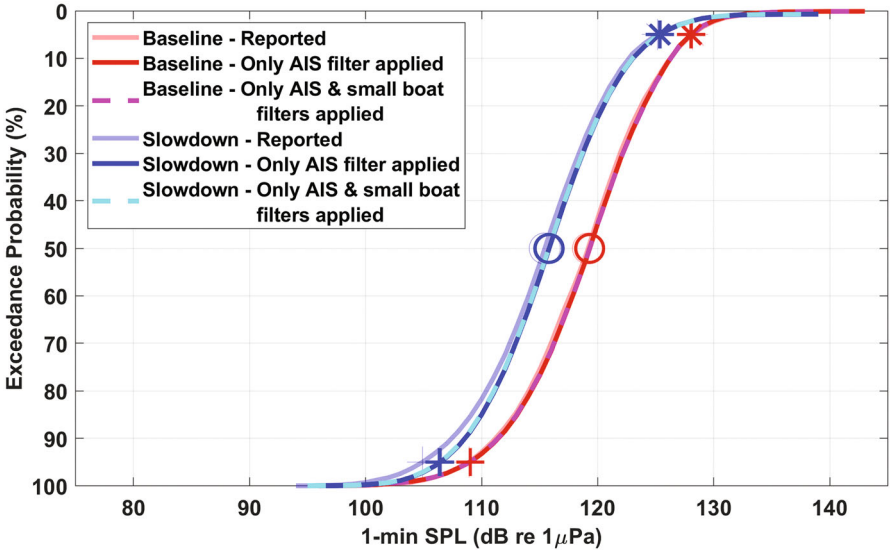

**Fig. 7** CDF plot when the only exclusion criteria was to remove confounding quiet and noisy periods, showing the cumulative distribution function for broadband acoustic data (10 Hz–100 kHz) at Lime Kiln, calculated using ECHO 2021 baseline and slowdown data (dashed, bright lines). The original CDF curves presented in Fig. 4 (as reported by the ECHO Program) are shown in muted tones, and the CDF curves presented in Fig. 6 (where only confounding quiet periods are removed) are shown in solid, bright lines. $L_{50}$ values are circled, $L_5$ values are denoted with an asterisk, and $L_{95}$ values are shown with a plus sign

confounding source of noise that was unrelated to the slowdown were filtered out of the analysis. Keep in mind here that this filtration strategy means that periods that may be noisy due to current speeds or wind speeds exceeding their given thresholds were still included in this specific noise mitigation evaluation scenario.

Here, the resulting $\Delta L_{50}$ of 3.5 dB in this scenario leads to the conclusion that the partially filtered slowdown is quieter than the partially filtered baseline, though this result is only 0.2 dB different than the final reported $\Delta L_{50}$ of 3.7 dB (Fig. 4). In other words, there was a 0.2 dB "cost" of excluding noise correlations with environmental covariates (e.g., wind and current), at least when considering the broadband frequency range, at this sampling site, during this particular year. Every year, samples will comprise a unique mixture of different origins of noise, whose relative contributions will differ year on year. Environmental noise, for example, had a greater individual contribution to the data exclusion in the previous ECHO 2020 evaluation year (Warner et al. 2021).

## Findings If Baseline and Slowdown Are of Equal Duration

The slowdown period in the ECHO 2021 season (122 days) was approximately double that of the baseline period (60 days) (Vancouver Fraser Port Authority

2022b). It has been a concern that this imbalance may skew the results used to evaluate noise mitigation effectiveness. To explore this, the amount of slowdown data (which passed *all* filtration criteria) to be included in the creation of the CDF plots was varied.

First, the longer slowdown period was reduced (via random sub-selection of each data point covering 1 min of acoustic data) so that the number of acoustic data points satisfying all filtration criteria for both baseline and slowdown periods was the same. In other words, the number of criteria-passing data points from the 2-month baseline exactly matches the number of criteria-passing data points from across the 4-month slowdown, all of which fed into the CDF analysis. This approach gave a broadband $\Delta L_{50}$ of 3.7 dB, which is the same as the ECHO 2021-reported broadband $\Delta L_{50}$ of 3.7 dB (Fig. 4).

Second, the longer slowdown period was reduced by instead drawing from the same duration of time as the duration of the slowdown (i.e., 2 months) in sequential minutes of SPL, as opposed to random sub-selection from the ~4-month slowdown, as above. Here, minor differences to the reported $\Delta L_{50}$ of 3.7 dB were found (presented in Fig. 4), with a broadband $\Delta L_{50}$ of 4.04 dB when comparing the baseline to a 2-month slowdown period pool of only July and August (0.34 dB different from the reported $\Delta L_{50}$ result). When this is repeated for different consecutive 2-month periods of slowdown, a broadband $\Delta L_{50}$ of 3.59 dB results when drawing from the 2-month slowdown period pool of only August and September (0.11 dB different), and a broadband $\Delta L_{50}$ of 3.54 dB when drawing from the 2-month slowdown period pool of only September and October (0.16 dB different).

This means that reducing the amount of slowdown data used for comparison with the baseline data had a broadband $\Delta L_{50}$ of anywhere from as little variation as $3.7 \pm 0$ dB to as big of a variation as $3.7 + 0.34$ dB. In other words, the scenarios with equal durations of baseline and slowdown periods had a broadband $\Delta L_{50}$ of 3.7–4.04 dB, compared to the final reported broadband $\Delta L_{50}$ of 3.7 dB when informed by a slowdown that was approximately double that of the baseline. Effectively the same overall broadband $\Delta L_{50}$ result occurs when reducing the amount of slowdown data available to compare with the baseline data and with which to assess any soundscape benefits of the slowdown (Fig. 8).

## Exploring How Much Data Are Needed for CDF-Based Conclusions

As mentioned earlier, only a fraction (~10%) of available acoustic data passes criteria and filtration metrics for inclusion in the assessment of the noise mitigation effectiveness. The logical next step to exploring this further is to reduce this amount even more and examine how much the overall conclusion, expressed at the difference between baseline and slowdown $L_{50}$ values, changes. In other words, how much data is needed for comparisons between baseline and slowdown periods to be justifiable? To do this, all acoustic data collected at times when criteria for inclusion were met were randomly subsampled to either 10% or 2% of this. These are extremely small amounts of time, with a 10% subsample drawn from a period where only ~10% of the data passed criteria for inclusion equivalent to a total of

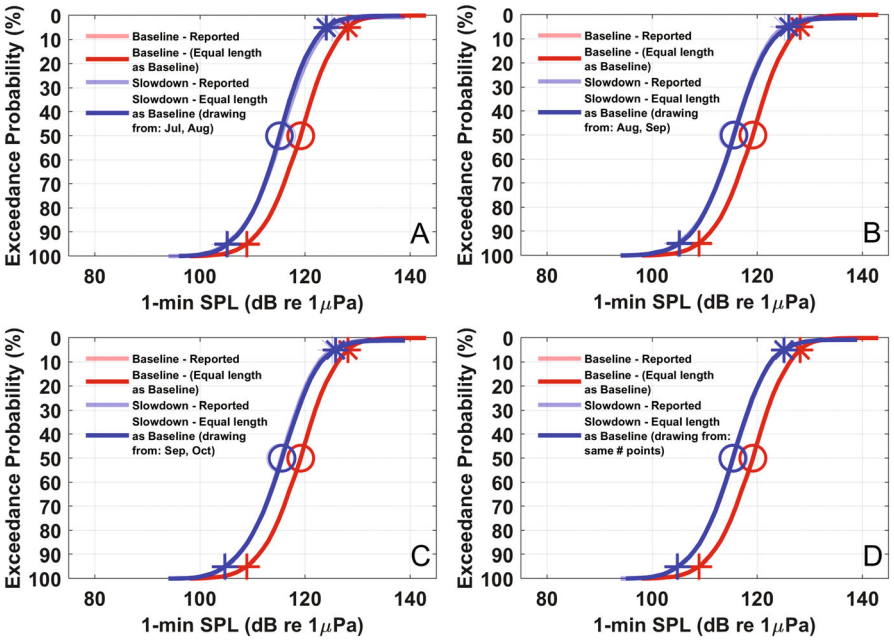

**Fig. 8** CDF plot when all filtration criteria listed in section "Methods" are applied, but the slowdown period is shortened to equal that of the baseline period, whereby in (**a**) the slowdown period is reduced to a 2-month duration from July and August, resulting in a change in $\Delta L_{50}$ value of 0.34 dB; in (**b**) the slowdown period is reduced to 2-month duration from August and September, resulting in a change in $\Delta L_{50}$ value of 0.11 dB; in (**c**) the slowdown period is reduced to 2-month duration from September and October, resulting in a change in $\Delta L_{50}$ value of 0.16 dB; and in (**d**) the slowdown period is reduced so that the total number of criteria-passing data points is randomly drawn and equals the number of criteria-passing points from the baseline, resulting in a change in $\Delta L_{50}$ value of 0 dB. Minor differences exist between the 4 sub-selection scenarios. The cumulative distribution function for broadband acoustic data (10 Hz–100 kHz) at Lime Kiln, calculated using ECHO 2021 baseline and slowdown data (bright lines). The original CDF curves presented in Fig. 4 (as reported by the ECHO Program) are shown directly underneath in muted tones. $L_{50}$ values are circled, $L_5$ values are denoted with an asterisk, and $L_{95}$ values are shown with a plus sign

only ~7.2 h per month of data feeding into the analysis. The differences in the $\Delta L_{50}$ values changed by only <0.3 dB for either case (Fig. 9). However, the non-smooth pattern of the cumulative distribution function when only 2% of criteria-passing data are included suggests that this CDF plot has been created with too few data.

Note that the limit on minimum amount of acoustic data that can be used for evaluating a noise mitigation measure depends on how much the filtration criteria have already subsampled the data and by how representative those acoustic data are of that period. The purpose of showing this is *not* to demonstrate that only a few days of data are sufficient to draw from to evaluate a noise mitigation measure. Instead, the purpose here is to show that it is acceptable to not use all available data and to show that it is fine to be strict with exclusion criteria.

A final way to explore the limits of how much data is needed between treatment (slowdown) and control (baseline) conditions is to reduce the number of consecutive

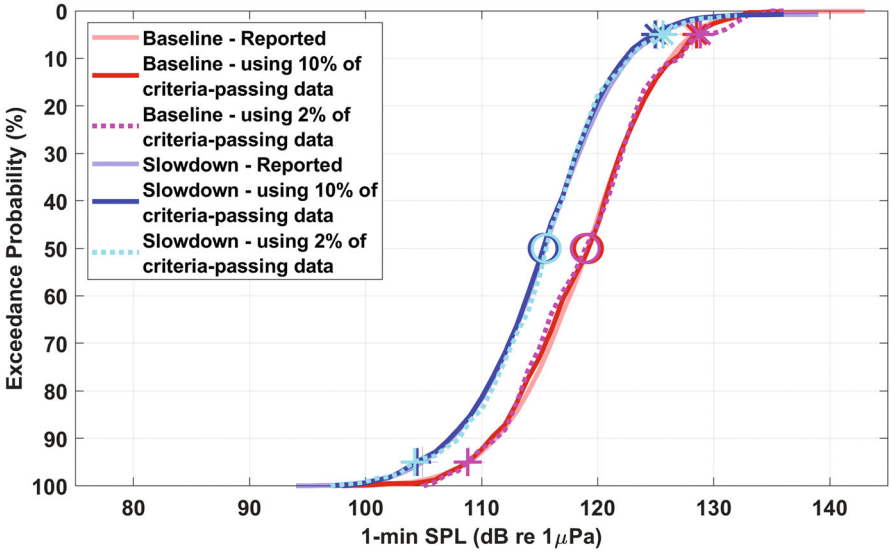

**Fig. 9** CDF plot when all filtration criteria listed in section "Methods" are applied, but the amount of acoustic data has been further reduced to either 10% (solid lines) or 2% (dashed lines) of the criteria-passing data available for both baseline and slowdown periods. The cumulative distribution function for broadband acoustic data (10 Hz–100 kHz) at Lime Kiln was calculated using ECHO 2021 baseline and slowdown data (bright lines, solid, and dashed). The original CDF curves presented in Fig. 4 (as reported by the ECHO Program) are shown directly underneath in muted tones. $L_{50}$ values are circled, $L_5$ values are denoted with an asterisk, and $L_{95}$ values are shown with a plus sign

days of available data from which to draw from can be modified. Below, another way to visualize how much data is enough – from which to draw conclusions on the effectiveness of a noise mitigation effort – is shown. Specifically, the difference in the $\Delta L_{50}$ values that would arise, depending on how much (or how little) consecutive data feeds into the analysis, is shown.

Figure 10 shows that only drawing from the first 10 consecutive days from the 60-day baseline of the ECHO 2021 dataset (May 3–Jul 1, 2021) produces a broadband $\Delta L_{50}$ result that was ~0.8 dB different than if drawing from the full 60 days of available baseline data. This dB difference diminishes with more consecutive days of available baseline. For example, when ~35 consecutive days of baseline are fed into the analysis, the difference in the broadband $\Delta L_{50}$ (of drawing from 35 consecutive days vs. 60 consecutive days) drops to ~0.3 dB.

The green lines on Fig. 10 shows a similar exercise, but here, data were only drawn from the baseline month of June (instead of a baseline of 2 months, from both May and June, as before). Here, it can be seen that only drawing from the first 10 consecutive days of a shorter, 30-day baseline period produces a broadband $\Delta L_{50}$ value that is now 1.2 dB different than if drawing from a 60-day baseline.

Such simulations are helpful when considering and informing what a sufficient amount of data would be for a given site. So, it would be possible to use only a

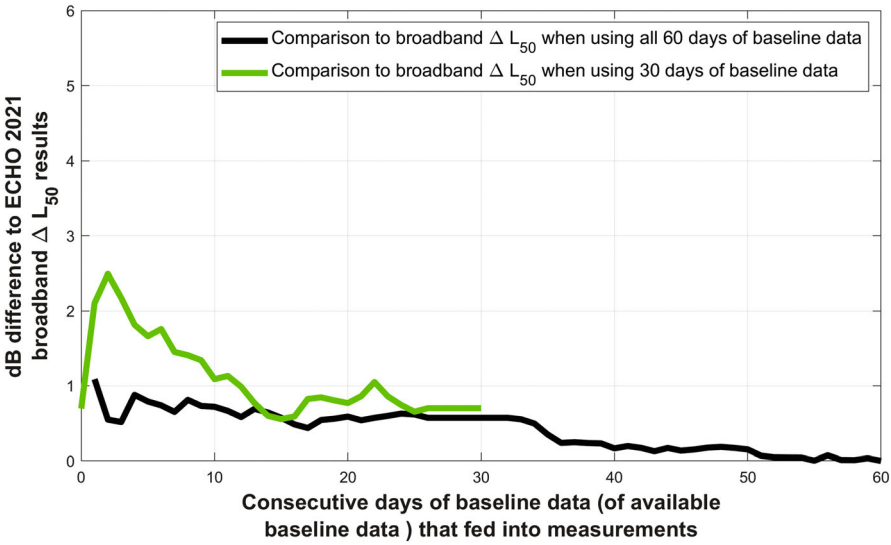

**Fig. 10** Exploration into how many consecutive days of baseline is necessary, via comparison to the broadband $\Delta L_{50}$ results reported for ECHO 2021. The difference in the $\Delta L_{50}$ value for broadband noise (10 Hz–100 kHz) that arose when comparing the baseline period with the slowdown period is shown as a function of a sub-selection on consecutive baseline days, from the entire 60-day baseline period (black, May and June) and from a reduced baseline period of only 30 days (green, only June). Differences in results remain low even with minimal consecutive day sub-selection. The first day is May 3, 2021 (i.e., the first 10 consecutive days of the baseline period correspond to May 3–13, 2021)

30-day baseline (instead of a 60-day baseline) alongside the 122-day slowdown to evaluate the difference in noise levels during the two periods; however, unless the additional baseline period exists, it is impossible to quantify the degree to which excluding that period impacts the resulting broadband $\Delta L_{50}$. In other words, more data are better, as the effect that a reduced-duration baseline period will have on the overall broadband $\Delta L_{50}$ result (showing the difference in broadband noise levels in baseline and slowdown conditions) would be unknown.

## Discussion

Using the ECHO Program's 2021 dataset, an overview has been provided here of the value and weight of different filtration metrics for including and excluding acoustic data in evaluations of noise mitigation evaluations. At Lime Kiln, AIS data were used to determine the range of vessels potentially participating in the slowdown to the acoustic recording station, the presence of small boats was automatically acoustically detected, and wind speed and current speed were measured near the hydrophone. Together, these confounding factors were monitored and filtered out to assess the noise mitigation effectiveness of the ECHO slowdown initiative. It is hoped that these considerations of removing periods with confounding noisy and quiet periods

are adopted by others trying to quantify the impact of a vessel slowdown period, or of any other noise mitigation initiative.

However, different locations have different soundscapes. Appropriate thresholds for different and/or additional variables (e.g., rainfall, sea state, etc.) that have a correlation with noise levels will need to be explored and defined for each site where acoustic recordings are taken. Nevertheless, understanding the variation in ambient noise levels at a given site is often lacking, and this can limit the effectiveness of evaluating noise mitigation initiatives (Vagle et al. 2021). The soundscapes at different sites can vary due to differences in sound speed profiles, bathymetry, bottom substrates, and sea surface conditions, for example (e.g., Eickmeier et al. 2021; Vagle et al. 2021). These variations may also be impacted seasonally (e.g., changes in sound speed profiles). At Lime Kiln, monthly CTD casts are taken to help inform the appropriate selection of baseline periods according to when the slowdown is in effect, as seasonal oceanographic processes in the Salish Sea can change the sound speed profile and therefore the recorded soundscape. Specifically, in Haro Strait, where the slowdown is in effect during the summer months and into the autumn, selecting a baseline period when the CTD data show the presence of surface ducts is avoided, as they are characteristic of winter conditions at this site. In other words, efforts are made to select a baseline period with a similar measured sound speed profile as that of the slowdown period. For the "quiet sound" vessel slowdown initiative into the Port of Seattle, the slowdown occurs during the late autumn and into the winter months, and so here too a period with a similar sound speed profile, as confirmed with CTD casts, should be selected as the baseline period.

Another variation in soundscape may arise based on how confined a body of water is. Both Lime Kiln in Haro Strait and Boundary Pass are quite constrained areas (Fig. 1) where measured soundscapes are less influenced by distant vessels. In a constrained area, more acoustic shadowing could be present (e.g., Cominelli et al. 2020). Furthermore, in a narrower channel or more confined body of water, it is more likely that vessel transits occur at similar ranges to a stationary hydrophone or at least that there is low variability in the range at the closest point of approach. If the soundscape is measured from a wider channel or an open ocean site, on the other hand, more variation in the range and the closest point of approach between passing vessels and a stationary hydrophone may be expected. However, this does not necessarily translate to more variation in received SPLs due to the logarithmic nature of transmission loss. It is therefore recognized that in open waters, data filtration methods suggested here might need further adaptation.

It is important to also note that even the covariates that are correlated with noise levels may vary from site to site. For example, colleagues applying a similar approach to data collected at a different site noted differences in noise levels depending on whether the wind was moving with the tide or current, versus when wind was moving against the tide or current (R. Burnham, pers. comm.). On a similar vein, the "dB cost" of forgetting to consider a covariate that has a correlation with underwater noise levels will vary from site to site.

It is also important that environmental sensors (measuring wind, current, etc.) are located as close as possible to the acoustic recording station (Eickmeier et al. 2021), and the temporal resolution of your environmental measurements needs to closely

match the temporal resolution of the acoustic analysis. If not, the available data could be filtered, but not in a way that necessarily serves the analysis, and more akin to a random sub-selection. For example, at Lime Kiln, wind data were sampled every minute near the hydrophone, current data were sampled at 10 Hz next to the hydrophone and averaged across 1-minute intervals, and acoustic data were sampled at 250 kHz with SPLs averaged across 1-minute intervals.

The soundscape at a given site can also vary with seasonal prevalence of biological noise. For example, cumulative distribution function plots created with the same acoustic data at the same site vary depending on whether periods with detections of animal sounds are included or excluded (Eickmeier et al. 2021). Therefore, keeping track of the presence of sonorous species is advised. Aural review of recordings, or a sub-selection of recordings, is also advised as this can pick up unexpected sounds (e.g., the repeated clinking of a chain anchoring equipment is readily aurally detected, and such instances should be excluded from noise mitigation evaluations). This and other potential confounds can be identified by appropriate plotting and quality assurance steps with the data; for the acoustic data, this could include reviewing daily/weekly/monthly time series of SPLs in different frequency bands, long-term spectral averages, power spectral density plots, and overviews of third octave levels for a given time period, all prior to any noise mitigation evaluation. The importance of this process cannot be over stressed, especially as such a review of the data can identify unexpected sound sources or draw attention to equipment deficiencies, etc.

In conclusion, comparative acoustic analyses to evaluate the effectiveness of a noise mitigation measure should be aware of different factors that may be correlated to noise levels but be unrelated to the noise mitigation measure. These covariates should be measured in similar temporal and spatial scales as the acoustic data, and how much they matter may vary from site to site and from year to year. Such analyses should consider filtering out these confounding noise covariates, and, as the above explorations with the ECHO 2021 dataset show, it both is acceptable to not use all available data and fine to be strict with exclusion criteria. Analysts should be mindful of the sound speed profiles of treatment and control conditions and appropriately select a baseline during a time where the sound speed profiles resemble one another. One should also be mindful that soundscapes can change over small regional scales and that interannual variability in the contributions of different noise confounds does occur. While the approaches suggested here may need further adaptation in different environments, it is hoped that the considerations presented here help to guide future comparisons evaluating the effectiveness of noise-related conservation measures.

40-day geophysical seismic survey along the Cascadia Subduction Zone offshore of Oregon and Washington. The study collected measurements of acoustic pressure and particle motion, accompanied by in situ tagging of the aforementioned species. Presented in this chapter are a characterization of the acoustic fields that can potentially drive observed behavioral responses of the tagged species.

The noise floor during the study period was strongly dominated by wind noise, with occasional contributions from small boat traffic. During the seismic surveys, received peak pressure levels were found to exceed 160 dB re 1 μPa (corresponding to peak measured particle velocity levels of 95 dB re 1 nm/s) when the seismic sound source was at a distance of 30 km from the vector sensor array. In contrast, band-averaged ambient pressure levels were in the 100–120 dB re 1 μPa range (corresponding to particle velocity levels that were in the 60 dB re 1 nm/s range).

Particle motion · Seismic survey · Vector sensor · Fishes

## Introduction

Fishes and many invertebrates use sound, primarily particle motion, not only to acquire information about their environment (i.e., an approaching predator or the presence of a potential mate), but also for communication or navigation. Popper and Hawkins (2018), in their review of the importance of particle motion to fishes and invertebrates, outline the long history of research in this field and point out that regulatory action has emphasized sound pressure (Popper et al. 2014), while disregarding the more important component for fishes and invertebrates – particle motion. They also note that fishes and invertebrates are not solely exposed to particle motion in water; these stimuli may be transmitted through the substrate and at the interface between the water and the substrate (Popper and Hawkins 2018).

Understanding the effects of particle motion on fishes and invertebrates is relevant to regulatory concerns. Adverse effects such as increased mortality, injury (and reduced survivorship or sensory capabilities), and physiological and behavior alterations (including but not exclusively reproductive) are important to understand and to inform the preparation of any environmental impact assessment. Among the issues raised by Popper and Hawkins (2018) requiring further investigation is the need for robust and concurrent measurements of particle motion and the associated behavioral response of fishes and invertebrates.

A seismic survey of the Cascadia Subduction Zone occurred offshore Oregon, Washington, and British Columbia during the summer of 2021 using an array of 36 airguns. This airgun activity presented a unique acoustic source and opportunity to examine the impact of loud anthropogenic sound on the behavior of reef fish and invertebrates. A study was conducted to measure in situ behavioral responses of reef fishes and invertebrates to sound from the seismic airgun survey (Borland et al. 2023). Most studies of the effects of seismic survey sounds in open ocean and shallow-water environments focus on the pressure component of sound (e.g., Cato

1976; Dahl et al. 2007; Martin and Popper 2016; Haxel et al. 2019), but few focus on the associated acoustic particle motion to which many animals have sensitivity (Nedelec et al. 2016; Popper and Hawkins 2018). Thus, the first objective of the study was to simultaneously measure the particle motion and pressure components of the seismic survey activity including the signals from airgun explosions and ensuing reverberation between pulses (Guerra et al. 2011). The second objective was to measure behavioral responses of rockfishes (genus Sebastes), lingcod, and Dungeness crab to these seismic pulses using acoustic telemetry. Described in this chapter are the acoustic measurements made on an acoustic vector sensor array (VSA), the NoiseSpotter® (Raghukumar et al. 2020), while an accompanying chapter ("Responses of Oregon demersal species to seismic survey noise: evaluating behavior and movement," Borland et al. 2013) describes the behavioral responses of rockfishes, lingcod, and Dungeness crabs to the seismic pulses.

## Methods

The R/V Langseth conducted a seismic airgun survey of the Cascadia subduction zone from May 31 to July 11, 2021. The survey commenced near Seattle, proceeded southward until near the Oregon-California border on June 17, and then continued northward until offshore of British Columbia on July 8 before concluding the survey on July 11, 2021 (Fig. 1).

Measurements of acoustic pressure and particle velocity before, during, and after the survey were made using an acoustic vector sensor array which was deployed within the Redfish Rocks Marine Reserve (RRMR) on May 15, 2021, and recovered on July 21, 2021. Two equipment turnarounds occurred within this deployment period.

The vector sensor array, NoiseSpotter® (Fig. 2), was deployed in approximately 36 m deep water using three sensors mounted 35 cm, 50 cm, and 75 cm above the seabed. Sensors are separated by 1 m in the horizontal. Particle motion measurements are comprised of three-dimensional particle velocity vectors (u, v, w), measured in a sensor reference frame. The sensor at 50 cm contains an integrated inertial motion unit (IMU), whose measurements are used to translate the particle velocity vectors into a true earth-referenced frame. The frequency sensitivity of the vector sensors spans the 50 Hz–3 kHz range. Omnidirectional pressure measurements have a flat frequency response, while the particle velocity measurements have a peak sensitivity at 1 kHz. The 50 Hz-3 kHz frequency range is suited to measurement of anthropogenic sounds such as those from seismic surveys and ships (frequency range 0–500 Hz), and biological sounds such as those from fishes, invertebrates, and baleen whales whose hearing sensitivities fall within this frequency range (Nedwell 2004). The vector sensors are capable of measuring sound pressure levels up to 240 dB re 1 μPa at a distance of 100 m from the sensor.

Strong hydrodynamic flow from waves and currents can induce nonacoustic pressure fluctuations that lead to contamination of acoustic signals. Flow noise contamination can be particularly acute with vector sensors due to saturation of the built-in accelerometer signal by energetic flows. To facilitate deployments in

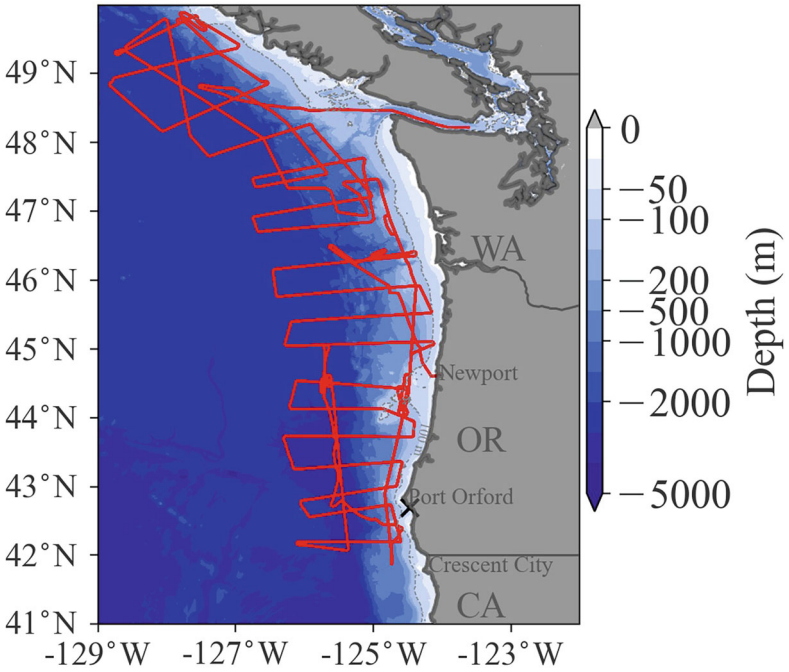

**Fig. 1** Map showing R/V Langseth transects and study location (black cross near Port Orford). Bathymetric data from https://www.gebco.net/

energetic environments, the VSA included flow noise suppression shields around each vector sensor. The flow noise suppression shields have been demonstrated to be effective in reducing flow noise effects, thereby improving data quality and signal detectability (Raghukumar et al. 2019).

## Results

For the purposes of analysis, the three deployment periods are categorized as "pre-survey" (May 18–29), "during" (June 8–16), and "post-survey" (July 3–11, at which point the R/V Langseth was over 500 km away from RRMR). Cumulative Sound Exposure Levels (cSELs, Southall et al. 2007) were computed on hour-long data segments for sound pressure measured at the sensor 70 cm above the seabed (Fig. 3). Also shown in Fig. 3 are wind speeds measured during the deployment periods, measured at the National Data Buoy Center Station PORO3 meteorological buoy, located roughly 3 km north of RRMR. During all three analysis periods, cSELs are seen to be strongly influenced by wind speeds, with a general increase in cSELs during the postsurvey period when wind speeds were highest. A diel modulation of cSELs due to diel variability in wind speeds is observed, most prominently in the

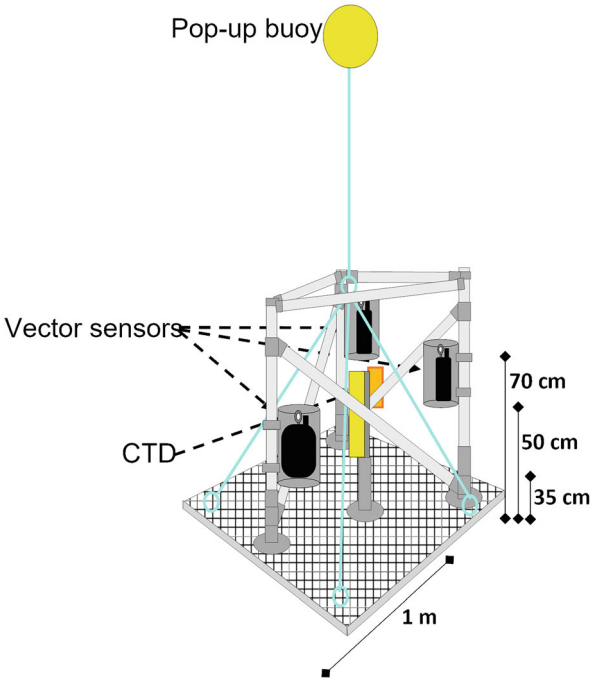

**Fig. 2** NoiseSpotter® vector sensor array consisting of three vector sensors and a conductivity-temperature-depth sensor

"before" period. cSELs are highest (approximately 145 dB re 1 $\mu Pa^2s$) on June 11, at which time the R/V Langseth was at its second closest point of approach (30 km). Wind speeds were also highest on June 11, suggesting that the high cSELs measured are a combination of sound from seismic airgun pulses and high wind-generated ambient noise.

A long-term spectral average (Fig. 4) of the acoustic pressure shows periods of elevated acoustic energy between 0 and 500 Hz associated with the seismic surveys between June 11 and 13, 2021. Similar to Fig. 3, a temporal banding of acoustic energy associated with diel changes in wind speeds is seen, with an increase in acoustic energy levels observed toward the end of May, 2021, likely due to increased wind speeds. Occasional boat passages (short-duration broadband spectral lines) are seen during all three data periods, with the most frequent boat passages occurring during the presurvey period (upper panel, Fig. 4). The postsurvey period shows higher acoustic energy across the 0–1000 Hz frequency band considered, with the exception of a dip in acoustic energy on July 7, 2021, that coincides with a drop in wind speeds during that period.

The contribution of seismic airgun pulses to the particle velocity soundscape is discerned in statistics of the frequency spectra (Fig. 5, x-component of particle velocity) for each of the deployment periods. The mean, maximum, and 99-percentile curves show an elevation in particle velocity levels due to the presence of seismic airgun pulses during these periods. In contrast, the remaining percentile

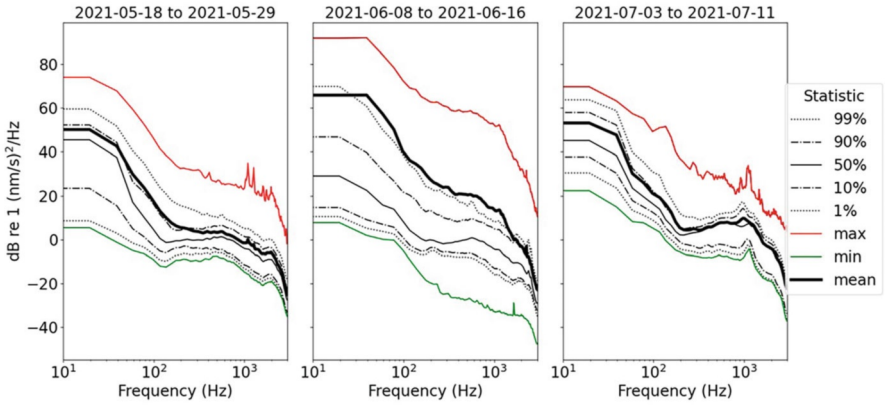

**Fig. 5** Power spectral densities for x-particle velocity before (left), during (middle), and after (right) the seismic airgun survey

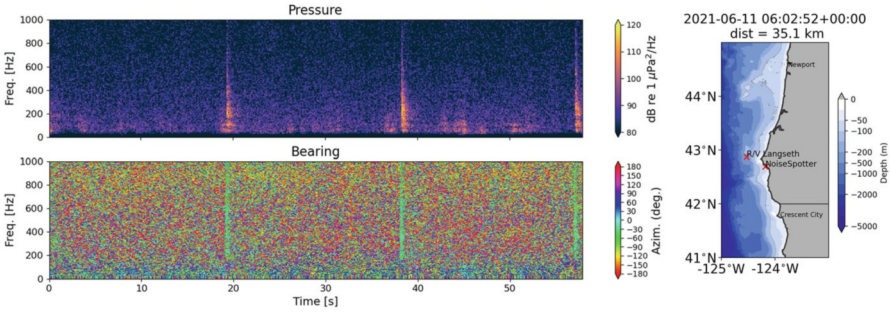

**Fig. 6** (Left) Example of acoustic pressure and azimuthal bearing estimated from particle velocity. (Right) Locations of R/V Langseth and NoiseSpotter® for data period shown above. Bathymetric data from https://www.gebco.net/

curves (minimum, 1%, 10%, 50%, and 90%) show the highest levels during the postsurvey period, likely due to sustained higher wind speeds during this period (Fig. 1).

An example of directional processing applied to the particle velocity data is shown in Fig. 6, for a minute-long data segment during which seismic airgun pulses were measured at a distance of 35.1 km from the R/V Langseth. The true bearing of the R/V Langseth relative to the NoiseSpotter® was −55° with respect to true north (i.e., to the northwest). Frequency-specific bearings were calculated to be in the range of −55–50° with respect to true north for the primary arrivals associated with the seismic pulses. While the pressure data show additional arrivals associated with multipath propagation, the signal-to-noise ratio was insufficient to sufficiently resolve the associated bearings for these multipath arrivals.

## Conclusion

In this chapter, acoustic particle motion was measured before, during, and after a seismic airgun survey of the Cascadia Subduction Zone. Measurements were made inside the Redfish Rocks Marine Reserve in southern Oregon and were accompanied by in situ tagging of rockfish, lingcod, and Dungeness crabs. The acoustic environment was found to be dominated by wind noise, with occasional contributions from boats and seismic airgun pulses from the R/V Langseth during the seismic surveys that exceeded 160 dB re 1 μPa (pressure) or 95 dB re 1 nm/s (particle velocity). The ambient noise floor (100–120 dB re 1 μPa range for pressure, 60 dB re 1 nm/s range for particle velocity) appeared to scale with wind speeds, with the highest ambient noise levels occurring during the postsurvey period. Episodic contributions from the seismic airgun pulses were most evident in the mean, maximum, and 99 percentile levels. The highest measured wind speeds during the study period coincided with the closest point of approach of the R/V Langseth; thus, it is likely that the high cumulative sound exposure levels during this period contain contributions from both wind noise and the airgun pulses. It will therefore be necessary in subsequent analyses to separate the contribution to the acoustic environment from each source. Efforts are ongoing to implement automated detectors for a better quantitative characterization of sound levels from the seismic pulses to inform a more granular understanding of behavioral responses to acute periods of elevated sound levels.

The extraction of periods when seismic pulses were present can also likely be conducted using directional processing of the particle velocity data. A good agreement of estimated azimuthal bearing relative to true location of the R/V Langseth lends confidence that a directional masking of data can shed additional light on sound pressure and particle velocity levels during the seismic surveys.

**Abstract**

The approaches for measurement and analysis of underwater vessel radiated noise are complex and evolving. As underwater noise gains increased attention internationally, ship owners and operators are faced with the challenge of understanding the noise emissions of their fleet. An owner seeking to determine if an existing or future vessel design may qualify for a quiet notation must carefully evaluate the available certification options and consider the cost. Differences in terminology,

methodology, and approach from international ship classification societies, coupled with the lack of a standardized approach for vessel measurements in shallow water, can make certification daunting to the owner. Recognizing this challenge, the Enhancing Cetacean Habitat and Observation (ECHO) Program led by the Vancouver Fraser Port Authority, supported by Transport Canada, initiated a project to work with ship classification societies and technical experts toward the alignment of quiet ship notations, through a series of three annual workshops. In 2017, Vancouver became the first port in the world to offer financial incentives to ships with quiet notations, and through the alignment project, strives to increase the number of ships achieving notations and being rewarded for this practice – at the Port of Vancouver and around the world.

Quiet ship · Metrics · Source levels · Classification society · Underwater radiated noise

## Introduction

The Enhancing Cetacean Habitat and Observation (ECHO) Program, led by the Vancouver Fraser Port Authority, is a research and management program that seeks to better understand and reduce the cumulative effects of shipping, particularly ship-generated underwater noise, on endangered whales. The Southern Resident Killer Whale (SRKW), with a population of 73 individuals, is a key focus of the program. The ECHO Program coordinates seasonal underwater noise reduction initiatives, including vessel slowdowns and route alterations, while also spearheading research and educational efforts on underwater noise. Additionally, the ECHO Program works internationally to promote cleaner and quieter commercial ships.

With a goal to assist port customers in understanding and achieving certification as a quiet vessel, the ECHO Program, supported by Transport Canada, initiated a project for improved alignment of quiet ship notations from classification societies.

The objective of the project is to improve the alignment of measurement, analysis, and reporting techniques among the various class societies' quiet ship notations. Such alignment would enable customers to compare the notations to each other and determine which may be the most appropriate quiet ship certification for their vessel. A key requirement of the recommended procedures is to identify an analytical method and reporting metric that would result in the same underwater radiated noise (URN) result for a given ship measured under the same operating conditions anywhere in the world. Notably, there is a requirement for appropriate formulae to convert the sound pressure level (SPL) received at the hydrophone to a URN level for the vessel that provides consistent results regardless of water depth, as there is currently no international standard for vessel

measurement in shallow water (Ainslie et al. 2022). The end goal is to increase the number of vessels achieving quiet notations and thus receiving incentives at the Port of Vancouver and internationally. In 2023, the Port of Vancouver offers vessels with a quiet ship notation from a ship classification society a platinum level (75% rate reduction) on harbor dues. To this end, the Port of Vancouver and other ports need to know that these quiet notations recognize those customers who are going above and beyond to support quieter oceans.

## Project Methodology

To achieve the project objective to improve the alignment of measurement, analysis, and reporting techniques between the various class societies, JASCO Applied Sciences Ltd., a project partner on vessel source level measurement since 2015, was retained to work with the ECHO Program on this project which included the following steps:

- Comparison of the ECHO Program vessel source level measurement database to existing quiet notations, noting the challenges in doing so given the different measurement and analysis methods.
- Preparation of a draft document proposing options for alignment.
- Engaging with the class societies on review and discussion of the draft document through in-person or online workshops.
- Repeating steps 2 and 3, refining the document based on input received.
- Potential amendments to existing quiet ship notations to reflect the results of this work in 2023.

Vessel noise measurement performed by the ECHO Program began in 2015 and work on the project (step 1 above) began in 2018. The first draft document (step 2) was distributed to participants in August 2020, followed by the first workshop in October 2020 (step 3). Based on information received from the 2020 workshop, the document was refined and re-distributed in 2021 and again in 2022. The third and final workshop was held in October 2022.

The final *Recommended Procedures for Measuring Underwater Radiated Noise Emissions of Ships, for Quiet Ship Certification*, was published in 2023 (Hannay et al. 2023).

## Quiet Ship Notations

Ship classification societies provides services to the maritime industry and regulatory bodies, using technical expertise and experience to support the development of standards and regulations, with a focus on maritime safety and pollution prevention. Classification societies develop their own rules that pertain to design, construction, maintenance, and survey of essential parts of ships and other marine

facilities. Through the development and application of their own rules, and by verifying compliance with international and/or national statutory regulations, classification societies play a key role in self-regulation within the maritime industry (IACS 2022).

Although there are over 50 organizations worldwide offering maritime classification services, there are currently only seven classification societies presently offering notations for quiet ships. These include:

- American Bureau of Shipping (ABS): Guide for the Classification Notation: Underwater Noise and External Airborne Noise (2021).
- Bureau Veritas (BV): Underwater Radiated Noise (URN). Rule Note NR 614 DT R02 E (2018).
- China Classification Society (CCS): Guidelines for Underwater Radiated Noise of Ships 2018. Release date 2019-12-26 (2018).
- Det Norske Veritas (DNV): Class Guideline. Measurement procedures for noise emission. DNVGL-CG-0313 (2021b). Rules for Classification. Ships. Part 6 Chapter 7. Environmental protection and pollution control (2021a).
- Korean Register (KR): Guidance for Underwater Radiated Noise (2021).
- Lloyd's Register (LR): ShipRight Design and Construction: Additional Design Procedures. Additional Design and Construction Procedure for the Determination of a Vessel's Underwater Radiated Noise (2018).
- Registro Italiano Navale (RINA): Rules for the Classification of Ships: Part F, Chapter 13, Section 25. Dolphin Quiet Ship and Dolphin Transit Ship (2021).

All the notations are well designed and generally follow established guidance from the International Organization for Standardization (ISO 2016, 2019) or the American National Standards Institute and Acoustical Society of America (ANSI and ASA 2009). The classification societies, however, utilize differing measurement and analysis procedures and, most importantly, differing reporting metrics for each quiet ship notation.

As the Vancouver Fraser Port Authority began the process to incentivize and reward customers whose ships are certified with a quiet notation, it was important to evaluate how the quiet notations compared to the vessel noise emissions collected while on approach to the Port of Vancouver. Unfortunately, the lack of harmonization among notations precluded direct comparison of notations to each other or to the vessel source level measurements collected by systems deployed on behalf of the ECHO Program and Transport Canada (Hannay 2018; Hannay et al. 2019). A key example of this challenge is that five of the seven classification societies' procedures are based on the radiated noise level (RNL) metric (ISO 2019), whereas two are based on source level (SL) (ISO 2019).

Attempting to undertake the first step of the project, the comparison of quiet ship notations to existing vessel measurements highlighted the importance of proceeding with subsequent steps of the project to align the measurement, analysis, and reporting of these quiet ship notations.

## Drafting Recommended Procedures

The process of drafting recommended procedures began with the identification of the four main aspects of each quiet ship notation:

1. Preparation and measurement – acquiring the raw data. This aspect includes considerations for site selection, oceanographic and weather conditions, deployment configuration of appropriately calibrated equipment, and definition of the measurement path(s).
2. Initial processing – calculating sound pressure levels (SPL) from raw data. This aspect must consider how the SPLs are calculated in specified frequency bands over specified time intervals, including corrections for high background noise.
3. Post-processing – converting sound pressure levels to an underwater radiated noise (URN) metric. The post-processing step is where the conversion factors and consideration of metrics (RNL or SL) come into play, and where the differences among the class society approaches pose the greatest challenge for alignment. The conversion of measured SPL in the data window to URN includes applying distance correction factors and averaging over multiple hydrophones and transits.
4. Thresholding for certification – comparing the calculated URN against previously established URN levels for certification as a quiet ship. This aspect must also consider the magnitude and number of exceedances (if any) of the threshold that may be considered acceptable.

The first draft technical document with proposed procedures for alignment, under the aspects listed above, was distributed to the project stakeholders in August of 2020. At the time of that document, five ship classification societies: ABS, Bureau Veritas, DNV, Lloyd's Register, and RINA had quiet ship notations known and available for review by the project team. The proposed procedures were shared with representatives from the five listed classification societies, as well as with representatives from the International Association of Classification Societies (IACS), and technical experts from the ISO working group on the development of requirements for measurements in shallow water for review and input.

## Stakeholder Engagement

The ECHO Program is built on a collaborative and successful model that brings interested and impacted parties together to advance initiatives. The project to advance alignment of the quiet ship notations followed this collaborative model, ensuring that the affected parties, the classification societies, played an important role in crafting the recommended guidelines. Another hallmark of the ECHO Program is ensuring that decisions and recommendations are based in science. To this end, the project team sought to include emerging research and technical experts in the drafting of procedures.

As noted above, the engagement process included hosting three annual workshops (2020, 2021, 2022) with representatives from the classification societies and technical experts. Prior to each workshop, a technical memorandum with proposed alignment parameters was distributed to the participants for review and feedback. Each workshop sought to refine the proposed parameters based on the input provided by the participants and discussed at each workshop.

The three-year timeframe of the project also allowed for incorporation of emerging research pertaining to the measurement of vessels in shallow water, and the opportunity to share this information with the project stakeholders, who may otherwise be unaware. Of particular relevance is the project sponsored by Transport Canada *Towards a Standard for Vessel URN Measurement in Shallow Water* (MacGillivray et al. 2022, 2023) which investigated several metrics for potential use in shallow water. Sharing the learnings from this project with the international classification society representatives allowed participants to fully understand and seek clarification on data and methodology underlying the recommended metric.

Feedback from the project stakeholders received through review of the technical memorandum and discussions at the annual workshops were integrated into a final document *Recommended Procedures for Measuring Underwater Radiated Noise Emissions of Ships, for Quiet Ship Certification* (Hannay et al. 2023).

## Recommended Procedures

The *Recommended Procedures for Measuring Underwater Radiated Noise Emissions of Ships, for Quiet Ship Certification* (Hannay et al. 2023) is structured to provide clear and concise guidance for classification societies (or others) seeking to accurately measure and report on URN measurements in varying water depths, locations, and oceanographic conditions. The document provides an introduction, background, and discussion of existing URN metrics, followed by detailed recommendations for the following:

- Follow the acoustical terminology of ISO (2017)
- Site selection and water depth
- Limiting weather conditions
- Consideration of tides and currents
- Selection of instruments (in particular, hydrophones and calibration)
- Measurement geometry (distance from ship track, hydrophone depths and measurement angles, number of transits)
- Ship speed and draught
- Initial data processing (data window period, SPL calculation time windows, frequency bands, correction for ambient noise)
- Calculating the recommended URN metric (using an acoustic model or the recommended seabed critical angle (SCA) method derived from MacGillivray et al. (2022, 2023))

The final step of a quiet ship notation entails specifying the decidecade frequency band level limits or thresholds, against which the measured URN values are compared for certification. A decidecade is approximately equal to one-third of an octave. This step is intentionally not included in the recommended procedures, but statistical information (percentiles) of URN vessel measurements collected by the ECHO Program were provided to the project partners. It has been left to the discretion of each classification society to select appropriate limits for their certification.

## Incentives

For nearly 15 years, the Vancouver Fraser Port Authority has been rewarding ships operating in more environmentally responsible ways in and around the Port of Vancouver. By taking voluntary actions that go above and beyond environmental regulations, shipping companies can qualify for up to 75% off their harbor dues fees through the EcoAction program. In 2017, Vancouver became the first port in the world to offer financial incentives to ships for reducing underwater noise. The EcoAction program provides financial incentives for positive environmental practices including the use of renewable energy or cleaner/alternative fuels, maintaining vessel technologies that reduce underwater noise, or participating in voluntary ship environmental certification programs.

In 2023, the Port of Vancouver is offering vessels with a quiet ship notation from a ship classification society a platinum level (75% rate reduction) on harbor dues. The alignment project strives to help ship owners and operators better understand and compare among the different class society notations, with a goal to increase the number of vessels achieving notations and being rewarded for this practice – at the Port of Vancouver and around the world. To this end, the Port of Vancouver and other ports need to know that these quiet notations are comparable, consistent, and recognize those customers who are going above and beyond to support quieter oceans.

## Summary

The ECHO Program and the Government of Canada continually work to reduce vessel underwater noise regionally and nationally, to support the recovery of several endangered marine mammal species in our waters. However, shipping is an international business, and to truly instigate change, work must be progressed on an international scale. The project to align quiet vessel notations from ship classification societies recognizes this need for collaboration from all affected organizations regardless of geographic location. The work advanced on this project provides clear and concise guidance on measurement and analysis, as well as a recommended metric that can be used in differing oceanographic conditions and water depths. The

hope is that this guidance will be adopted by ship classification societies, making quiet ship certification more accessible and appealing to vessel builders, owners, and operators. In turn, prompting port authorities, government agencies, or other organizations to encourage and incentivize ship quieting for the benefit of ocean life around the world.

**Abstract**

Underwater radiated noise from shipping is the most widespread and pervasive human noise in marine ecosystems. Mounting evidence indicates that this noise source can cause changes to the behavior and physiology of marine mammals, and that cumulative exposures can have detrimental effects on their fitness and survival. Concern for the impacts of shipping noise to marine species has led regulators to propose measures to reduce underwater radiated noise from shipping either through

reductions in vessel source levels via technological modifications and operational slowdowns, or through measures to reroute vessels away from important marine habitats. In this overview, we provide a brief discussion of the potential impacts of vessel noise to marine mammals as a group of particular concern, and conclude that technological, operational, and routing measures can be used by the shipping industry independently or synergistically to reduce both global cumulative noise levels from commercial vessels, and potential impacts to marine mammals.

Anthropogenic noise · Noise mitigation · Shipping · Slowdown · Rerouting

## Introduction

Over the last century, global maritime traffic has steadily increased, with ship numbers growing by a factor of 3.5 and gross tonnage by a factor of 10 between World War II and 2008 (Frisk 2012). Today, motorized vessels transport over 80% of international trade (UNCTAD 2021), navigating the world's oceans following shipping lanes which provide the shortest and fastest pathways between maritime ports (Hsu and Hsieh 2007; Jalkanen et al. 2022). The ubiquitous nature of shipping has resulted in ships becoming the most widespread and pervasive human noise source in marine ecosystems (Hildebrand 2009; Jalkanen et al. 2022); projected to increase with the future growth in shipping activity in accordance with economic demand (Kaplan and Solomon 2016).

Sound is an important acoustic cue used by many marine species for critical ecological functions. Mounting evidence shows that the introduction of human-made underwater noises can have detrimental effects on species (Richardson et al. 1995; Williams et al. 2014; Shannon et al. 2016). Noise from both continuous (e.g., shipping) and impulsive (e.g., pile driving, seismic activity, sonar and acoustic deterrents) sound sources has been suggested to affect individuals behavior and physiology, and if prevalent, these effects may culminate in population-level consequences for species (Richardson et al. 1995; National Research Council 2005; Madsen et al. 2006; Kastelein et al. 2013; Slabbekoorn et al. 2016; Harris et al. 2018; Nabe et al. 2018; Erbe et al. 2019).

Concern for the increasing and widespread effects of ship noise, in particular on marine ecosystems, has led regulators to take measures aimed at reducing underwater radiated noise from shipping (European Commission 2008; IMO 2014; OSPAR 2014; Chou et al. 2021; HELCOM 2021). Three general approaches have been proposed: (1) technological modifications to reduce radiated noise levels (Leaper and Renilson 2012; Gassmann et al. 2017); (2) reducing the noise produced through operational solutions such as vessel slowdowns (Joy et al. 2019; MacGillivray et al. 2019; Burnham et al. 2021); and (3) reducing the received noise by implementing alternative routing measures (Laist et al. 2014; Burnham et al. 2021). In this chapter, we provide an overview of the potential effects of vessel noise to marine mammals as a group of particular concern and discuss proposed approaches for reducing underwater radiated noise from commercial vessels.

## Vessel Noise as a Threat for Marine Mammals

Marine soundscapes are composed of both natural and anthropogenic sources. Natural sources can include sounds from waves, rainfall, and earthquakes, as well as a variety of biological sounds from animals. Anthropogenic noise is generated by human activities ranging from oil and gas exploration and naval operations, to commercial shipping, fishing, recreational boating, and offshore infrastructure (platforms, offshore renewables, etc.) (Hildebrand 2009). Sound travels with little attenuation in the aquatic environment, particularly at lower frequencies (Urick 1983), and many marine species have evolved to exploit these advantageous sound propagation characteristics. Marine mammals in particular rely on acoustic cues for active and passive communication, and as a means of perceiving their environment, using acoustic cues for navigation, biosonar-based foraging, and/or detection and localization of predators (Tyack and Clark 2000). Marine mammals have adapted to carry out these important biological functions in fluctuating natural noise conditions; for example, rain can produce noise as loud as a passing vessel (Wisniewska et al. 2018). However, the rapid growth in human activities at sea has raised concerns as to whether the addition of anthropogenic noise sources to marine environments may negatively affect the auditory scene analysis, behavior, and/or physiology of marine mammals (Richardson et al. 1995; Nowacek et al. 2007; Weilgart 2007; Tyack 2008).

Vessel noise in deep water peaks at low frequencies, which co-occur with the frequencies at which baleen whales (presumably) hear best and produce sound (Fig. 1) (Erbe et al. 2019; Southall et al. 2019). Initial concerns for the effects of shipping noise on marine mammals centered on the potential for low-frequency vessel noise to mask the 20 Hz calls produced by fin whales (*Balaenoptera physalus*) (Payne and Webb 1971). Since this hypothesis, studies on a wide range of baleen whale responses to vessel noise have reported a suite of reactions, including changes in behavior (Sprogis et al. 2020; Arranz et al. 2021), foraging (Blair et al. 2016), physiological stress levels (Rolland et al. 2012), and communication signal characteristics (Dahlheim and Castellote 2016). More recent studies have also reported substantial vessel noise at higher frequencies (Hermannsen et al. 2014; Veirs et al. 2016) (Fig. 1), illustrating that shipping noise is not only audible for, and hence affect, baleen whales, but also for other marine mammal groups, such as pinnipeds, sirenians, and toothed whales (Fig. 1).

Underwater noise from vessels has the potential to mask or alter the communication of pinnipeds (Terhune et al. 1979; Southall et al. 2000; Southall et al. 2003), and affect both their haul-out (Jansen et al. 2010; Andersen et al. 2012; Blundell and Pendleton 2015) and diving behavior (Mikkelsen et al. 2019). Both manatees (*Trichechus* spp.) and dugongs (*Dugong* spp.) also demonstrate the ability to detect and respond to approaching boats by changing orientation, diving behavior and behavioral state (Hodgson and Marsh 2007; Miksis-Olds et al. 2007; Rycyk et al. 2018). In the case of toothed whales, reported responses to vessel noise have included changes in echolocation and communication signal parameters (Kragh et al. 2019), behavior (Nowacek et al. 2001; Lusseau et al. 2009), social interactions (Marley et al. 2017), physiological stress responses (Lyamin et al. 2015), reductions

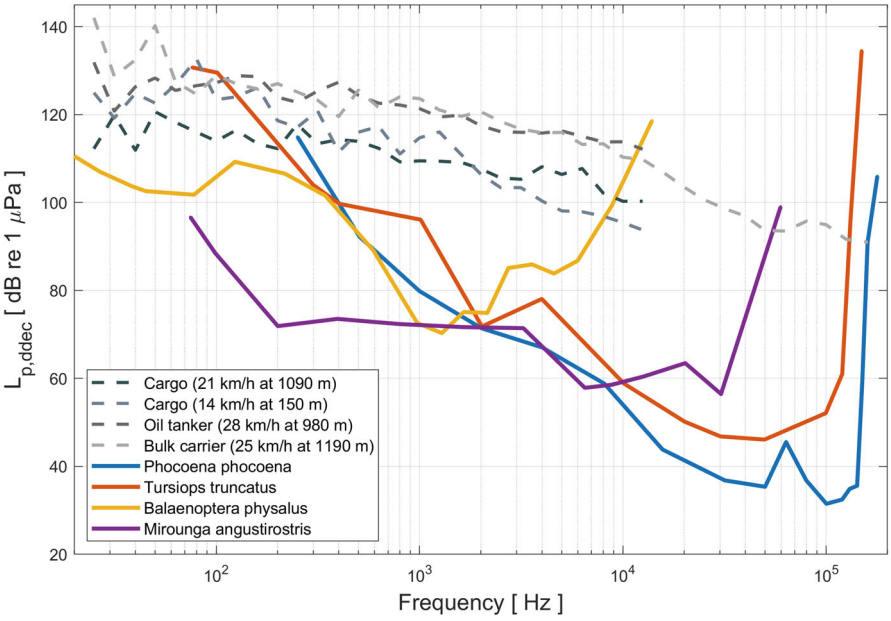

**Fig. 1** Audiogram of different species of marine mammals in relation to four vessel noise recordings (received decidecade levels root-mean-square, $L_{p,ddec}$ RMS). The numbers in brackets in the legend indicate the speed and distance of the vessels to the recording hydrophone. Vessel data taken from Hermannsen et al. (2014). Note that some examples of vessel noise recordings were limited to 20 kHz. Audiograms are presented for harbor porpoise (*Phocoena phocoena*) (Kastelein et al. 2002); bottlenose dolphin (*Tursiops truncatus*) (Johnson 1967); northern elephant seal (*Mirounga angustirostris*) (Kastak and Schusterman 1998); and a predicted audiogram of a fin whale calf (*Balaenoptera physalus*) (Cranford and Krysl 2015)

in foraging effort (Wisniewska et al. 2018), and even habitat displacement (Bejder et al. 2006; Rako et al. 2013). Nonetheless, while numerous studies have focused on these short-term adverse effects, there remains a paucity of quantitative data on how these noise-induced physiological and behavioral changes impact the fitness and survival of the exposed individuals, and in turn also the long-term viability of populations of animals.

While lethal threats from vessel activity, such as ship strikes, can have a direct impact on the survival of marine mammals (Silber et al. 2012; Laist et al. 2014), little is known about the potential for non-lethal threats, such as exposure to vessel noise, to lead to fitness consequences for individuals. In a terrestrial context, chronic exposure to road noise has been shown to reduce the breeding productivity of Eastern Bluebirds (*Sialia sialis*) (Kight et al. 2012). Although the mechanisms responsible for these effects are unclear, the breeding depression experienced by this species indicates that anthropogenic noise have a negative effect on individual fitness either directly, as a physiological stressor, or indirectly, by masking important vocalizations or leading to behavioral changes (Kight et al. 2012). Animals have

evolved to react to generalized threat stimuli, and according to the risk-disturbance hypothesis, perceive human disturbance as non-lethal predation stimuli by exhibiting comparable responses: displaying an aversive response and diverting time and energy from other fitness-enhancing activities such as feeding, parental care, or mating displays (Frid and Dill 2002). Substantial alterations in behavior in response to noise may therefore offset the time- and energy budgets of individuals. Reductions in the time spent foraging, socializing, or resting, or increases in energetic costs through initiation of fleeing responses could lead to an energetic imbalance between energy intake and energy expenditure (Costa and Williams 1999). However, the effect of vessel noise on the energy budget and individual vital rates greatly depends on how often and severely an animal is disrupted, how fast animals return to normal behaviors, and whether individuals are able to compensate for these interruptions (New et al. 2014; Christiansen and Lusseau 2015). Individuals repeatedly disturbed and unable to compensate for these disturbances will suffer a sustained imbalance between energy intake and expenditure that can have repercussions for the growth, reproduction and survival of individuals (Bejder 2005; Lusseau et al. 2006; Fortuna 2007). Importantly, depending on the proportion of the population affected, these cumulative negative impacts on individuals' vital rates can translate into population-level consequences.

To understand the processes by which nonlethal anthropogenic disturbances affects populations, the Population Consequence of Disturbance (PCoD) framework for marine mammals was developed (National Research Council 2005; New et al. 2014). Since its development, this framework has become a useful method for understanding the potential population-level consequences of disturbances (New et al. 2014; Villegas-Amtmann et al. 2017; Nabe et al. 2018). However, despite the extensive and growing literature documenting effects of human disturbance on wildlife, there are still glaring absences of empirical evidence on how short-term behavioral alterations translate into long-term biologically significant impacts on individual vital rates (McHuron et al. 2022). Regardless of the mechanistic link between the vessel noise disturbance and individual and population fitness consequences, exposures to loud vessels has the potential to cause detrimental effects to marine mammals (see review by Erbe et al. 2019). This is of particular concern in highly industrialized and/or densely trafficked areas overlapping with important habitats for marine mammals where animals are likely to be repeatedly or chronically exposed. Thus, to reduce the widespread impacts of vessel underwater radiated noise to marine wildlife, approaches that reduce the overall noise levels of vessels or that move vessels away from important habitats are needed to reduce the general risk of disturbance.

## Measures to Reduce Underwater Radiated Noise from Commercial Vessels

### Technological Measures

Above the cavitation inception speed of a vessel, rotating propellers create oscillations in water pressure, resulting in water vapor bubbles that produce broadband noise when they collapse (IMO 2014; AQUO 2015). Propeller cavitation is

consequently the most significant source of underwater radiated noise from vessels (Ross 1976; IMO 2014; Wittekind 2014), and modifications to vessel technology (i.e., propellers, hulls, rudders, etc.) are increasingly being trialed in attempts to reduce cavitation noise.

A significant proportion of modifications to reduce cavitation noise have centered on amendments to vessel propellers. These amendments aim to improve the propeller blade surface and coatings, and/or change blade number, diameter, pitch, skew, shape, tips, and weight (Leaper and Renilson 2012; IMO 2014). Spence and Fisher (2017) note that cavitation can be efficiently reduced through propeller design. Evidence from studies of a variety of proprietary propeller and hub cap concepts (e.g., High Skew Propellers; PressurePores™; Contracted and Loaded Tip; Kappel Propellers; New Blade Section Propellers; New Profile Technology Propellers; and Propeller Boss Cap Fins) have reported significant reductions in underwater radiated noise ranging from 3 to 20 dB (Ouchi et al. 1991; Ouchi and Tamashima 1992; Mewis and Hollenbach 2006; Ligtelijn 2007; Andersen et al. 2009; Hansen et al. 2011; Hilliard et al. 2014; Ma et al. 2014; Carchen et al. 2015; Sun et al. 2016; Bagheri et al. 2017; Gassmann et al. 2017; Aktas et al. 2020). However, although amendments to propellers seem to be an effective and supported approach for reducing radiated noise from vessels (IMO 2014), these modifications are complex, as they must address an unfavorable trade-off between radiated noise emissions and propeller propulsion efficiency (i.e., fuel consumption; Fig. 2) (Leaper and Renilson 2012; Leaper et al. 2014). Successful propeller designs are also not universal and must be developed for the specific wake profile of the vessel in question (Spence and Fischer 2017). Thus, radiated noise and propeller efficiency need to be considered simultaneously during the development and installation processes (Leaper and Renilson 2012).

Reductions in vessel cavitation can also be achieved through modifications to improve wake inflow and propeller/rudder interactions. Presently, the International Maritime Organization (IMO 2014) recommends that the hull form and propeller design are adapted together during ship manufacturing, as the hull form has a direct influence on water inflow to the propeller and resulting underwater noise. Additional devices which alter the wake flow into the propeller have been recommended to reduce noise and fuel consumption, for example, Mewis and Schneekluth ducts, simplified compensative nozzle, and Grothues spoilers (Breslin and Andersen 1994; ITTC 1999; Mewis and Hollenbach 2006; Carlton 2009; Feizi Chekab et al. 2013; Ebrahimi et al. 2019). Further, interactions between the propeller and rudder can be mitigated using twisted rudders and rudder fins developed to increase efficiency (Leaper and Renilson 2012); or Costa Propulsion Bulbs, which have been shown to reduce noise by 5 dB as a result of hydrodynamically integrating the propeller with the rudder, by fitting a bulb to the rudder in line with the propeller shaft (Ligtelijn 2010).

An increasing number of novel technological solutions are being proposed to reduce radiated noise from commercial vessels. For example, air injections through propeller blades were found to reduce noise by 10 to 15 dB in frequency bands from 40 to 400 Hz; and bubble curtains that isolate the propeller and hull from the

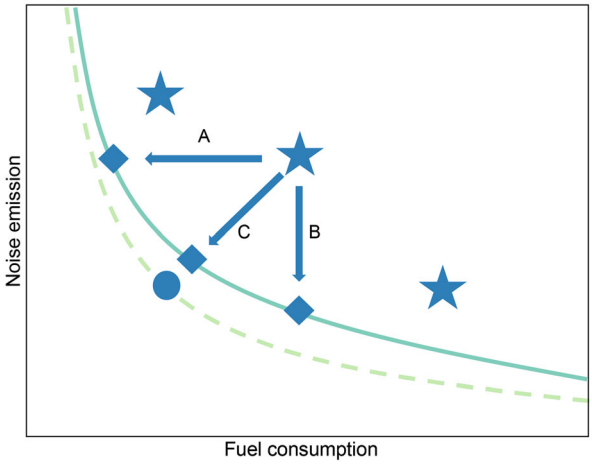

**Fig. 2** Trade-off between fuel efficiency and noise emissions illustrated in a Pareto-diagram for ships operating at their design speed. The solid line, the so-called Pareto front, describes the best possible combinations of fuel consumption and noise emission (for a constant speed). While it is possible to be inefficient in both parameters, i.e., high-fuel consumption and high-noise emission (stars illustrating three different ships poorly designed or maintained), vessels cannot go lower than the Pareto front (by definition). According to the Pareto front, the fuel consumption of a vessel can be reduced without additional noise emissions (as in A), the noise emission can also be lowered without additional fuel consumption (as in B), or any combination of these (as in C). However, once on the curve (diamonds), it is no longer possible to reduce one of the two without increasing the other. The only approach left to push back the Pareto front (broken line) is through innovation and new design approaches

surrounding fluid reduced the radiated noise of a cargo vessel travelling at 14 knots by 3 to 6 dB (AQUO 2015). These novel solutions could be applied to both new and retrofitted vessels but may be less popular than propeller or hull modifications as they are likely to require additional maintenance.

Underwater radiated noise is, to a lesser extent, generated by vibrations of onboard machinery (e.g., engine generators). In these instances, approaches to reduce noise have tended toward changing the engine type (e.g., 2- or 4-stroke diesel, steam/gas, hybrid, electric, etc.), isolating machinery from the vessel hull (e.g., elastic mounting, dampening) (AQUO 2015), or optimizing machinery placement in the hull (IMO 2014). In particular, the use of elastic mountings, where appropriate, can have a considerable effect, reducing noise outputs by up to 10 dB at low-frequencies and 20 dB at high frequencies (AQUO 2015). Such approaches may help to limit vibrational noise and could be used in combination with those that reduce cavitation noise to further reduce overall noise levels from commercial vessels.

Evidence clearly indicates that technological modifications can have a direct impact on underwater radiated noise produced by commercial vessels (Leaper and Renilson 2012; AQUO 2015), and consequently will result in fewer noise impacts to marine mammals. Furthermore, technological measures are advantageous as they

can reduce overall noise levels regardless of vessel speed, giving ship operators greater flexibility in lowering noise pollution while also balancing economic and time constraints placed on shipping. It is therefore anticipated that the shipping industry will adopt many of these ship-quieting technologies for future vessels operating within the global fleet. Even so, the implementation of ship-quieting technologies is expected to be expensive and complex, and less practical beyond the design stage (Spence and Fischer 2017). Consideration will therefore need to be given to the costs of implementing such modifications in existing vessels, as opposed to utilizing alternative (e.g., operational) measures to reduce the source levels of vessels.

## Operational Measures

Operational measures are predominantly viewed by the shipping industry as important techniques to increase energy efficiency (Holsvik and Williksen 2020). However, operational measures such as the maintenance of the hull and propeller, and speed reductions have been shown to also reduce radiated noise (McKenna et al. 2013; MacGillivray et al. 2019). These operational measures are an attractive approach for the industry as they require little effort to implement, few technological amendments to ship structures, and smaller investments compared to technical measures (Faber et al. 2011).

The regular maintenance of the propeller and hull of commercial vessels during the dry-docking process is an operational solution for reducing underwater radiated noise. Regular maintenance will maintain fuel efficiency, reducing overall fuel costs, while also reducing frictional resistance caused by biofouling. This allows vessels to reach greater speeds with less propulsive power and consequently produce less noise (Hilliard et al. 2014; IMO 2014; AQUO 2015). For example, regular maintenance to reduce biofouling was suggested to increase speed by 5% and reduce radiated noise by 1 to 2 dB (AQUO 2015), demonstrating that this is a simple and effective method for reducing noise which can be applied to all ships.

Underwater radiated noise increases with vessel speed, size and load (Ross 1976; Urick 1983; MacGillivray et al. 2019; MacGillivray and de Jong 2021). Extensive empirical observations indicate that radiated noise is proportional to the sixth power of speed for fixed pitch propeller vessels, and this reduction is approximately equal across frequency (Fig. 3) (Ross and Alvarez 1964; Ross 1976; MacGillivray and de Jong 2021). Accordingly, operational slowdowns of fixed pitch propeller vessels can be expected to achieve reductions in vessel source levels across a broad range of frequencies. In the case of controllable pitch propellers, this relationship is inconsistent (IMO 2014; Leaper 2019). Higher revolution rates can result in the emission of loud underwater noise even at low speeds, making operational slowdowns a less effective approach for this propeller type. Regardless, controllable pitch propellers make up only a small proportion of the global fleet (typically tugs, ferries and specialized vessels) (IMO 2014; Leaper 2019) and during higher speed transits, these vessels may perform more like fixed pitched propeller vessels.

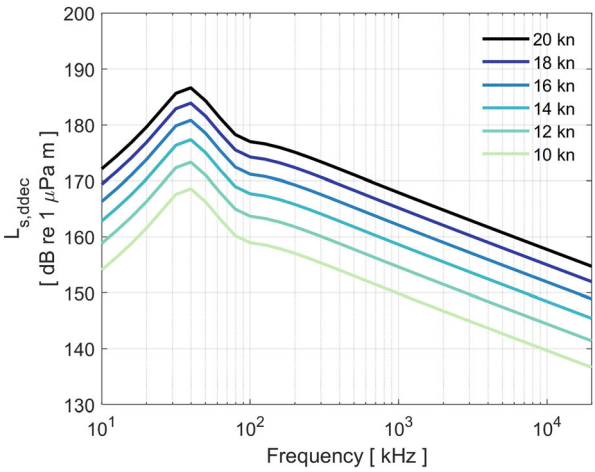

**Fig. 3** Example of the predicted decidecade source levels ($L_{s,ddec}$; dB re 1 µPa m) for a 300 m container ship with a fixed pitch propeller travelling at 20 knots and then 10% to 50% slower. (Source-level predictions are based on the latest vessel reference spectrum model (JOMOPANS-ECHO) (MacGillivray and de Jong 2021) (This figure has been adapted from Findlay et al. 2023)

Voluntary slowdowns to 11 knots as part of the Vancouver Fraser Port Authority Enhancing Cetacean Habitat and Observation (ECHO) program have illustrated that reductions between 11.5 and 5.9 dB can be achieved in the mean broadband monopole source levels of a variety of vessel classes, including container ships, cruise vessels, vehicle carriers, tankers and bulkers (MacGillivray et al. 2019). Further, the voluntary slowdown approach adopted during the ECHO program resulted in a 22% decrease in potential lost foraging time for the Southern Resident Killer Whale (*Orcinus orca*) population (Joy et al. 2019), demonstrating how slowdowns can simultaneously reduce fitness impacts to marine mammals inhabiting areas in the vicinity of high densities of ship traffic. Although the source level relationship with speed varies by and within vessel class due to differences in design and maintenance (Simard et al. 2016; Joy et al. 2019; MacGillivray et al. 2019), it is becoming increasingly clear that running at a lower operational speed is a broadly effective and immediate way to reduce the source levels of all vessels (IMO 2014; MacGillivray and de Jong 2021) and consequently, noise levels experienced by marine wildlife (Findlay et al. 2023).

Speed reductions are already used for economic reasons in commercial shipping when overcapacity in the market exists and when transport costs can be lowered by traveling slower than the vessel design speed (Jalkanen et al. 2018). Faber et al. (2017) suggested that a 10% to 30% reduction is feasible for most ship types, but this may require an increase in fleet capacity to maintain cargo throughput. This approach also has added benefits of reducing fatal ship-strikes (Silber et al. 2012; Laist et al. 2014), greenhouse gas emissions (Leaper 2019) and fuel consumption (Leaper and Renilson 2012; Cullinane and Cullinane 2013; Jalkanen et al. 2018; Leaper 2019), thereby helping the shipping industry to not only reduce underwater radiated noise but also reduce economic costs, meet climate targets set by the IMO (Khan et al. 2012; Cullinane and Cullinane 2013; Faber et al. 2017; IMO 2018;

Leaper 2019), and promote conservation efforts (Laist et al. 2014; Jalkanen et al. 2018; Leaper 2019).

Implementing coordinated slowdown policies to reduce underwater radiated noise from commercial vessels, especially at an international level, presents challenges (Merchant 2019). For example, a review of barriers to operational slowdowns notes that contractual clauses concerning demurrage (a charge payable by the ship on failure to load/discharge the ship within an agreed time slot) and laycan (delivery period for the cargo) often leads to vessels travelling at high speeds to meet delivery deadlines (Faber et al. 2011; Holsvik and Williksen 2020). Furthermore, complex ship traffic dynamics and geographic conditions may require ships to operate at certain speeds to maintain safety (IMO 2018). As a result, the adoption of slowdowns is likely to require coordination and collaboration between numerous stakeholders (e.g., government officials, the shipping industry, ports, vessel pilots, researchers, etc.) (AQUO 2015). Regardless, reducing the absolute (i.e., mandatory speed limits), or relative speed of vessels (i.e., percentage reduction of design service speed) (Faber et al. 2017), are effective and immediately implementable approaches to lower the amount of noise radiated by fixed pitch propeller vessels and reduce potential noise impacts to marine wildlife. Further, these operational and technological measures could be aided by the introduction of "noise labels" for individual ships (e.g., DNV 2010; Bureau Veritas 2014), able to denote louder ships which could be required to travel at slower speeds in areas known to be of importance to acoustically sensitive marine wildlife, or be targeted for technological modifications to reduce vessel source levels.

## Rerouting Measures to Reduce Vessel Noise Impacts to Marine Mammals

Commercial vessels travel along shipping lanes which provide the shortest and fastest routes between maritime ports (Hsu and Hsieh 2007; Jalkanen et al. 2022). Sea areas in proximity to these routes experience high levels of underwater radiated noise from shipping (Folegot et al. 2016; Farcas et al. 2020; Jalkanen et al. 2022), and changes to these routes have been shown to alter local underwater soundscapes. For example, an opportunistic study by McKenna et al. (2012) documented a rapid decline in noise along the California coast by 5.2 dB and 2.5 dB in the 40 and 90 Hz frequency bands, during the enforcement of a regional air-quality regulation zone (California Air Resource Board; CARB). Additionally, the rerouting of a major shipping lane in the Kattegat between Denmark and Sweden to increase maritime safety also resulted in significant and measurable changes to the regional soundscape in the 125 Hz decidecade frequency band (Tougaard et al. 2023).

The use of maritime spatial planning measures that consider ship traffic density, environmental conditions and local wildlife when establishing routes for commercial shipping could prove to be effective for reducing radiated noise in some areas (AQUO 2015). Shipping activity could, as an example, be concentrated or convoyed

along routes that avoid noise-sensitive areas or periods of high animal density (Laist et al. 2014; Chou et al. 2021; Ménard et al. 2022); or traffic could be diluted to homogenize vessel density and prevent the creation of high intensity noise hotspots (Erbe et al. 2012; Williams et al. 2015). Maritime spatial planning measures could also exploit bathymetric features along proposed shipping lanes, taking advantage of areas where the scattering of sound at the ocean surface and seafloor will be greatest, such as in shallow waters, or where natural features such as underwater canyons or islands will limit sound propagation (Urick 1983; Jensen et al. 2011; Etter 2018).

Studies have reported reductions in both noise impacts and the risk of lethal ship-strike impacts to marine mammals when vessels are rerouted. A voluntary lateral displacement of tugs and barges away from known feeding areas for Southern Resident Killer Whales resulted in an approximate 5 dB reduction in broadband noise, which included frequencies used for calls and echolocation (Burnham et al. 2021). The spatial and temporal rerouting of shipping lanes on the east coast of the United States to areas and periods outside of those known to be important for North Atlantic right whales (*Eubalaena glacialis*), combined with a speed limit of 10 knots, was found to result in reductions in noise levels and lethal ship strikes (Silber et al. 2012; Laist et al. 2014). Thus, increasing the distance between vessels and animals in both time and space, especially when combined with vessel speed reductions, can be expected to have considerable conservation benefits for marine wildlife.

Nevertheless, the efficacy of routing as a noise mitigation strategy is strongly dependent on the local sound propagation conditions (e.g., Tougaard et al. 2023); geographic and bathymetric constraints, especially in restricted waterways (e.g., rivers, channels, etc.); and the degree to which species under protection remain within well-defined areas. Speed reductions may therefore be more effective than routing measures to protect species with a broader or variable distribution, or if a change in routing to protect one species risks increasing the impact on another group of animals, in particular when rerouting vessels from shallow to deeper waters. Routing measures will therefore need to be considered on a case-by-case basis, and if possible, be combined with operational and/or technological modifications to further reduce overall noise levels at the source.

## Conclusions

Mounting evidence shows that vessel noise has detrimental effects on marine mammals that may culminate in population-level consequences. Global reductions in vessel radiated noise are therefore required to reduce the impact of commercial shipping activity to marine mammals and other acoustically sensitive marine species. Here, we highlight that technological, operational, and routing measures can be used by the shipping industry independently or synergistically to reduce both global cumulative noise levels from commercial vessels and potential impacts to marine mammals.

**Abstract**

Best Available Techniques/Technology (BAT) and Best Environmental Practice (BEP) are required under several international agreements. For shipping noise, this generally includes minimizing cavitation by optimizing the propeller design to the hull and to usual operating conditions, and better maintenance, which often also improve efficiency. Slow steaming, or reducing ship speed, has the advantage that no retrofitting is required, and greenhouse gas emissions are reduced. Quieter seismic airgun alternatives, such as Marine Vibroseis, a controlled sound source that can be tailor-made to the specific environmental conditions, can reduce the unnecessary mid- or high-frequency energy and sharp rise time of airguns. Mitigation measures for airgun surveys should show proof of efficacy, avoid sensitive areas and times, and not proceed in conditions of poor visibility such as at night. Quieting technologies would almost certainly require fewer mitigation measures. Especially many new quieting technologies and alternative low-noise foundations have been developed for pile driving, mainly due to governments like Germany setting noise limits. Application of quieting technologies that reduce sound at source will likely be the most effective way to reduce the environmental impacts of underwater noise, and quieting methods that also reduce greenhouse gas emissions or encourage technological innovation should be especially encouraged.

Quieting technologies · Underwater noise · Mitigation · Best available technology · Best environmental practice · Seismic airgun surveys · Shipping · Pile driving

## Introduction

The application of Best Available Techniques/Technologies (BAT) and Best Environmental Practice (BEP) to prevent and reduce marine pollution is a requirement under several international agreements and conventions, e.g., under the Convention on Migratory Species (CMS) and the Convention on Biological Diversity (CBD). Regional agreements, such as the Convention for the Protection of the Marine Environment of the North-East Atlantic (OSPAR Convention) and the Convention on the Protection of the Marine Environment of the Baltic Sea Area (Helsinki Convention), as well as species-focused regional agreements, including the Agreement on the Conservation of Cetaceans in the Black Sea, Mediterranean Sea and Contiguous Atlantic Area (ACCOBAMS) also require BAT and BEP.

In this report, the term "best" is used as in Best Available Technology and Best Environmental Practice, to denote what is best, possible, realistic, and practical now, with the choices we have at present. These recommendations, however, are still just steps toward what is truly "best" and require ongoing adjustment and innovation to achieve more substantial reductions in the harmful effects of noise on the marine environment and species therein. "Best" here should not be misconstrued to mean the ideal for restoring ocean health.

## BAT for Shipping Noise

### Noise Levels

Hildebrand (2009) noted that peak spectral levels for individual commercial ships of around 195 dB re $\mu Pa^2$/Hz at 1 m (for fast-moving, >20 knots, supertankers) occur in the frequency band of 10 to 50 Hz. A 173-m-long cargo vessel traveling 16 kts registered a source level of 192 dB dB re 1 μPa at 1 m over a bandwidth of 40–100 Hz (Hildebrand 2009). Shipping noise is not restricted to only low frequencies, though. Shipping noise can extend into the high kilohertz (kHz) range, particularly at close ranges and in shallow water. Findlay et al. (2023), for instance, note that noise from a container ship extended into the 20 kHz range. Vessel noise from various ship types substantially raised noise levels over the whole recording band from 25 Hz to 160 kHz at ranges between 60 and 1000 m (Hermannsen et al. 2014). The study estimated that such noise levels resulted in a hearing range reduction in the harbor porpoise (*Phocoena phocoena*) of more than 20 dB (at 1 and 10 kHz) from ships passing at distances of 1190 m, and more than a 30 dB reduction (at 125 kHz) from ships at 490 m distance or less (Hermannsen et al. 2014). Such a hearing range reduction (20–30 dB) represents a 100- to 1000-fold reduction in intensity.

## Impacts

Rolland et al. (2012) found that shipping noise is associated with increased stress levels in endangered North Atlantic right whales (*Eubalaena glacialis*). Broadband ship noise caused a significant change in beaked whale movement during foraging over a distance of at least 5.2 km, which could reduce their food intake (Pirotta et al. 2012). Putland et al. (2018) found that routine vessel passages shrank communication space by up to 61.5% for bigeye fish (*Pempheris adspersa*) and 87.4% for Bryde's whales (*Balaenoptera brydei*) and by up to 99% for both species at a large commercial vessel's closest point of approach. Nedelec et al. (2015) exposed larval Atlantic cod (*Gadus morhua*) to shipping noise in the laboratory and discovered they were easier to catch in a predator-avoidance experiment and in worse condition. Shipping noise playbacks increased stress indicators in European perch (*Perca fluviatilis*), common carp (*Cyprinus carpio*), and gudgeon (*Gobio gobio*) (Wysocki et al. 2006), European seabass (*Dicentrarchus labrax*) and gilthead sea bream (*Sparus aurata*) (Buscaino et al. 2010; Celi et al. 2016), juvenile European eels (*Anguilla anguilla*) (Simpson et al. 2015), and shore crabs (*Carcinus maenas*) (Wale et al. 2013). Bluefin tuna (*Thunnus thynnus*) schools became more uncoordinated with shipping noise, something that could compromise their homing accuracy during migration (Sarà et al. 2007).

Excessive underwater shipping noise is mainly the result of (a) poor propeller design or one not optimally matched to the vessel and its usual operating conditions; (b) poor hull design particularly of the aft end of the ship, which causes an uneven water flow into the propeller (poor wake field); or (c) a fouled (dirty) or damaged propeller. When a propeller is especially noisy, it probably signifies a ship operating inefficiently. Existing ships can solve these issues by installing newer, more efficient propellers, maintaining them well by cleaning and repairing damaged ones, using wake flow devices that improve the flow into the propeller, and maintaining the hull well.

## Propeller Cavitation

A major source of shipping noise is propeller cavitation, a hissing noise caused by the formation and collapse of air bubbles on the rotating propeller's surface when the pressure falls below the water vapor pressure. Cavitation is broadband, across a wide range of frequencies, but has narrowband or tonal noise peaks related to the rotation rate (rpm) multiplied by the number of propeller blades and the harmonics thereof. The lowest speed at which cavitation begins is called the cavitation inception speed (CIS). CIS occurs around 10 kts or even lower for many ships (Leaper and Renilson 2012). While some cavitation occurs even with efficient propellers, excessive cavitation from the noisiest ships is a sign of possible inefficient operation, with poor wake flow into the propeller and/or poor propeller design (Leaper et al. 2014). If noise from one noise source is 10 dB louder than other sources of noise, then the quieter noise sources are mostly irrelevant

(McCauley et al. 1996). For the noisiest merchant ships, the noise from propeller cavitation is likely to dominate all other noise sources from that ship (IMO 2013). Cavitation noise also dominates other propeller noise, apart from singing (high-pitched notes), and is louder than all other hydroacoustic noise from a ship (Ligtelijn 2007). Propeller singing is easy to remedy by altering the shape of the trailing edge (Leaper and Renilson 2012).

## Overlap Between Increased Energy Efficiency and Noise Reduction

As explained by Leaper and Renilson (2012), a greater blade area can produce the same thrust but with a smaller difference in pressure between the blade's face (pressure side) and the back (suction side). Since cavitation is caused by the difference in pressure, a greater blade area reduces cavitation. Unfortunately, the torque needed to turn the propeller is larger with this greater blade area. There is an optimum design for efficiency in merchant ships that is a trade-off between cavitation and blade area. Generally, one must tolerate some cavitation to design an optimally efficient propeller, so as to minimize blade area and reduce the necessary torque to turn it. The goal, however, is to reduce *excessive* cavitation that can lessen the thrust and cause erosion on the propeller and, in some cases, even on the rudder (Leaper and Renilson 2012). It is likely, by some estimates, that a 5–10 dB reduction in noise can be achieved before there is a loss in efficiency, though, depending on the specific circumstances. This degree of quieting (5–10 dB) would diminish the acoustic footprint of ships appreciably and substantially improve the quality of the marine environment. The amount of quieting necessary to make a difference in reducing environmental degradation is relatively modest, not on the order of that required of stealthy naval vessels.

Improved wake flow around the hull ahead of the propeller, the other major factor in reducing cavitation, will both reduce noise and improve efficiency. The goal is that the propeller, as it rotates through its full circle, does not encounter much of a difference in flow, i.e., a uniform wake field. A nonuniform wake, in contrast, can diminish propulsive efficiency and cause cavitation to fluctuate through the rotation cycle, producing tonal noise and its harmonics. Hull shape also affects the wake going into the propeller (Chris Waddington, pers. comm.). The bulbous stern is designed to provide clean flow into the propeller, thereby reducing cavitation and the noise from it (Chris Waddington, pers. comm.). Designs for new build ships should be evaluated using appropriate modeling techniques to optimize the propeller and hull configuration in consideration of underwater radiated noise (URN). Similar modeling may also assist with retrofitting existing ships with optimized propellers or wake flow devices.

Ideally, propellers should be clean, free of fouling, well maintained, and polished, with no nicks or imperfections, particularly on the leading edge (Leaper and Renilson 2012). Leaper and Renilson (2012) note that such damage can cause more cavitation, reduce efficiency by around 2%, and cause noise. At each dry docking of a vessel, propellers should be assessed and repaired for any damage that

might make it noisier. Well-built and well-designed propellers can improve efficiency and reduce noise. To produce an optimal wake field, the propeller and hull should be designed as a unit. Designing propellers and hulls to the actual operating conditions, rather than the ideal, would improve propulsive efficiency and reduce noise (Leaper and Renilson 2012).

Leaper and Renilson (2012) state that propellers can generate vortices from their hub that reduce efficiency and are prone to cavitate, as well as cause higher-frequency noise. Efficiency gains and noise reduction can be achieved by well-designed hub caps along with devices that can be affixed to the hub such as Propeller Cap Turbines (Leaper and Renilson 2012).

Wake flow optimization is always most effective if done at the design stage, but there may be scope for minor modifications for existing vessels with less-than-optimal wake flow. To improve the wake going into the propeller, wake inflow devices can be employed, which reduce cavitation, likely increasing efficiency while reducing noise. Schneekluth duct, Mewis duct, and Grothues spoilers are such devices that can be fitted to the hull for this purpose (Leaper and Renilson 2012).

There is certainly overlap between noise reduction, and increased fuel efficiency and reduced greenhouse gas emissions. In 2009, the International Maritime Organization (IMO) recommended that member states should identify which of their commercial vessels would benefit most from efficiency-improving technologies since these would also probably quiet their ships as well (IMO 2009). It would be a missed opportunity not to address noise at the same time as fuel efficiency and greenhouse gas emission reduction. Small changes in propulsive efficiency could dramatically lower noise output (Leaper and Renilson 2012).

## Hull Vibration, Engine, and Machinery Noise

The main treatments to reduce noise and vibration to the hull from onboard machinery are vibration isolation, noise insulation, and damping. Onboard machinery can generate tonal sounds but generally less broadband sound energy than propeller noise.

## Onboard Real-Time Noise Monitoring

Giving ship operators immediate feedback about which operating conditions (e.g., trim) are generating the most noise and cavitation could be useful. This could be achieved through a real-time noise or cavitation monitoring system using onboard sensors for both engine and propeller noise. For real-time onboard monitoring of propeller noise, sensors could be mounted near the propeller. The operator would thus be informed which conditions alter the cavitation inception speed or change the noise output. Studies underway as part of the Saturn project (https://www.saturnh2020.eu/) will provide detailed comparisons of measurements from onboard sensors and underwater radiated noise levels.

## BEP for Shipping Noise

### Slow Steaming to Reduce Noise

The practice of operating transoceanic merchant ships, especially container ships, at considerably slower speeds than maximum, mainly to save fuel, is known as slow steaming. A big advantage of slow steaming is that no retrofitting is required so it can be implemented immediately. Most ships use fixed pitch propellers [controllable pitch propellers were only used in 10% of tankers, 1% of bulk carriers, and 9% of container ships in 2000–2004 (Carlton 2007)], and for these, slowing down reduces the overall noise across all frequencies (Findlay et al. 2023). Even vessels with controllable pitch propellers, such as tugs and ferries, perform like fixed pitch propellers at higher speeds (Findlay et al. 2023). Slow steaming since 2007 reduced average speeds from 15.6 kts (sd = 4.2) in 2007 to 13.8 kts (sd = 3.0) in 2013 in the major eastern Mediterranean shipping routes (Leaper et al. 2014). Leaper et al. (2014) estimate that this 11.5% slowdown probably reduced the overall broadband acoustic footprint from these ships by over 50%. In the Haro Strait (between Seattle and Vancouver), 3 dB of overall noise reduction (i.e., a 50% reduction in sound energy) could be achieved by enforcing a vessel speed limit of 11.8 knots (Veirs et al. 2018). The mean ship speed across all classes was 14 kts; the mean for container ships alone was 19 kts. Slower ships due to COVID-19 resulted in less ocean noise pollution (Dunn et al. 2021). Vessel speed was highly correlated to sound pressure level (SPL) of the noise. A 2-month-long trial (MacGillivray et al. 2019) where ships slowed down to 11 knots showed that slowing down was an effective method for lowering mean broadband noise source levels for 5 categories of piloted commercial vessels: containerships (11.5 dB), cruise vessels (10.5 dB), vehicle carriers (9.3 dB), tankers (6.1 dB), and bulkers (5.9 dB).

Some argue that slower vessels generate overall more noise over time [larger sound exposure levels (SELs)] because they remain in an area for longer. This is incorrect, though, since underwater radiated noise (URN) is correlated with the sixth power of speed (Leaper 2019), a very steep curve, and time is just linear, so slower ships will produce lower SELs in addition to lower sound pressure levels (SPLs). Findlay et al. (2023), using modeling, also conclusively demonstrated that when animals were exposed to slower vessels, not just the maximum received level but also the exposure duration were reduced. Additionally, the rate of increase of noise as ships approached was slower, likely causing ships to be perceived as less alarming by animals.

### Slow Steaming to Reduce Noise and Co-benefits with Greenhouse Gas Emission Reduction

Slow steaming across shipping fleets is also an effective short-term measure to cut greenhouse gas (GHG) emissions. In April 2018, the IMO adopted the goal of reducing the total annual GHG emissions by at least 50% by 2050 relative to

2008. To achieve this, the IMO introduced various carbon dioxide reduction measures that could drive a reduction in vessel speed and, thus, noise reduction. The Energy Efficiency eXisting ship Index (EEXI), applied after January 1, 2023, is a technical design-related measure for existing ships above 400 gross tons. Many vessels could achieve compliance by adopting overridable power limitations, i.e., they will slow down (Chris Waddington, pers. comm.). The Energy Efficiency Design Index (EEDI) provides a new building standard, ensuring that ship designs achieve a particular level of efficiency and decrease carbon emissions. It was introduced for new vessels of 400 gross tons and above, in 2013. Ships must meet the reference level, which is tightened every 5 years, for their ship type. Ship owners can select the efficiency measures they deem as most appropriate, which may include speed reduction (Chris Waddington, pers. comm.). Unlike EEDI and EEXI that are design indices, the Carbon Intensity Indicator (CII) is an operational measure that must be reported annually. It is a nonprescriptive measure of how efficiently a ship transports goods or passengers, given in grams of carbon dioxide emitted per cargo-carrying capacity and nautical mile. From January 1, 2023, onward, it applied to new and existing ships above 5000 gross tons. Whether or how much these measures will reduce overall vessel speeds and consequent underwater noise has yet to be fully assessed. This will partially depend on ongoing discussions within the IMO on ways to reduce GHG emissions. Rutherford et al. (2020) found that most ships are being operated at engine loads that would be unaffected by the technical efficiency standard the EEXI sets, and thus EEXI requirements may not result in substantial speed reductions. However, speed reduction can be a very effective way to reduce emissions, so some ship owners may adopt further speed reductions beyond those possibly adopted for EEXI compliance (Chris Waddington, pers. comm.). It has been further proposed that an overridable power option be available for EEDI compliance (new ships). This is the same overridable power option that can be used for EEXI compliance (existing ships). If adopted, this could bring about further speed reductions of new vessels (Chris Waddington, pers. comm.).

Leaper (2019) reviewed modeling work on GHG emissions and its relationship to underwater noise, ship-whale collision risk, and ship speed. He factored in research which considered that slow steaming would increase the number of ships needed to transport the same volume of goods, the cost of operating those extra vessels, and the increase in ship construction that might be necessary. Faber et al. (2017) examined speed reductions of 10, 20, and 30% compared to "business as usual." They determined that in 2017, 3.5% of container vessels were idle or laid up and estimated that bringing these vessels back into service would allow the container fleet to reduce speeds by 8% (Faber et al. 2017). Speed reductions of greater than 10% would probably require an increase in fleet capacity to meet current demand (Leaper 2019). Following an economic model developed by Lee et al. (2015), the savings in total fuel consumption from slow steaming was usually higher than the cost of operating the extra vessels necessary to transport equivalent goods. Slowing down also had business advantages beyond saving fuel in that it increased delivery time reliability (Lee et al. 2015). Leaper (2019) examined various speed reduction scenarios that would help achieve the GHG reduction targets while simultaneously providing the

additional environmental benefits of reducing noise and the risk of ship strikes on whales. Leaper (2019) concluded that modest, 10%, reductions in speeds across the global fleet could reduce the total sound energy produced by shipping by around 40%.

When slow steaming, the propellers and hull should be redesigned for this operational difference, especially controllable pitch propellers (Leaper and Renilson 2012). Controllable pitch propellers are fairly rare in the long-distance commercial fleet, but considering noise from such propellers may be important in localized situations, for example, where CPPs are fitted to ferries.

While slower speeds with the same fixed pitch propeller will substantially reduce noise levels because cavitation will be reduced, it is more complicated if the propeller is optimized for slower speeds for fuel efficiency, since optimizing for fuel efficiency may involve reduced blade area and accepting a greater amount of cavitation. Optimizing for fuel efficiency is of primary importance, but noise should still be considered so as not to inadvertently increase it by modifications, if at all possible. If there are options that can improve efficiency yet not increase noise, those should be prioritized.

## Vessel Load Condition

Propellers are generally designed for vessels under full load, despite ships not spending all their time in this state (Leaper and Renilson 2012). The ship is never loaded close to its full load condition when in ballast, which means the propeller is closer to the surface. The propeller tip may even be above the waterline. Cavitation on a propeller can be increased in ballast because of the lower water pressure on the blades, despite reduced propeller loading (Paik et al. 2013). Moreover, a ship in ballast is usually trimmed by the stern, which worsens the wake field to the propeller, causing yet more cavitation (Leaper and Renilson 2012). As a result, a tanker or bulk carrier in ballast will often be noisier than one in full load (Leaper and Renilson 2012). Installing air injection to a propeller in ballast conditions or Ship Trim Optimization software could help rectify this problem. The development of onboard sensors (see section "Onboard Real-Time Noise Monitoring") that can give a reliable indication of underwater noise may also assist in adjusting vessel trim.

## Cold Ironing

Using a shoreside electrical power connection when a ship is at berth in port while its main and auxiliary engines are turned off is known as cold ironing. It is also called shore-to-ship power (SSP) or alternative maritime power (AMP). Cold ironing is clearly quieter, with fewer emissions. Cold ironing may also reduce biofouling on ship hulls. Multiple studies have shown faster settlement of mussel larvae (*Mytilus edulis*) or other biofouling organisms with generator or ship engine noise (Wilkens et al. 2012; McDonald et al. 2014; Stanley et al. 2014; Jolivet et al. 2016). Only one

study showed a low-frequency sound inhibiting only very young barnacle larvae (*Balanus amphitrite*) from settling (Branscomb and Rittschof 1984). The US Navy spends about US$1 billion annually and US$56 million per single Navy vessel class on biofouling (McDonald et al. 2014), so reducing biofouling can save money as well as reduce noise (biofouling increases turbulence), increase efficiency, and even avoid the spread of invasive species on hulls. Biofouling on ship hulls can be responsible for at least 75% of the invasive species brought in by vessels (McDonald et al. 2014). A clean ship entering a port infected with invasive species and running a generator could attract pest species from around a 500 m radius (McDonald et al. 2014).

## Acoustic Anti-biofouling Systems

Acoustic antifouling use has increased steeply in the last few years. It is a concern as it is likely very damaging to beaked whales and other cetaceans. This technology has been available since about 2007–2012, but only recently (since around 2022) has it become ubiquitous. Legg et al. (2015), reviewing various acoustic antifouling systems, concluded that around 20 kHz is optimal to reduce the settling of most invertebrates. Most systems operate between 17 and 30 kHz. These devices elevated received levels by 40 dB in the 20–30 kHz range (Martin et al. 2022). Their median energy source level (0.1 s) was 183 dB re 1 $\mu Pa^2s$. High-frequency sensitive cetaceans were estimated to be disturbed at ranges of 3 km, with potential to quickly cause temporary or permanent hearing damage. There was an almost complete listening range reduction for high-frequency echolocation up to 5 km, lasting 25 min for a vessel traveling 14 kts, with a hull-mounted device (Martin et al. 2022). Trickey et al. (2022) found tourist vessels with hull-mounted ultrasonic antifouling devices caused clear avoidance by Cuvier's beaked whales (*Ziphius cavirostris*). These devices started at a frequency of 19 kHz, ranging up to 42 kHz or more, with a transmission range of over 2 km.

## Maintenance

Keeping the hull and propeller clean and repaired can yield cost savings, efficiency gains, and noise reductions. Other onboard machinery and engines will almost certainly be quieter and more efficient when well maintained. Proactive in-water ship hull grooming, where the hull is cleaned before it is badly fouled, can also help with both reducing noise and increasing efficiency (Swain et al. 2022). An analysis of how common fouled vessels are and the additional drag associated with fouling (Munk et al. 2009) showed that around 50% of vessels may need an extra 30% of power to maintain cruising speed. Using the observed relationships between underwater radiated noise (URN) levels and engine power (Leaper 2019), an increase in required power of 30% would likely produce an increase in URN of 2.3 dB. Since

Munk et al. (2009) found that around 17% of vessels had an increased drag of greater than 50%, URN levels would probably increase by more than 3.5 dB. These raised URN levels would greatly increase the number of animals unnecessarily affected. The rate of fouling can vary considerably between areas and the operational pattern of the vessel. The degree of fouling should be regularly assessed so that vessels can be cleaned as soon as fouling is likely to measurably worsen drag.

## Port Incentives

Since January 1, 2023, the Vancouver Fraser Port Authority through its EcoAction Program introduced a discount of up to 75% off harbor dues for ships that are certified as quiet vessels by an international ship classification society, such as American Bureau of Shipping (ABS), Bureau Veritas (BV), Det Norske Veritas Germanischer Lloyd (DNV), Lloyd's Register (LR), and Registro Italiano Navale (RINA). The Port of Prince Rupert has a similar program. Best practice for measuring and certifying noise from ships might be a combination of various methods such as computational predictions validated by onboard measurements over a range of speeds, with perhaps one or two at-sea verifying measurements. Such quieter ship incentives should be expanded to other ports worldwide to create a level playing field.

## Underwater Noise Management Plans

Underwater noise management plans can be developed for individual vessels or for all vessels using a particular area. Transport Canada, for example, has encouraged Canadian vessel operators to have plans to reduce their fleet's overall noise output. Noise management planning represents the development of a plan to reduce URN and achieve URN goals. Plans should include measuring a noise baseline, setting a goal or target, and defining operational, organizational, and technological measures to reduce noise. Measures should repeatedly be evaluated to determine their effectiveness. Such noise management plans should become mandatory, as should the targets.

A 5-grade scale (A–E, similar to the Carbon Intensity Indicator) could be developed for URN, given this approach is familiar to the industry. Depending on the rating received during an annual review, the ship could be required to install design upgrades or conduct substantial operational improvements. Each ship could be evaluated for its URN and guidance given on how to make it quieter. The focus here would not be to meet a particular noise target, but rather to make each ship as quiet as possible within the scope of its operational requirements and size, as per the noise management plan for that vessel. This would allow ships to understand the extent of measures that they should consider, to reduce URN to less adverse levels. The hope is also that it would direct attention to the noisiest ships first.

### Focus on the Noisiest Vessels

It is challenging to set source-level standards for each vessel type. Focusing on the noisiest vessels aims to achieve the most benefit with the least economic impact, as the noisiest vessels will likely be operating inefficiently. Differences of 20–40 dB have been reported between the quietest and noisiest ships of a similar type (Carlton and Dabbs 2009). Leaper and Renilson (2012) estimated that the noisiest 10% of ships (those that are 6.8 dB or more over the average) contribute to 48–88% of the total acoustic footprint (the area over which the ship noise increases the background noise over a certain level). Similarly, Veirs et al. (2018) found that, of 1582 ships measured in the Haro Strait between Seattle and Vancouver, half of the total power radiated by this modern fleet came from just 15% of the ships – those with source levels above 179 dB re 1 μPa at 1 m. More than two-thirds of these worst noise polluters were cargo and container ships (Veirs et al. 2018). About 43% of container ships were worst polluters, by far the highest proportion of any ship class of those studied (Veirs et al. 2018).

## BAT for Seismic Airgun Survey Noise

### Noise Levels

An airgun array has a nominal source level of around 260 dB re 1 μPa at 1 m (SPL), with a bandwidth of 5–300 Hz (Hildebrand, 2009). While the energy from airgun impulses is mostly concentrated in the lower frequencies, there is still substantial energy in the tens of kHz to even over 100 kHz (Goold and Coates 2006).

### Impacts

Fin whales (*Balaenoptera physalus*) were displaced from their habitat at the beginning of a seismic survey, and the displacement continued well beyond the 10-day length of the seismic survey (Castellote et al. 2012). Bowhead whale (*Balaena mysticetus*) calling was repressed within a 50–100 km radius of a seismic survey, representing 8000–30,000 sq. km in area. Bowhead calling was almost entirely absent within 10–40 km of the seismic survey or 300–5000 sq. km (Blackwell et al. 2015). Pirotta et al. (2014) found that the probability of recording a prey capture attempt by harbor porpoise declined by 15% in the 25 km x 25 km area exposed to seismic survey noise. Prey capture probability increased the further away the seismic vessel was. Seismic airgun noise killed zooplankton, especially immatures, with a 2–3-fold increase in dead zooplankton at ranges of up to 1.2 km from the airguns (McCauley et al. 2017). Day et al. (2017) discovered a fivefold increase in scallop (*Pecten fumatus*) mortality when subjected to four passes of an airgun. These effects occurred 4 months after airgun noise ceased. Southern rock lobsters (*Jasus edwardsii*) showed a chronic reduction of immune competency and

impairment of nutritional condition, also 120 days post-airgun exposure (Fitzgibbon et al. 2017). Lobsters also showed significant damage to sensory organs, impairing important reflexes, even a year post-exposure to an airgun (Day et al. 2019). Catch rates for haddock (*Melanogrammus aeglefinus*), cod, and rockfish dropped from 21 to 70% (Engås et al. 1996; Skalski et al. 1992) during or after seismic airgun surveys. Declines in fish abundance were also documented (Slotte et al. 2004; Paxton et al. 2017).

## Lowering Source Levels and Reducing High-Frequency Content

According to Leaper et al. (2015), there are seldom cases where mitigation based on visual observation can achieve a greater risk reduction than would be achieved by a 3 dB reduction in source level throughout the survey. This is because visual observation is of limited value since Marine Mammal Observers (MMOs) miss spotting many marine mammals and turtles as they are cryptic, elusive, and often underwater and because survey activities often take place at night and in other limited-visibility conditions. The use of MMOs therefore only results in a limited risk reduction in all cases (Leaper et al. 2015). Therefore, the most effective mitigation for seismic airgun surveys is probably to (a) separate the surveys from areas or times rich in marine life and sensitive species and (b) to lower the source level (quiet the noise). Seismic operators should be required to develop a detailed plan describing how they will keep sound levels to a minimum, including calculations of the minimum required levels to meet survey objectives, how these will change within the survey area and with different weather conditions, and how the survey equipment will be configured to ensure only the minimum sound level is generated. If a 3 dB reduction in source level makes a great difference to the quality of the seismic data, then more controllable sources [e.g., Marine Vibroseis™ (MV), see below] rather than airguns are essential to adapt real time to different conditions. Otherwise, seismic operators must use the source level that applies to the most difficult conditions expected during the survey, which may be much higher than is needed most of the time. This is wasteful and adds more environmental risk than is necessary.

As previously stated, there is still considerable energy in the tens of kHz from airguns, extending even to over 100 kHz (Goold and Coates 2006), which explains why cetaceans with middle- or higher-frequency sensitivities react to the noise (Goold and Fish 1998). Geophysicists do not make use of, nor even record, any energy over about 200 Hz, however. This wasted energy therefore needlessly impacts marine life, especially animals with mid- or high-frequency hearing. There is currently considerable effort being expended by several companies to develop alternative marine seismic sources that are expected to have a reduced environmental impact while being at least as effective as airgun arrays. Improvements in receivers have also allowed for quieter sources. It is challenging to get more information on technological alternatives to airguns, as much is proprietary and still under development.

Several industry players have developed alternative pneumatic marine seismic sources that aim to limit bandwidth, increasing low-frequency content (Brittan et al. 2020) while reducing higher-frequency output. Pneumatic sources have been physically modified to reduce the high-frequency content generally by slowing the release of the air (Coste et al. 2014; Supawala et al. 2017; Tellier et al. 2021). Placing elements close to one another in a "cluster" can also help to produce a larger low-frequency peak output (Hopperstad et al. 2016). These various methods can result in substantial reductions in the signal strength at high frequencies (Brittan et al. 2020; Li and Bailey 2017; Tellier et al. 2021).

Teledyne Marine's eSource™ airgun, developed by Bolt Technology Corporation and WesternGeco and Sercel's Bluepulse™, release air more gradually than the conventional airgun, reducing or attenuating the higher frequencies. The advantage of this alternative is that it does not require any retrofitting of the seismic vessels, as MV does, and can be used as a conventional airgun. The disadvantage is that the approach may be too piecemeal and not comprehensive enough, as other potentially damaging characteristics of airgun pulses (e.g., higher source level and sharper rise time than MV) remain, though rise time is slowed and the SEL, energy over time, is lower. They are also not controlled sources.

The SERCEL TPS (Tuned Pulse Source) is an impulsive pneumatic source with a slower rise time than a conventional airgun. The spectral output is mostly at frequencies under 10 Hz. TPS is 13x quieter in maximum SPL than a conventional airgun array. The frequency at which the source signal gets lost in the background noise is at 140 Hz for TPS vs. 1 kHz for airguns, at 15 km distance. TPS can work as a stand-alone survey even without being supplemented by higher-frequency sources, unlike very low-frequency (1–2 Hz imaging) sources such as Wolfspar™. TPS has been used commercially (Ronen 2022).

## Marine Vibroseis™ (MV)

Another principle is to replace the short, high amplitude, wide frequency-bandwidth signal produced by an airgun array with a much longer duration, lower-amplitude signal, with the same acoustic energy in the frequency band required for the seismic survey (below 200 Hz and sometimes below 120 Hz). To be useful, the signal would have the same energy, just spread over a longer duration, allowing for a lower source level and less wasted energy at frequencies that are not used. The effectiveness of a signal for seismic imaging is solely determined by the signal's energy and bandwidth, so a longer, quieter signal should be just as effective as a shorter, louder one provided they have the same energy and cover the necessary frequencies. The quieter signal should reduce the risk of damage to an animal's hearing at short range.

Marine Vibrator™ (MV) systems are technically not commercially widely available yet and thus could not truly be called a Best Available Technology. This is despite the fact that MV has been in development since 2008 and yet has made slow progress. Still, this technology remains promising. If regulators were to insist on the use of quieter alternatives to airguns, these would be available very quickly, but

regulators feel they cannot require a technology that is not available yet, so it becomes a Catch-22. Moreover, seismic operators do not feel like regulations to pursue quieter technologies are incentivized and are even penalized. Seismic vibrators have been used successfully in land-based seismic exploration for many years. In 2009, when the Okeanos Foundation held a workshop on more environmentally friendly seismic airgun alternatives, the 16 participants (geophysical scientists, seismologists, biologists, and regulators) concluded that controlled sources such as marine vibrators probably offer the best chance at eventually replacing airguns (Weilgart 2010).

Tenghamn (2006) introduced a completely new electromechanical MV concept, using frequencies from 6 to 100 Hz. MV is a scalable source, and output level can be adjusted in real time to environmental and operational conditions (Pramik 2013). MV output can be altered by changing (a) the number of vibrators used in the array (more difficult with airguns due to undesirable acoustic side effects), (b) the output level, and (c) the length of the sweep (Pramik 2013). The emitted frequency band, phase, amplitude (loudness – SPL), or energy over time (SEL) can be selected, something largely impossible for airgun surveys. The controllable nature of MV could also bring advantages in signal processing. Phase and amplitude control could allow for more effective reduction in residual noise and allow sources to improve the reconstruction of the wavefield between source lines with less shots acquired and faster acquisition. Additionally, MV produces no cavitation. The initial capital cost of the MV array is large, but the operational cost is similar to airguns, with geophysical and operational benefits (Jenkerson 2022). MV works best from 5 to 100 Hz.

TotalEnergies, ExxonMobil, and Shell have sponsored the Marine Vibrator Joint Industry Project (MV JIP) since 2011, supporting the development of three separate marine vibrator technologies. Currently, the MV JIP is working exclusively with APS to develop and commercialize the Integrated Projector Node (IPN) powered by an electromagnetic system.

The only MV technology to have acquired seismic data as part of a pilot project is the HUP104 unit developed by Mobil, Total, and Geco in 1996 at Schooner Bayou, Louisiana, and the SAE developed Aquavib™ Marine Vibrator, which acquired a series of 2D lines in Louisiana (Pramik et al. 2015) and east offshore Malaysia in 2019. The Aquavib™ technology is currently in production targeting transition zones. It works better than airguns in water depths less than 5 m. BASS (Broadband Acoustic Seismic Source) MV is a hydraulic-based system developed by Shearwater, supported by the Norwegian Research Council and Equinor.

Most airgun arrays have an effective source level of 255 dB (0-p) re 1 μPa at 1 m in the downward direction, compared with a MV array of about 223 dB rms re 1 μPa at 1 m (Bird 2003) or 226 dB (0-p). Since the decibel scale is logarithmic, MV has a peak pressure that is a factor of 28 lower than that of an airgun array. LGL and MAI (2011), through modeling, estimated that a MV survey would expose only about 1–20% of whales and dolphins to $\geq$180 dB re 1 $\mu Pa_{rms}$ when compared to those exposed to an airgun survey. Matthews et al.'s (2021) modeling comparison of potential impacts on marine mammals from MV vs. airgun noise also concluded

that injury was less likely from MV arrays. High peak pressure and sharp rise time or onset (sounds quickly increasing in amplitude), both of which describe airgun emissions, are two characteristics of sound thought to be particularly injurious to living tissues (Southall et al. 2007). Southall et al. (2007) believed a non-impulsive sound such as MV would have to be 12–17 dB louder than an airgun-like impulse to be as injurious, due to the damage inflicted by the sharp rise time. Duncan et al. (2017) modeled sound levels from a realistic MV array and airgun array with similar downward energy at frequencies <100 Hz and compared the two under various scenarios. MV was 20 dB lower in peak-to-peak sound pressure level vs. the airgun array at 100 m range, decreasing to 12 dB lower at 5 km, the maximum modeled range for peak levels (Duncan et al. 2017). MV also produced 8 dB lower SELs than the airgun array at 100 km range because of MV's reduced bandwidth (Duncan et al. 2017). There are thus benefits to MV even at long ranges and even for animals with good low-frequency hearing. Duncan et al. (2017) also found that changing the layout of the MV array's higher-frequency sources reduced SELs by 4 dB. MV's lower sound exposure level advantage is most obvious in shallow water, as SELs drop off more rapidly in these waters. Moreover, shallow waters are often the most productive and biologically rich, in need of more protection.

In summary, Duncan et al. (2017) listed the main benefits of MV over airguns as:

- Lowering peak pressure (sound level) over short ranges
- Eliminating sharp rise time
- Eliminating unnecessary middle and high frequencies
- Lowering sound exposure levels for distances of over 10 km
- Allowing for greater control and tailoring of the signal (amplitude, frequency, duration, etc.) in real time
- Operationally superior in shallow water and transition zones

Therefore, MV shows potential in providing an environmentally safer alternative to airguns without compromising effectiveness for seismic exploration. MV surveys were predicted to cause less impact (behavioral, physiological, auditory) than airgun surveys in all habitats and environments regardless of water depth or environmental conditions (LGL and MAI 2011). The roughly 20 dB reduction in short-range peak-to-peak SPLs decreases the safety or exclusion zone radius by about a factor of 10, which converts to a reduction in safety zone area of around a factor of 100, exposing far fewer animals to potentially injurious noise.

The greatest disadvantage of MV compared with airguns is the greater potential for masking, since the MV signal is of longer duration (seconds vs. tens of milliseconds for an airgun pulse), and MV will probably have a higher duty cycle (percentage of time it is "on"). MV signal duration estimates range from 5 to 12 s (LGL and MAI 2011). This would impact mainly low-frequency hearing specialists such as baleen whales and some fish. Slight masking effects could extend to a few tens of kilometers from the MV source. Using narrowband FM sweeps would likely lower the potential for masking (LGL and MAI 2011). Moreover, airgun pulses are also not always as short in duration as they appear, if heard over larger distances

from the source. Reverberation and multipaths "stretch" the signal from its original 10 ms to sometimes seconds at long ranges (Guerra et al. 2011). Noise levels often do not have a chance to return to ambient in the 10 s between airgun shots, since there is still reverberation from the previous shot (Guerra et al. 2011). A similar situation can occur with MV signals, but such "stretching" would be proportionally less than for airgun pulses, since MV signals are longer in duration initially, close to the source (LGL and MAI 2011). Most importantly, MV signals would likely fade more quickly into the background ambient noise levels.

MV should certainly be field-tested for impacts on a wide range of sensitive marine taxa, something that should ideally happen in tandem with operationally testing various MV designs. As with other noise reduction measures from seismic surveys, the development of MV could be greatly expedited with incentives, encouragement, and pressure from regulatory governmental agencies (Duncan et al. 2017).

### Monitoring Technology

Monitoring, especially ahead of time, of the proposed survey areas should be conducted with fixed acoustic detectors (buoys, bottom recorders, etc.) or mobile gliders to assess the population density, abundance, and distribution of marine life before, during, and after seismic surveys. Gliders can be used for both vocal marine mammals and fish species.

Infrared (IR) or thermal imaging is promising in detecting warm-blooded marine life, such as whales and dolphins, which can assist with nighttime monitoring, especially of baleen whales (Zitterbart et al. 2013). It is meant to supplement, not replace Marine Mammal Observers, by alerting them to possible whale blows (exhalations). IR imaging also does not function well in some conditions, such as fog, or with species that do not remain long at the surface or with obscure blows, such as smaller whales, even the size of minke whales (Zitterbart et al. 2013). It is also very expensive. It appears to work best in polar regions.

Passive Acoustic Monitoring (PAM) should be used anytime there are vocal species in the area, daytime or nighttime. Towed arrays or other suitable technologies with enough bandwidth to be sensitive to the whole frequency range of animals expected in the area should be used to improve detection capabilities. PAM should be mandatory for night operations or when visibility is scarce. However, PAM may still be inadequate mitigation for night or poor-visibility operations if species in the area are not vocal or easily heard.

## BEP for Seismic Airgun Survey Noise

As previously mentioned, the most effective mitigation for seismic airgun surveys is to (a) separate seismic surveys from areas rich in marine life and sensitive species and (b) to lower the source level (quiet the noise). However, to separate seismic surveys from marine life, good, current knowledge of the abundance and distribution

of that life must be available. Therefore, baseline studies of biological abundance and distribution should occur at least a year, preferably two, in advance of seismic surveys. These should be of sufficient quality and statistical power to detect changes in abundance and distribution of marine life over natural variation. Sensitive and important habitats and seasons (spawning, breeding, feeding, etc.) should be avoided. Turtles, fish, and invertebrates should be included in mitigation and monitoring, wherever possible. Acoustic refuges of still quiet habitat should be established, and marine protected areas should be managed for noise and include acoustic buffer zones around them, considering the possible impact of long-range noise propagation. Seismic airgun surveys should avoid these acoustic refuges and marine protected areas.

The ACCOBAMS (Agreement on the Conservation of Cetaceans in the Black Sea, Mediterranean Sea and contiguous Atlantic area) Resolution 7.13, Guidelines to Address the Impact of Anthropogenic Noise on Cetaceans in the ACCOBAMS Area, are very close to BEP for seismic airgun survey noise. Where new mitigation measures not contained in the Resolution have been added, these are marked "NEW." ACCOBAMS is only focused on cetaceans, whereas this document is concerned with all marine species and overall ecosystem health, so sometimes more mitigations, or the present mitigations slightly modified, are considered necessary. Other helpful mitigation measures are contained in the Resolution that are not included here in the interest of brevity. The Resolution also contains useful guidelines to address noise from shipping and from coastal and offshore construction, such as pile driving, but only some of the "guidelines for seismic surveys and airgun uses" are included here, as these are particularly detailed, current, and extensive:

(a) Seismic survey planning to avoid key habitat and areas of density of marine life, ensuring that entire habitats or migration paths are not blocked and that cumulative seismic noise is limited within any area (e.g., special regulation or prohibition of multiple vessels operating in the same or nearby areas at the same time).
(b) Some proof of efficacy of the mitigation measures used for all sensitive species (NEW).
(c) Transparent, public notification of when and where seismic surveys will occur as soon as this is known by the operators (months in advance) (NEW).
(d) Use of the lowest practicable source power and (NEW:) have this verified by independent evaluators.
(e) Limit horizontal propagation by adopting suitable array configurations and pulse synchronization.
(f) Elimination of unnecessary high frequencies.
(g) No operation of airguns for any reason outside the permitted project area (NEW).
(h) Adapt the sequencing of seismic lines to account for any predictable movements of animals across the survey area and avoid blocking escape routes.
(i) Model the generated sound field in relation with oceanographic features (depth/temperature profile, water depth, seafloor characteristics) to dynamically set the

safety or exclusion zone (EZ). Verify models of the EZ in the field. (NEW:) EZ should be at minimum 500 m but may be larger depending on the propagation.

(j) Continuous visual and passive acoustic monitoring (PAM) by a specialized team of Marine Mammal Observers (MMOs) and PAM operators to (NEW) reduce the risk that animals are in the exclusion zone before turning on the acoustic sources and while sources are active.

(k) Prohibit airgun surveys at night, during other periods of low visibility, and during significant surface-ducting conditions since mitigation tools are likely inadequate to detect and localize sensitive marine life. Prohibit seismic surveys over Beaufort Wind Speed of 3 because of the impact of adverse weather conditions on the visual detection of animals. (NEW:) Only if passive acoustic monitoring (PAM) alone is shown as effective in detecting sensitive marine life as the combination of PAM together with MMOs should seismic surveys in poor visibility and at night be allowed.

(l) Passive acoustic monitoring (towed array technology or other suitable technologies with enough bandwidth to be sensitive to the whole frequency range of sensitive marine life expected in the area) should be used to improve detection capabilities. PAM may be inadequate mitigation if animals in the area are not vocal or easily heard.

(m) At least two dedicated Marine Mammal Observers (MMOs) should be on watch at one time on every operative ship; shifts should be organized to allow enough rotation and resting periods for MMOs. At least one PAM operator should be on watch and shifts should be organized to allow 24/24 h operation, unless automatic detection/alerting systems are proven to be as effective as PAM operators. Standardized tests (written and in the field) for MMOs and PAM operators, used worldwide, should be developed to ensure MMOs and PAM operators pass standard qualifications.

(n) Before beginning any sound transmission, there should be a dedicated watch of at least 30 min to reduce the risk that animals are within the EZ.

(o) Establish a minimum pre-clearance zone (i.e., pre-ramp-up watch zone) that extends 500–1000 m from the outer perimeter of the airgun array(s). (NEW).

(p) Extra mitigation measures should be applied in deepwater areas if beaked whales are expected or if habitats suitable for beaked whales are approached: In such cases, the watch should be at least 120 min to increase the probability that deep-diving species are detected.

(q) Every time sources are turned on, there should be a slow increase of acoustic power (ramp-up or soft start) to increase the chances that animals might leave the ensonified area (the effectiveness of this procedure is still debatable).

(r) Delay sound transmissions if sensitive species are observed within the exclusion zone (EZ) or approaching it. Ramp-up may not begin until 30 min after the animals are seen to leave the EZ or 30 min after they are last seen (120 min in case of beaked whales).

(s) Shutdown of source(s) whenever a sensitive species is seen to enter the EZ and whenever aggregations of vulnerable species (such as beaked whales) are detected anywhere within the monitoring area.

(t) If more than one seismic survey vessel is operating in the same area, they should maintain a minimum separation distance (dependent on propagation) to allow escape routes between sound fields.
(u) Encourage data sharing among seismic surveyors to minimize duplicate surveying. Also, encourage use of old seismic data if these can be usefully reanalyzed using new signal processing or analysis techniques. (NEW:) Duplicated surveys need to be justified.
(v) Conduct a quantitative analysis of cumulative and synergistic impacts not just of noise but of all anthropogenic threats over time as part of thorough Environmental Impact Assessments (EIAs) following the CMS Family Guidelines on EIAs for marine noise-generating activities, including consideration of historical impacts from other activities (shipping, military, industrial, other seismic) in the specific survey area and nearby region. Develop databases and noise registries to allow such analyses. (Addition of CMS Family Guidelines and synergistic impacts is NEW.)
(w) Include monitoring and reporting protocols to provide information on the implemented procedures, on their effectiveness, and to (NEW:) improve data on biological abundance and distribution, as well as examine impacts from seismic survey noise. Monitoring should be proven to be statistically powerful enough to detect subtle impacts, strandings, fish kills, etc. Before During After (BDA) or Before After Control Impact (BACI) studies to examine impacts must also contain power analyses to show whether possible impacts would be detectable or not. Impact and biological baseline studies should include more fish, turtles, and invertebrates. All biological and impact data collected for mitigation should be publicly available.
(x) Standardize MMO and PAM reporting so that data can be harmonized across all seismic surveys worldwide for maximum statistical power. (NEW).
(y) Conduct a biological survey after the seismic survey is completed to verify if changes in the abundance or distribution of species or anomalous deaths occurred.
(z) In the case of strandings, deaths at sea, or abnormal behavior possibly related with the operations, any sound transmission should be stopped, and maximum effort devoted to understanding the causes of the deaths or abnormal behavior.

## BAT for Pile-Driving Noise

### Noise Levels

Impact pile driving is the most common method of foundation installation for offshore windfarms (OWF) and other structures such as piers and bridges. Pile driving using a hydraulic hammer with an energy of 1000 kJ results in sound levels around 237 dB re 1 μPa at 1 m. The noise generated has a predominant bandwidth of 100–1000 Hz (Hildebrand 2009), but it also extends into the tens of kHz. Currently

used hydraulic hammers have a rated energy range of up to 4000 kJ, which increases noise emissions further, also with increasing pile size.

## Impacts

A broad range of marine life can be affected by piling because of the wide frequency range of the noise generated underwater. The harbor porpoise avoids pile driving out to a mean distance of 17.8 km. At 22 km, this avoidance was no longer apparent. Porpoise activity and possibly abundance were reduced over the entire 5-month windfarm construction period (Brandt et al. 2011). Once piling noise ceases, it can take up to 2 days until harbor porpoise behavior returns to pre-piling conditions (Brandt et al. 2016). Blue mussels (Spiga et al. 2016; Roberts et al. 2015) and seabream (Bruintjes et al. 2017) showed indicators of stress from pile driving. In addition, swimming and schooling behavior was impacted by piling in cod and sole (*Solea solea*) (Mueller-Blenkle et al. 2010), sprat (*Sprattus sprattus*) and mackerel (*Scomber scombrus*) (Hawkins et al. 2014), and juvenile seabass (Herbert-Read et al. 2017).

## Underwater Noise Limits

Largely due to the German government setting an action-forcing standard for noise, major progress in quieting technology has been made for pile driving. In 2004, The German Federal Maritime and Hydrographic Agency introduced noise guidance values for single strikes of 160 dB re 1 $\mu Pa^2$ s (SEL) and maximum 190 dB re 1 μPa (peak) at 750 m in the licenses of offshore wind farms within the German EEZ. In 2008, these became mandatory and were successfully applied in 2013, reaching state-of-the-art reliable compliance despite increasing pile diameters and water depths through 2018. No offshore windfarm in German waters has since been constructed without complying with these underwater noise limits. In 2013, the German Federal Ministry for the Environment also published its Sound Protection Concept. Along with technical mitigation measures, pile-driving companies purposely use lower piling/hammer energies to stay under the German noise limits. A growing number of countries across Europe, Asia, and North America are following Germany's lead and now also impose underwater piling noise restrictions during offshore windfarm (OWF) construction.

## Noise Mitigation and Abatement Systems

Noise mitigation systems (NMS) work to avoid or reduce the noise inputs into the water, whereas noise abatement systems (NAS) function in reducing the impact of existing pile-driving noise already in the water. Koschinski and Lüdemann (2020) detail technical noise mitigation measures for pile driving as well as alternative

low-noise foundation concepts and analyze their applicability. Bellmann et al. (2020) also provide a comprehensive overview of currently available noise abatement systems as well as a thorough explanation of underwater piling noise transmission and the factors that influence it. The report provides estimated noise mitigation levels for almost all NAS available on the market using empirical data sets from the North and Baltic Seas. Bellmann et al. (2020) conclude that the IHC Noise Mitigation Screen (IHC-NMS) is the most effective near-pile mitigation system available, estimating reductions in SELs of up to 17 dB. Quieting further improves up to 22 dB in depths of 40 m when combined with an optimized double big bubble curtain (DBBC). The report addresses a broad range of site-specific influencing factors such as soil parameters, water depth, bathymetry, sound propagation, and measuring details.

Verfuss et al. (2019) reviewed NAS for OWF construction noise and how applicable these were for Scottish waters. The main findings of Verfuss et al. (2019) were that:

- Big bubble curtains (BBCs), the IHC noise mitigation system (IHC-NMS), the hydro-sound damper (HSD), and vibrohammers (VH) have all been commercially deployed as NAS in OWF projects.
- With either the BBC, IHC-NMS, or HSD, broadband sound levels can be reduced by at least 10 dB.
- The NAS are generally more effective at reducing the risk of noise impact on marine mammals and fish sensitive to higher frequencies than on those that are only sensitive to frequencies below 100 Hz.
- VH is an NAS that has been applied in industrial projects in water depths prevailing in potential future Scottish OWF sites (up to 77 m).
- BBC, VH, HSD, and NMS are NAS that have been commercially deployed in OWF projects in water depths up to 45 m.
- The AdBm-noise abatement system (AdBm-NAS) completed its full-scale test in 2018 and deployed commercially in an OWF project in 2019.

Those abatement systems that can be considered Best Available Technology under certain circumstances and some of their limitations are described below.

Recently, piles with diameters of 9 m have been installed, compared with initial piles around 2.5 m. Even 12-m-diameter piles are proposed for the future. Different substrates and water depths require different types of foundations. Driven piles are typically used in sandy soils, such as areas in the North Sea, whereas drilled piles require a higher substrate strength, though substrate strength could be high enough when the drilling gap is filled with a specific filling material. Site-specific calculations are necessary to determine the method of installation.

During pile driving, the acoustic pressure wave can enter the substrate and re-emerge into the water column at a greater distance from the pile ("ground-coupling effect"). Therefore, mitigating the noise emitted through the water near the pile (e.g., by deploying an HSD, AdBm, or IHC-NMS system) may not be sufficient. Big bubble curtains (BBCs) can thus be highly effective, as they can

mitigate noise that reenters the water column at distances up to 150–160 m from the pile. NAS can be categorized as near-pile or far-field systems. It may be necessary to deploy both a near-pile and a far-field system in certain situations for sufficient mitigation.

Primary noise reduction, occurring at the source, has the advantage of solving this substrate transmission problem. Secondary noise reduction occurs once the sound has already been transmitted into the water or substrate. The most effective way to reduce noise at the source is to use a foundation that does not require impact pile driving such as gravity-based, bucket, drilled, or floating foundations.

## Vibropiling

Vibration pile driving, or vibropiling, avoids impulsive sound and thus could be a promising alternative to conventional pile driving. The advantages include lower (but continuous) noise levels, faster installation (and therefore less exposure time), material saved on the monopile, and less mitigation for noise (based on current regulations). There is also considerable offshore experience using vibropiling. First full-scale installations have taken place in the OWF Kaskasi 2 in the German Bight (https://ocean-energyresources.com/2022/04/28/cape-hollands-vlt-completed-work-at-kaskasi-ii-owf-video/), though this installation method is still somewhat experimental. Vibration piling is 10–20 dB lower in peak levels vs. mitigated pile driving. Levels fall to 140 to 145 dB in 8 km for pile driving compared to 1.5–3 km for vibropiling. The area over which these levels are exceeded is thus 7–28 sq. km for vibropiling compared to 201 sq. km for pile driving. Vibropiling, however, produces very low frequencies, so further mitigation using a bubble curtain would not reduce the noise substantially. The noise peaks arise from rattling from the loose connections of the vibrohead. While vibropiling may reduce peak noise levels, the continuous noise still likely causes some impact to marine life, though probably less.

### BLUE Piling

The BLUE Piling hammer replaces the typical steel ram weight of an impact hammer with a large water mass. The resulting blow is considerably longer in duration than a conventional impact hammer, which reduces underwater noise and material fatigue. This could be a cheaper alternative, given the lower material fatigue and less need for costly noise mitigation systems. Whether one can operate the hammer on a large enough scale to handle large monopiles remains to be validated.

## Adaptation of Hydraulic Hammers

By incorporating an adjustable cushion between the ram weight and anvil of either steel or water, the impact force can be prolonged, and the amplitude reduced, resulting in a 4 to 6 dB lower SEL (Koschinski and Lüdemann 2020), while also achieving up to a 60% reduction in material fatigue and stress on the equipment.

Reducing the amplitude of the peak force can, however, result in premature refusal, i.e., when five or more blows of an adequate hydraulic impact hammer will not budge the pile, as the peak driving forces may no longer be sufficient to overcome the soil resistance. Continued operation without this add-on to the hammer or use of a higher energy might then be required which, in both cases, would increase the radiated underwater noise.

The Menck Noise Reduction Unit (MNRU) incorporates a steel cushion block. The IHC-PULSE, currently being developed by IHC, uses a cushioning chamber filled with water. If premature refusal occurs due to insufficient peak forces, the water in the IHC-PULSE system can be drained within minutes and the system operated as a conventional hydraulic hammer to achieve greater peak forces. MNRU can be combined with other noise mitigation methods since the piling cushion is inside the hydraulic hammer.

## Smart Pile Driving

With sufficient engineering preparation and the assistance of online noise monitoring, a piling approach can be followed to minimize noise levels. By optimizing hammer energy and blow frequency in line with real-time noise measurements, noise levels can be reduced while ensuring the pile continues to penetrate at an acceptable rate.

## Bucket Foundations

Suction Caisson/Bucket Foundations are used for low substrate strength (sandy soils, clay, or combinations thereof) and, preferably, a relatively flat seabed. The structure sinks into the soil by its self-weight, and noise barely exceeds background levels. There are installation challenges in very shallow water (water depths $<$20 m). A lower length-to-diameter ratio (and thus a larger "footprint") compared to their deep-water use allows applications for OWFs in shallower water ($<$100 m).

There are two types of bucket foundations: Suction Bucket Jackets (SBJs) and Monobucket foundations. In SBJs, several buckets are connected rigidly to a welded framework structure, whereas the monobucket foundation is a monopile foundation with a suction bucket-seabed interface. SBJ can be used in many substrate conditions, but not very hard soils, soft soils, or rocks. Also, high seabed mobility and loss of substrate could compromise the stability. There is an impact on soil and benthic biotypes. Between 2014 and 2020, 32 three-legged SBJs were successfully installed in depths from 23 to 29 m. A monobucket was also installed successfully in Denmark (Koschinski and Lüdemann 2020).

## Gravity-Based Foundations

Gravity-based foundations, most suitable for depths of up to 50 m, are reinforced concrete or steel/concrete hybrid structures whose stability is achieved by the

submerged weight of the structure, supplemented by additional ballast (e.g., sand). They can also be designed for deeper waters and have been used extensively by the oil and gas industry in depths of up to 300 m. They may have a relatively larger impact on benthic life, however, since at least some types remove the upper layers of the seabed, and their footprint area is larger than that of a monopile.

Crane-free gravity foundations are an example of a noiseless foundation. It is proven technology and is inexpensive. The foundations are self-floating so they do not require cranes or large installation vessels. They are more cost-effective at larger depths and bigger turbines compared to other foundation types. There is no sound emission from the subsea installation process and no deep penetration of seabed. In current prototypes, the base diameter is 31–34 m. Two tow vessels (tugs) pull the vertical pile through the water, and they can be installed in seas up to 2 m. Installation is estimated to take 4 h. Ballast is used so the foundation can withstand high turbine and wave loads. Gravity-based foundations can be designed for life spans of 50 years or more. They require a minimum water depth of 10 m.

## Drilling

There are several offshore foundation drilling techniques for various substrate conditions.

1. BAUER MIDOS-Pile combines mixing and drilling technology to install a structural pile. The drilling and mixing tool is full of grout. This can be used in mainly sandy substrates but also clay and rock. The substrate is mixed with cement and creates a slurry that is injected during drilling. XXL monopoles are too big for this technology, however. The noise is much lower than piling and the structural capacity is better. The substrate must be mixable, e.g., sand with some clay.
2. BAUER Dive Drill Technology is used for the installation of drilled and grouted piles. Drilling occurs inside a casing and is replaced with the pile. Dive Drill Technology installs piles in fully cased boreholes and is suitable for all soil conditions including hard rock. It makes pile driving in marginal soil unnecessary.
3. BAUER BSD 3000 is for drilling piles in rock. The pile is installed and grouted afterward. In 200–300 m, the noise is under background noise (125 dB rms).

## Push-In and Helical Piles

Push-in and helical piles are two concepts for silently driven piles. Both concepts can serve as an alternative for jacket foundation piles and are therefore suitable for deepwater wind turbine foundations. Both have been proven onshore. The push-in pile foundation uses a static force to drive piles into the seabed, and the helical pile foundation uses a rotating motion to drive piles fitted with several helical blades into

the soil. Both concepts are fully silent but will require special tools and, in the case of the helical pile, an interface with the installation vessel using dynamic positioning.

## Floating Wind Turbines

Many waters are too deep for non-floating structures. Floating turbines can be used in all different sediment types. The anchors are fully retrievable, and no effect on marine life has been observed in a prototype wind farm, WindFloat, off the Portuguese coast. The effects of anchors, however, may depend on anchor type. Different anchor types such as gravity anchors, suction buckets, or drilled or driven piles can be used to hold the floating substructure and the wind turbine on top in place. Suction buckets are used most often as anchors. Drag anchors impact the seabed, though they are quiet. Moreover, there are some concerns regarding the high number of vertical mooring lines in important habitats for baleen whales, which could cause harmful collisions.

There are three types of floating wind turbine platforms:

1. Float-stabilized structures or barges
2. Tension leg platforms (TLPs)
3. SPAR buoys

For 1), float-stabilized structures (semi-submersibles), the platform is floating and anchored to the seabed by cables which, in combination with ballast water, provide stability. Semi-submersible floating wind turbines have been deployed in some of the roughest seas of the Atlantic where they survived 17 m waves. Just one tug is needed to place the turbine, and it can be towed up to 500 km.

For 2), TLPs, the wind turbine rests on a platform supported by several cables anchored to the seabed. The cables are tensioned to stabilize the platform by counteracting its buoyancy and to maintain position of the turbine under any type of load. A TLP emits minimal noise. It is best used in $>$20 m water depth. To gain stability, TLPs require a fixed connection to the seabed, which is under tension due to the buoyancy of the floater. Mooring cables come in various types (taut leg, tension leg mooring, etc.). It is a one-step installation, only small tugboats are needed, and little assembly time or seabed preparation is necessary.

For 3), SPAR buoys, used for deepwater applications, the wind turbine is supported on a long concrete or cylindrical steel column, completely submerged, which is ballasted at the bottom to stand upright and to provide stability, withstanding loads produced by the wind and waves.

## Secondary Noise Mitigation

There are currently multiple near-pile NAS on the market compared with far-field systems. Examples of secondary noise reduction include:

1. A big bubble curtain (BBC) consists of a large, perforated pipe positioned around the construction zone. Air is pumped through the hose from both sides using several compressors and is released through the perforations delivering a continuous flow of bubbles around the periphery of the construction zone. From industry experience, BBCs can reliably provide an enclosed ring up to a length of 1000 m (approx. 160 m radius if deployed in a circular layout). BBCs are not limited to the size of the pile being installed since they are deployed at a large distance from the pile. BBCs are extremely effective as they can attenuate acoustic energy that reenters the water column from the seabed, a common drawback of all near-pile systems. Two BBC hoses can be deployed in concentric circles spaced at least the water depth apart, forming what is known as a double big bubble curtain (DBBC) for additional mitigation. The use of (D)BBCs is independent of foundation design and installation vessel. The noise reduction depends on the air supply, water depth, subsea soil conditions, and current/direction/shape. Each deployment therefore needs to take project-specific considerations into account. With an air volume stream of 0.3 $m^3$/min*m (comparatively low), the reduction in SEL for a single bubble curtain was 11–15 dB at 25 m water depth, but only 8–14 dB around 30 m and 7–11 dB at about 40 m (Koschinski and Lüdemann 2020), since the bubble size becomes too small under the pressure of greater depths. Such a loss in mitigation can be overcome by increasing the amount of air or combining it with near-pile mitigation systems like the IHC-NMS, HSD, or AdBm (see below).
2. The IHC Noise Mitigation Screen (IHC-NMS) is a proven near-pile NAS previously applied on piles under 8 m in diameter (though it is being considered for 10-m-diameter piles) and under 40 m water depth. It has been used in hundreds of monopile installations. This system is a double-walled steel pipe with an air gap between the two layers. A multilayered bubble curtain is also used in the center around the pile. Ground-coupling effects are not mitigated, however. Noise reduction is independent of water depth. Noise reductions up to 17 dB SEL have been achieved in water depths up to 40 m (Bellmann et al. 2020).
3. Hydro-sound dampers (HSD), used in hundreds of monopile installations, consist of foam resonators affixed to ballasted nets. HSD baskets, consisting of a net sleeve, container, and ballast, are dropped down into water around the pile, which collapse back up once the pile is installed and the basket is returned. Noise reduction is independent of water depth, and attenuation is predominantly in the low-frequency ranges. HSD are customizable, allowing tuning of the frequency bands in which noise reduction needs to take place by choice of resonator sizes. If the balloons are appropriately sized, their resonant frequencies can align with the peak frequencies of piling noise or with frequency bands of best hearing in sensitive animals for optimum damping effects. Data from multiple OWF projects in Germany suggest the HSD nets reliably achieve reductions up to 12 dB SEL (Bellmann et al. 2020). Overall, the system works for water depths up to 40–60 m and pile diameters up to 8–13 m. It is easily adaptable, weighing very little, and is not affected by water currents. A disadvantage is still the ground-coupling effects.

4. The AdBm noise mitigation system, ready for offshore use, uses rugged Helmholtz resonators whose acoustic properties can also be modified or "tuned" to optimally reduce noise. The system consists of several layers of inverted air-filled chambers, whereby the arrays of each layer are sized according to the depth at which they will be situated during piling. These resonators simply need to surround the sound source, and once they are in place, the resonators will passively absorb the noise. The principle of this system is like that of the HSD nets and also most effective in the low-frequency ranges. The system can theoretically work in water depths beyond 70 m (Verfuss et al. 2019). Although the AdBm noise mitigation system has been used for a full-scale OWF project, very limited data on its acoustic performance have been published.

## BEP for Pile-Driving Noise

Quieting technologies (see the above section on BAT) represent most of the mitigation for pile-driving noise, having great potential to dramatically reduce the area and the number of animals impacted by the noise. Additional BEP can consist of some operational procedures related to the behavior of animals such as deterrence by using acoustic deterrent devices (ADDs) or a soft start for those animals remaining at risk despite noise reduction. There is some debate, however, whether or how much marine life should be purposely displaced at the start of pile driving or over the effectiveness of ADDs or soft starts. Not all animals respond to them as intended, as they may be motivated to remain in an area, despite harassment by noise, because of access to food or mates. FaunaGuard is one device that has been used since research, mostly carried out on harbor porpoises, showed pinger and seal scarers produced more displacement than was necessary. Mitigated pile-driving noise itself can be used but initially at lower energy and/or repetition rate (ramp-up or soft start) to give marine life a chance to flee the area before more harmful levels of noise are generated. As with seismic surveys, the use of MMOs and PAM operators can reduce the risk of exposing marine life to dangerous noise levels. Visual and acoustic monitoring should be used in combination 24 h a day to maximize the probability of detection of wildlife during periods of poor visibility. If this monitoring is deemed insufficiently effective, pile driving should be prohibited during nighttime and periods of poor visibility.

Some examples of best practices for pile driving that have been developed in the United States for the highly endangered North Atlantic right whale are listed below. The full document is available at https://www.nrdc.org/sites/default/files/best-management-practices-north-atlantic-right-whales-during-offshore-wind-energy-construction-operations-along-us-east-coast-20190301.pdf.

- Construction activities with noise levels that could cause injury or harassment in marine mammals must not occur during periods of highest risk for priority species.

- During construction, developers should commit to minimizing impacts of underwater noise on priority species to the full extent feasible through (i) the consideration and use of foundation types and installation methods that eliminate or reduce noise and (ii) the use of technically and commercially feasible and effective noise reduction and attenuation measures, including the use of the lowest practicable source level.
- Developers should commit to carrying out scientific research and long-term monitoring in lease areas to advance understanding of the effects of offshore wind development on marine and coastal resources and the effectiveness of mitigation technologies (e.g., noise attenuation).

As mentioned above, the German Federal Ministry for the Environment, Nature Conservation and Nuclear Safety (BMU) adopted the *Sound Protection Concept.* In it, in addition to the technical noise reduction systems required, the following are also mandatory:

- Modeling of sound level emission for each specific wind farm project
- Restrictions regarding the maximum duration of a piling operation for a single pile
- Restrictions regarding the maximum energy used to drive the piles
- Application of deterrents and ramp-up procedure to avoid injury close to the piling operation
- Measurement and documentation of SELs
- Monitoring of harbor porpoise activity in the vicinity of construction sites
- Requirements regarding a maximum percentage of area that is allowed to be affected, also with due consideration of protected areas or areas and seasons of biological significance

## Conclusions

One of the difficulties in responsibly managing ocean noise pollution is the challenge in detecting the ecosystem and population consequences of underwater noise. There is sufficient evidence that impacts are occurring in at least 150 marine species (around 100 fish and invertebrate species alone – Weilgart 2018), but being able to ascertain exactly to what degree, in which contexts, for which species, and at what sound types and levels these impacts occur remains imprecise. Because of the large natural variability in ocean systems (e.g., in currents, prey availability, chemistry), detecting human-caused changes in ecosystems and populations at all is a daunting task. The ocean is not a controlled laboratory. On top of that, isolating changes that are solely due to ocean noise pollution and not other human-caused stressors such as climate change, overfishing, and toxins is formidable (Weilgart 2023).

As a result, a more precautionary approach is warranted, one of simply turning down the volume of ocean noise pollution, especially in cases where there are ancillary benefits of quieting, such as reducing GHG emissions by finding the

overlap between greater efficiency and less underwater radiated noise in shipping. In this respect, it must be noted that the great variety of quieting technologies and noise abatement systems for pile driving is in stark contrast to the lack of or slow innovation that is occurring for quieter alternatives to the seismic airgun, though more have emerged recently. This may be due to offshore windfarms being a relatively new development compared with seismic airgun surveys, but it does raise questions. Certainly, having governments that are prepared to regulate the offshore windfarm construction for noise, mainly due to the noise-sensitive and protected harbor porpoise, helps, as do European laws, but it is high time that regulators insist on quieter alternatives to airguns, something that seems well within technological capabilities and which would drive innovation. After all, explosions on land to search for hydrocarbons were replaced with Vibroseis™ because explosions were no longer acceptable to humans. Keeping more fossil fuels in the ground would also reduce our need for seismic surveys and cut greenhouse gases. With humans, we do not find the precise point where noise is just tolerable to newborns in neonatal intensive care units, and we do not fund countless studies on exactly how stressed and disturbed they must be to take remedial action – we simply try and quiet the noise, wherever possible and safe to do so. If we value our life-sustaining oceans, we should provide them with the same care and protection.

**Acknowledgments** I thank Russell Leaper, Louis Lederwasch, Sven Koschinski, Peter Tyack, Andrew Feltham, Nicolas Entrup, and Johannes Müller for their very valuable help and input. Chris Waddington and Ross Compton, as well as other reviewers, also provided useful additions.

**Abstract**

Currently, the impact pile-driving procedure is the most commonly used installation method for foundation structures in offshore wind farms (OWF). Thereby, the foundation structures are driven into the sediment (seabed) by using a hydraulic (impact) hammer. The pile-driving works result in noise immissions (pile-driving noise) in the water body, which can potentially be harmful to marine life, especially to the noise-sensitive species like harbor porpoises (e.g., Lucke, Siebert, Lepper, Blanchet, J Acoust Soc Am 125:4060–4070, 2009; Southall, Finneran, Reichmuth, Nachtigall, Ketten, Bowles, Ellison, Nowacek, Tyack, Aquat Mamm 45:125–232, 2019). However, since 2011, any impact pile-driving activity shall comply with the German noise mitigation values of 160 dB for the 5% exceedance level of the single strike sound exposure level $SEL_{05}$ and 190 dB for the zero-to-peak sound pressure level $L_{p,pk}$ at a distance of 750 m to the source. Up to the end of 2019, more than 2400 piles were installed in Germany (North Sea and Baltic Sea) by using impact piling with and without noise mitigation measures. Most of the underwater noise measurement data and the lessons learnt by using different noise mitigation systems (NMS) and/or noise abatement systems (NAS) were not published or are not publicly available. Within the funded R&D-project NavES (Bellmann, Brinkmann, May, Wendt,

Gerlach, Remmers, Underwater noise during the impulse pile-driving procedure: Influencing factors on pile-driving noise and technical possibilities to comply with noise mitigation values. Supported by the Federal Ministry for the Environment, Nature Conservation and Nuclear Safety (Bundesministerium für Umwelt, Naturschutz und nukleare Sicherheit (BMU)), FKZ UM16 881500. Commissioned and managed by the Federal Maritime and Hydrographic Agency (Bundesamt für Seeschifffahrt und Hydrographie (BSH)), Order No. 10036866. Edited by the itap GmbH. https://www.itap.de/media/experience_report_underwater_era-report.pdf, 2020), the most influencing project- and site-specific parameters for impact pile-driving noise were identified by a cross-project analysis, based on the German noise registry database MarinEARS (https://marinears.bsh.de). Furthermore, the lessons learnt with applied NMS as well as NAS were summarized. The most influencing parameters on unmitigated pile-driving noise are: (i) pile diameter, (ii) blow energy, (iii) foundation type, and (iv) bathymetry/transmission loss. Currently, only two close-to-pile NAS (Hydro Sound Damper – HSD and noise mitigation screen/cofferdam) as well as one far-from-pile NAS, the single or double Big Bubble Curtain (BBC/DBBC), are offshore reliable and were used in serial applications. With one NAS, a broadband noise reduction between 10 and 16 dB can be achieved. By applying two independent NAS, up to 20 dB for the SEL can be obtained. Slightly higher noise reductions are possible for the $L_{p,pk}$. The effectiveness of all NAS significantly depends on frequency: increasing frequency results in increased noise reduction. But also, other parameters, like water depth or current, partly have effects on the achieved noise reduction. At present, only one reliable and robust NMS – the noise-optimized piling procedure – can be used, which leads to an overall noise reduction of 2–3 dB by halving the used blow energy.

Percussive pile-driving noise · Noise mitigation · Noise abatement system

## Introduction

The installation of renewable energy sources like offshore wind farms (OWF) has increased rapidly in the last decade. In Germany, more than 20 OWFs were in operation in 2020 (~8.1 GW) and it is planned to reach 30 GW in 2030; therefore, several OWFs are planned to be installed in the years to come. The main goal of all these renewable energies shall go hand in hand with the awareness of sustainable issues and protecting nature and environment. Most offshore foundations are anchored in the seabed by the impact pile-driving procedure, and this leads to impulsive noise emissions, which could harm or will cause a reaction to pile-driving noise by marine life (e.g., Lucke et al. 2009; Southall et al. 2019).

In 2008, the German regulation authority BSH, as first country worldwide, set a dual noise mitigation value criterion to avoid temporal threshold shifts (TTS) for marine mammals, in particular harbor porpoises: (i) The 5% exceedance level of the single strike sound exposure level ($SEL_{05}$ or $L_E$) shall not exceed 160 $dB_{SEL}$ (re 1 μ $Pa^2s$) and (ii) the zero-to-peak sound pressure level ($L_{p,\ pk}$) shall not exceed 190 $dB_{Lp,pk}$ (re 1 μ Pa) at a distance of 750 m to piling. Based on experiences gained from the test OWF *alpha ventus* (2009), the application of noise abatement as well as noise mitigation systems for compliance with the noise mitigation values mentioned above is mandatory in German waters for any pile-driving activity. Furthermore, sufficient monitoring by, e.g., underwater noise measurements, according to the guidelines of the BSH (2011), shall be applied.

The performed underwater noise measurements during unmitigated impact pile-driving, without applying NAS or NMS, have shown values at a distance of 750 m of (i) up to 183 dB for the sound exposure level (SEL resp. $L_E$) and (ii) > 200 dB for the zero-to-peak sound pressure level ($L_{p,\ pk}$); Fig. 1. This will lead to a required overall noise reduction of up to 23 dB for the SEL.

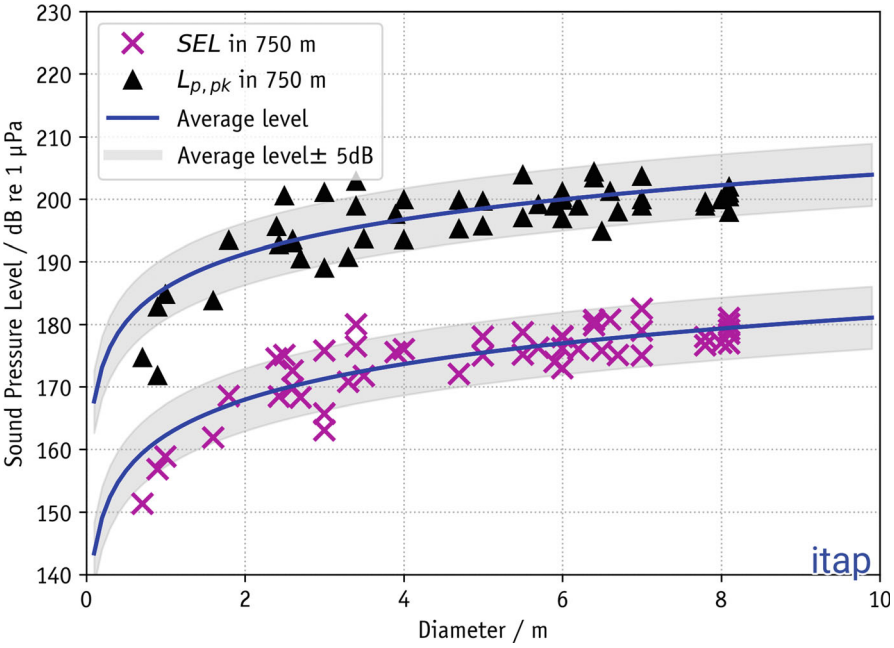

**Fig. 1** Examples of unmitigated pile-driving activities (zero-to-peak sound pressure level – $L_{p,\ pk}$ in dB re 1 μ Pa and broadband 5% exceedance sound exposure levels – $SEL_{05}$ in dB re 1 μ$Pa^2s$) measured by itap GmbH at a distance of 750 m as function of the pile diameter in different European OWFs

Furthermore, during the last decade, guidelines for measuring underwater noise from pile-driving as well as the evaluation of the effectiveness of NAS and NMS were defined on a national level (BSH 2011, 2013; DIN SPEC 45653 2017), but also internationally (ISO 18406 2017), to ensure that empirical data from different OWFs can be compared. The background to this is that all pile-driving activities since 2011 shall be monitored in a comparable manner and integrated into the underwater noise specialist system MarinEARS in Germany.

Most of the underwater noise data form German OWFs as well as the experiences with different NAS/NMS were not published or are not publicly available. Therefore, the funded R&D-project NavES (phase 3), managed by the BSH, was set up in 2016 to perform a cross-project analysis of all available measured underwater noise data in German waters. The aim of this project was to identify the most relevant influencing site- and project-specific parameters on impact pile-driving noise. Furthermore, the experiences with the application of different NAS including the effectiveness of these systems shall be summarized. Based on this cross-project analysis, minimum requirements for the applications of different NAS and combinations of NAS were compiled. In Bellmann et al. (2020), extensive experiences and data from the application of noise mitigation measures during pile-driving procedures in Germany are summarized and made publicly available. The benefit is that the main lessons learnt regarding mitigated and unmitigated pile-driving becomes available in a condensed manner which can be used not only for authorities during the approval process but also support the industry to plan upcoming OWF projects.

## Underwater Noise Specialist Information System MarinEARS

Based on the mandatory extensive underwater noise monitoring during impact pile-driving activities, the BSH developed a specialist information system in 2016 for underwater noise data: the MarinEARS. This database consists of raw data (time recordings) and standardized, post-processed result files of the underwater noise measurements. Additionally, relevant project-specific and technical-constructive information (metadata) of each single OWF construction project are linked to the underwater noise data in a standardized manner for all projects since 2012 in the German EEZ. Such metadata consists of, e.g., geo-reference, pile-driving protocols and description of the used noise mitigation measures, and support an evaluation of the underwater noise data. Table 1 gives an overview of the used measured and post-processed data sets, which were used for the cross-project analysis (Bellmann et al. 2020).

## Site- and Project-Specific Influencing Parameters on Pile-Driving Noise

Based on the cross-project analysis, the site- and project-specific influencing parameters on unmitigated pile-driving noise were determined (Table 2).

**Table 1** Overview of the installed OWFs in the German Baltic Sea and North Sea. For the cross-project analysis (Bellmann et al. 2020), a subsample of all available empirical data was used, since the OWFs erected between 2008 and 2012 in the German EEZ have not yet been implemented in the MarinEARS. Additionally, the OWF projects within the 12-sea-mile-zone were also excluded since these data were not included in the MarinEARS in 2020 either

## Offshore-Reliable and Market-Ready Noise Mitigation Measures

In case the source level of the impact pile-driving noise can be reduced, such techniques will be named noise mitigation systems (NMS): the only offshore-tested and reliable NMS is currently the "noise-optimized pile-driving procedure" (high blow rate and low blow energy). Besides that, alternative foundation structures and methods like vibro-piling and suction buckets can be used to avoid noise-intensive construction phases, but these methods and foundations mostly produce continuous noise instead of impulsive noise according to the definition of MSFD (2008). Typically, continuous noise will not produce any injury but can cause behavioral effects on marine life (Southall et al. 2019).

Noise abatement systems (NAS) try to reduce the resulting impact pile-driving noise in water to the greatest extent. Until 2014, the German government supported a total of 18 pcs R&D-projects in the field of developing and enhancing NAS and NMS with a total funding of 27 M€ (Verfuss 2014). Additional money was spent by the industry (developer as well as construction companies) to accelerate the development and enhancement of these new technologies and to test them under real offshore conditions.

A general technical overview of technical NAS and NMS as well as possible alternative low-noise foundation structures and installation methods were summarized in 2011 and updated in 2013 and 2019 on behalf of the Federal Agency for Nature Conservation (BfN) (Koschinski and Lüdemann 2011, 2013, 2019). Furthermore, the effectiveness and the costs of an application of NAS and NMS were evaluated by questionnaires and published on behalf of the Scottish Natural Heritage (Verfuss et al. 2019). In Table 3, only the offshore-reliable NAS, which were used in serial application, are summarized with a short description including advantages and disadvantages. However, all NAS currently require a project-specific design.

The achieved broadband insertion losses (overall broadband noise reduction) of an applied single NAS as well as an applied combination of a close-to-pile NAS and Big Bubble Curtain are summarized in Table 4. Therefore, only the offshore-reliable NAS from Table 3 were listed without any technical malfunctions and with its optimized system configuration since the effectiveness of the listed NAS significantly depends on the system configuration, e.g., the amount of compressed air for a BBC. However, also the water depth of the applications of the NAS is listed since the achievable noise reduction significantly depends on the water depth in some cases, especially for the BBC. Due to the fact that the effectiveness of NAS or combinations of NAS are based on a cross-project evaluation, with slightly varying site-specific and project-specific conditions a statistical representation of the minimum, averaged (mean) and maximum achieved noise reduction is summarized in Table 4. The variance of the overall noise reductions achieved by each applied NAS or combination of NAS reflects the importance of the project-specific adaptation and the influence of the optimized system configuration of each system since otherwise the measured variance was much higher and the achieved noise reductions much lower than described in Table 4. Furthermore, the analysis did not explicitly consider the type of the impact hammer. In this respect, the values shown here are for orientation purposes only.

Table 4 also shows the effect of used compressed air on the achievable noise reduction of a single or double BBC: a larger airflow leads to an increased noise reduction. However, Table 4 also indicates that the noise reduction of any kind of bubble curtain also significantly depends on water depth: the deeper the water, the less overall noise reduction. In Bellmann et al. (2020), a specification list for single and double BBC system configurations regarding the state-of-the-art is summarized.

Nevertheless, the achieved overall broadband noise reductions summarized in Table 4 for NAS and combinations of NAS are highly dependent on frequency. The lower the frequency, the lower the achieved overall noise reduction in the specific 1/3-octave band for all existing NAS; Fig. 2. In principle, the most acoustic energy is

**Table 3** Overview of offshore-robust and reliable noise abatement systems that were used in serial application within German waters, including a brief description with advantages and disadvantages

| Secondary, technical noise abatement system | Description/experiences | Advantages/disadvantages |
|---|---|---|

emitted by pile-driving in the frequency range between 63 and 250 Hz, depending on the site-specific conditions and the used pile design: the bigger the pile diameter, the lower the unmitigated pile-driving spectrum.

Examples of the outputs of the MarinEARS system and the effectiveness of a "noise-optimized piling procedure" are depictured in Figs. 3 and 4. Figure 3 shows an example of the OWF *Butendiek* in the North Sea (year of construction 2014). All sound exposure levels ($SEL_{05}$) measured at a distance of 750 m to the monopiles are summarized in chronological order. For the first monopile installations, only one noise abatement system was used. A second noise abatement system was applied in parallel starting with monopile installation #9 due to the permanent noncompliance with the German noise mitigation values. Thereafter, the sound exposure level complies with the noise mitigation values as 1st OWF

**Table 4** Summary of the achieved overall noise reduction of single noise abatement systems and combinations of noise abatement systems based on a cross-project analysis (Bellmann et al. 2020). Only offshore-reliable NAS and combinations of NAS are listed in its optimized system configuration and applied water depths since the effectiveness depends on these project- and site-specific parameters, especially for any application of BBCs

[a] (D)BBC applications were performed by current $\leq$0.75 m/s to avoid unwanted drifting effects

project in German water except for a few installations with technical problems with one of the applied NAS.

Figure 4 shows an example of an OWF construction project in 2016 which used a combination of a near-to-pile and a far-from-pile noise abatement system and a noise-optimized pile-driving procedure. This method includes active feedback between the measured pile-driving noise at 750 m with real-time techniques and the applied blow energy for each single strike by the hammer operator. By combining different mitigation measures, the German noise mitigation value can be complied with and the construction time can be optimized as well, as shown in Fig. 4.

## Discussion

Figure 5 summarizes a typical mitigated and unmitigated impact pile-driving noise of a monopile installation in shallow water ($< 40$ m), measured at a distance of 750 m to piling. Additionally, the measured permanent background noise at the same

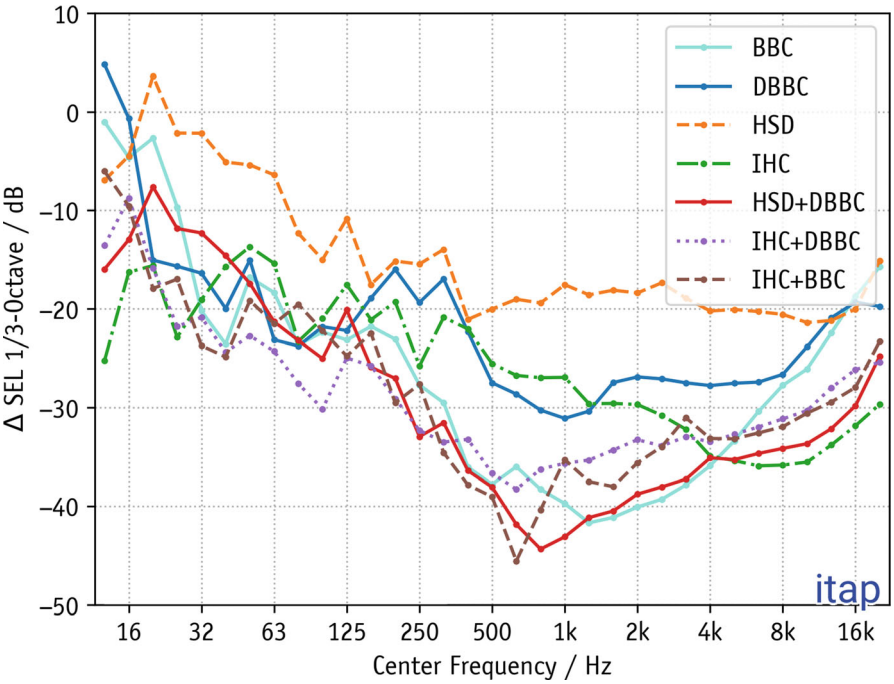

**Fig. 2** Resulting insertion loss of the offshore-reliable noise abatement systems tested in German OWF projects (Bellmann et al. 2020). Note: The differences of mitigated subtracted by the unmitigated pile driving activities are shown which indicates a higher noise reduction for lower dB values on the y-axis

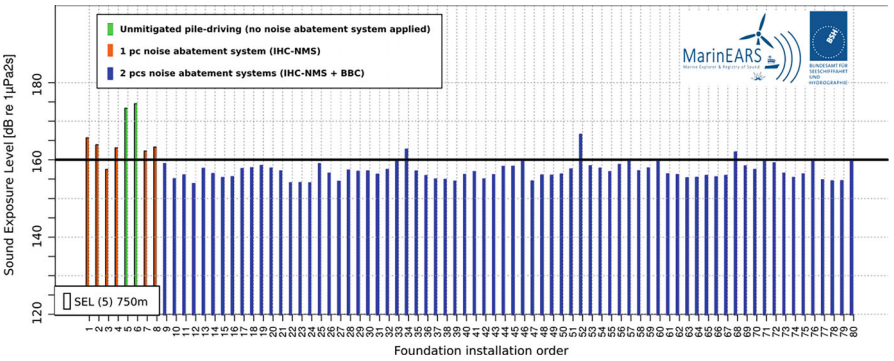

**Fig. 3** Sound exposure level resp. exceedance level ($SEL_{05}$) measured at a distance of 750 m to the respective monopile of the OWF Butendiek in the North Sea in chronological order. Due to the exceedance of the German noise mitigation values, a second NAS was applied starting with monopile installation #9. Additionally, two unmitigated monopile installations were performed to evaluate the effectiveness of the applied NAS combination (Source: https://marinears.bsh.de)

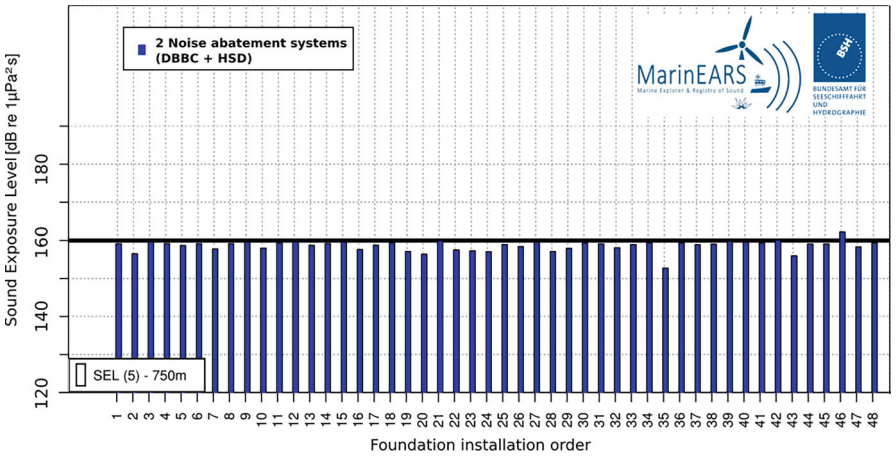

**Fig. 4** An example of another OWF project within 2016 in the North Sea is summarized in chronological order with an application of two NAS and a noise-optimized pile-driving procedure (reduced blow energy and real time underwater noise monitoring) in comparison to the OWF in Fig. 3 (Source: https://marinears.bsh.de)

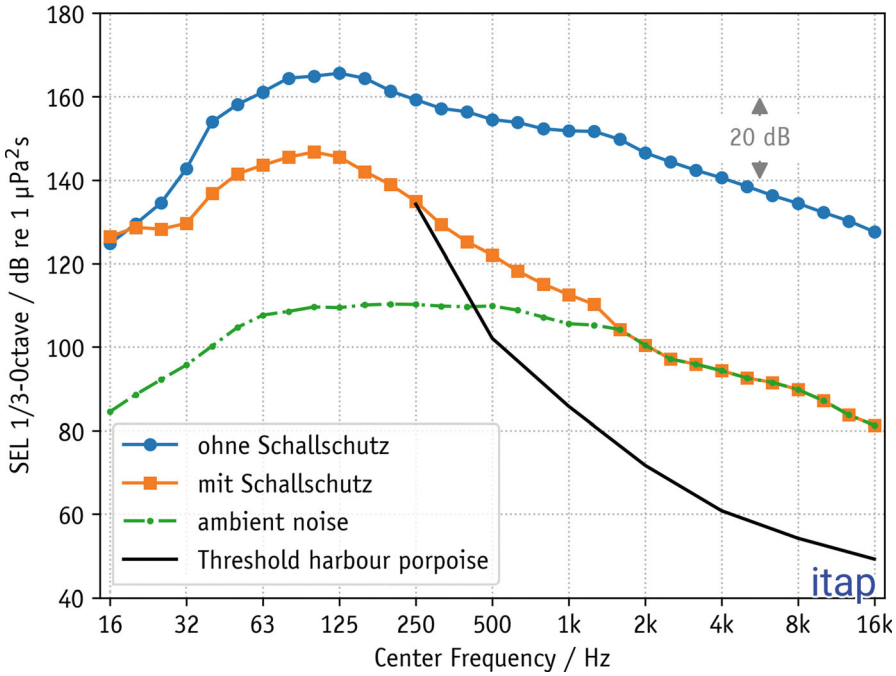

**Fig. 5** Mitigated and unmitigated pile-driving noise 1/3-octave spectrum, measured at a distance of 750 m to a large monopile installation. Moreover, the measured permanent background noise at the same positions as well as the absolute auditory threshold of the harbor porpoise (Lucke et al. 2009) is shown (Source: Bellmann et al. 2020)

measuring position prior to piling as well as the absolute auditory threshold of a harbor porpoise (Lucke et al. 2009) is shown.

Figure 5 shows, as expected, that the noise reduction achieved by applying a combination of two NAS significantly depends on frequency: the higher the frequency, the higher the insertion loss. The signal-to-noise ratio between impact pile-driving and the ambient noise decreases significantly with increasing frequency. This also explains why the determined insertion loss of all NAS and combinations of NAS (Fig. 2) decreases towards a few kHz and a larger variance in the determined insertion loss curves at several kHz occurs. This means the insertion loss of NAS in Fig. 2 might be biased by the ambient noise in the high frequency range (greater than several kHz).

However, studies like Southall et al. (2019) indicate that the individual hearing ability of any marine species should be taken into account by an evaluation of the influence of noise entry into water regarding permanent/temporal threshold shifts as well as reactions of marine species to underwater noise. This might lead to significantly different evaluations of the tested NAS and combinations of NAS with partly much higher overall achieved noise reduction, depending on the observed species, since the mitigated pile-driving noise might not be harmful or audible for some species even at a distance of 750 m to pile-driving.

However, new noise mitigation systems like the new hammer technologies Menck Noise Reduction Unit (MNRU) and Piling Under Limited Stress Equivalent of IQIP b. v. (PULSE) are coming onto the market, which lead to a prolongation of the impact duration and a decrease of the peak force (pulse lengthening techniques). Such new technologies might increase the overall achievable noise reductions of currently available NAS or combinations of NAS. First tests of the new techniques showed that in principle, a reduction of the source level by several decibels is likely. First empirical evaluations of the achieved overall noise reduction will be available in 2023.

Furthermore, new NAS as well as enhanced offshore-reliable NAS are currently under development and will hopefully be tested within the next years, especially in Germany, since the turbine sizes of OWTGs will increase significantly. Larger turbine sizes lead to larger foundation structures in deeper water, so that a compliance with the German noise mitigation values might become more challenging for the upcoming OWF projects.

**Acknowledgments** The project NavES (Phase 3) was funded by the German Federal Ministry for the Environment, Nature Conservation and Nuclear Safety (BMU) and commissioned by the Federal Maritime and Hydrographic Agency (BSH). Special thanks go to all itap seafarers as well as to all involved developers, transport and installation contractors, and noise abatement/system suppliers for the good and proactive support.

**Abstract**

Sounds of anthropogenic origins are becoming increasingly prevalent in aquatic soundscapes. Acoustic disturbance of individuals, populations, and species is, therefore, increasingly a threat to their success and survival. To better understand the level of risk and implications of elevated sound exposure, the application of a more animal-centric approach is described. Indeed, it is believed that the design of mitigation measures could also follow this approach to diminish the effects. The key to taking the species-centered approach is to first consider the sound frequencies that are most relevant to their acoustics use, including those used for

conspecific communication, auto-communication such as echo- or electro-location, and acoustic cues interpreted to understand their surroundings. Then, determine how the anthropogenic sound input masks these ecologically important signals, effectively reducing the individuals' active space. Metrics of exposure and the application of hearing thresholds and audiogram data are also explored. Further, how these can be used to estimate the potential for behavioral modifications, physiological stress, or injury is considered. A change in the interpretation of human-made sound sources in the environment is suggested, whereby anthropogenic acoustic additions are considered more than simply a polluter to an individual's niche but as a competitor for acoustic space, habitat, and prey.

## Introduction

The introduction of anthropogenic sound sources into aquatic and marine habitats is increasing. These human-made sounds have the capacity to shape soundscapes and elevate ambient sound levels over a variety of spatial and temporal scales. Although the additions from vessels to sound fields has been well described, there are a large variety of on-water and coastal activities that elevate ambient sound levels. These include, but are not limited to, resource extraction, such as offshore drilling (Blackwell et al. 2004; Wyatt 2008), pile driving (Bailey et al. 2010), dredging (Reine et al. 2014), seismic exploration (Nieukirk et al. 2004; Madsen et al. 2006; Turner et al. 2006; Hildebrand 2009), and sonar use (Watts 2003; Ainslie 2010). Coastal construction and airborne sources have also been characterized, including airplanes and helicopters (Wyatt 2008) or float planes (Burnham and Duffus 2019; Moore et al. 2022).

The acoustic sense is the principal means by which aquatic species send and receive information about their surroundings. The use of sound by animals that contains information regarding an individual's position and surroundings, or physical and emotional state has been well described (Seyfarth and Cheney 2003; Townsend and Manser 2013; Filippi 2016), especially for cetacean species (Au and Lammers 2007; Charles 2011; Filatova et al. 2013; Rendall and Owren 2013; Sayigh 2013). Evidence is also accruing for a similar use of acoustic signaling by fish species (Bass and McKibben 2003; Amorim 2006; Ladich 2014, 2019). This chapter is primarily focused on cetaceans, as the available literature predominantly has focused on the effects of changing soundscapes on whale, dolphin, and porpoise species (Burnham 2023; Burnham and Duffus 2023). However, there are significant implications for other aquatic species. The study of these species could add much to the analyses and management of noise, and so examples are added to the chapter where appropriate.

Marine animals use both passive (Deecke et al. 2002; Gannon et al. 2005; Allen 2013; Cure et al. 2013) and active sensory processes to extract information from the

environment. This adds to the body of information that guides navigation and prey detection; location of conspecifics and identification of the intrusion of another species; defense or territory definition; social hierarchy (e.g., fish species, Amorim 2006); and the search and competition for a mate. Calling can also help maintain group cohesion (e.g., in fish species, van Oosterom et al. 2016) and conspecific contact. Specifically, calls carry messages of warning or alarm, for example, to relay the presence of a predator to conspecifics (e.g., gobies *Asterropteryx semipunctatus,* McCormick and Larson 2008), hierarchy or aggression (e.g., humpback whales *Megaptera novaeangliae*, Seger et al. 2016), habitat suitability or prey abundance (e.g., bottlenose dolphin *Tursiops truncatus*, King and Janik 2015; humpback whales, Stimpert et al. 2011a, b; Parks et al. 2014; killer whales *Orcinus orca,* Ugarte et al. 2006, Deecke et al. 2011), or appeasement or social-sexual activities (e.g., gray whales *Eschrichtius robustus,* Youngson and Darling 2016).

Species have their own distinct call repertoires, with call types or parameters adapted to deliver information in different applications. Call patterning, and timing of pulses, project meaning and is used as part of mating displays (e.g., fin *Balaenoptera physalus*, Croll et al. 2002; Širović et al. 2013; bowhead *Balaena mysticetus,* Johnson et al. 2015; humpback whales*,* Payne and McVay 1971; Darling et al. 2006). Social calls guide courtship or agonistic behaviors (e.g., dolphin species, Dudzinski 1996; Herzing 1996; Díaz López 2011; gray whales, Youngson and Darling 2016). Vocalizations represent caller context, physiological state, or behavioral or social state (Dunlop et al. 2022), and identify group members (e.g., dialects for killer whales, Ford 1987, 1989, 1991; codas for sperm whales *Physeter macrocephalus,* Weilgart and Whitehead 1997) or individuals' identity (e.g., dolphin species, Caldwell and Caldwell 1965; Janik and Sayigh 2013). Those, in turn, are employed for group reunion or, for example, using "motherese" calls between mothers and their young (e.g., pinnipeds, Insley et al. 2003; Charrier et al. 2010; gray whales, Ollervides 2001; Charles 2011; Burnham et al., 2018; Burnham and Duffus 2020, 2022). The transfer of information from a signaling animal to a receiving animal can influence the current or future behavior of one or both individuals. In addition, for echolocating species, the echoes from their own acoustic projections returns information including target type, distance, orientation, direction, and speed of movement (Culik 2011).

However, the reliance on the acoustic sensory modality leaves aquatic species vulnerable to changes in their surrounding soundscape. Any interference with their ability to detect sounds has the potential to generate adverse effects (Popper et al. 2020). Human-generated acoustic additions from our activities in aquatic ecosystems are increasingly being recognized as potential disturbance that may injure or even lead to the death of an animal. To fully appreciate the implications of changes in the soundscape for aquatic species, taking a more "animal-centric" approach is advocated for (Burnham 2017; Popper et al. 2020). Species-driven examples will be used to illustrate suggested approaches and metrics to assess the potential risk and subsequent cost of acoustic disturbance. Much of the work done to date has focused on the noise implications for marine mammals, and so the examples will predominantly come from these species. Increasingly, work is being done to characterize the impacts on fish and invertebrate species, and these will be indicated where possible.

Interest in these species has been taken to understand the effects on populations in their own right and as prey species for upper-trophic species. Following this, research priorities and regulatory actions that reduce the effects of anthropogenic noise, while taking the perspective of the animal or ecosystem, will be discussed.

## Anthropogenic Noise as a Pollutant in the Soundscape

The term "soundscape" describes the acoustic landscape of an area. It was first used by Schafer (1977), who recognized that locations had their own distinct acoustic "sense of place" created by unique tones and "soundmarks." The natural components of the sound field are the non-biological, geophonic components and the biophonies. Geophonies include the acoustic additions from wind, water turbulence, tides, currents, waves, and precipitation. These account for great variation in the background ambient sound conditions (Richardson et al. 1995; Wysocki et al. 2007; Coers et al. 2008; Lugli 2010; Ladich 2013). The biophonies include invertebrate, fish, or marine mammal vocalizations, or acoustic byproducts of their behaviors, which at times dominate certain frequency bands (Zelick and Mann 1999; Cato and McCauley 2002; Myrberg and Fuiman 2002). Anthropogenic sources of underwater sound result from human use of waterways and their surrounding coastlines. The introduction of the mechanically driven vessels and the reliance on oceanic shipping has increased the anthrophonic component of the soundscape and raised the ambient sound level substantially. Pervasive noise from vessel traffic as well as coastal and pelagic construction and resource harvesting can propagate to areas far removed from the source (Jasny 2005; NRC 2005; Hildebrand 2009; Frisk 2012; Gillespie 2016; Miksis-Olds and Nichols 2016).

Vessel noise additions can propagate over great distances but are focused around shipping routes and in shallow coastal waters around cities with major ports and marine-based tourism (Andrew et al. 2002; Malakoff 2010; Frisk 2012). Distant commercial shipping noise dominates the low frequencies, below 100 Hz. However, propeller cavitation and propulsion noise can radiate sounds up to 100 kHz (Ross 1976; Gray and Greeley 1980; Richardson et al. 1995; Arveson and Vendittis 2000; Veirs et al. 2016). In the mid to high frequencies, recreational vessels dominate in the additions to sound spectra, as well as emissions from construction or resource exploration, extraction, and production, which adds sounds over a wide range of frequencies at a variety of intensities (Schoemann et al. 2022). The addition of anthropogenic noise to sound fields has been likened to a pollutant, causing habitat degradation and changes to species diversity, distribution, and habitat use.

## Animal Response to Human-Derived Noise

The impacts of elevated ambient levels or introduced human-derived sound on aquatic species can range from benign to fatal: startle and avoidance behaviors, stress responses, call masking, hearing threshold changes, and tissue damage have

been noted. In extreme cases, fatality may ensue (Casper et al. 2012; Halvorsen et al. 2012; Hawkins and Popper 2018). Therefore, the implications of anthropogenic additions to the sound field can range from sublethal to those that have short-term implications for energy budgets, long-term physiological stress, or permanent hearing damage (Southall et al. 2007, 2018). Growing concern around the impacts of human-made sound additions has increased the research and marine environmental management efforts in this area. Acoustic disturbance is now listed as a threat to the success and survival of several threatened and endangered species (e.g., killer whales, NMFS 2005; DFO 2021; belugas *Delphinapterus leucas*, DFO 2012; right whales *Eubalaena glacialis*, Oleson et al. 2020).

## Masking

Masking is a sublethal effect where an individual is unable to detect a signal of interest in the presence of elevated sound levels and/or interfering signals or noise. In this case, an animal is subject to sound levels that interrupt calling or the reception of biologically significant sounds (Clark et al. 2009; Dooling and Blumenrath 2014; Erbe et al. 2016; Dooling and Leek 2018). The extent to which the frequencies of the human-made sound additions overlap with the vocalization frequencies of aquatic animals provides an indication of the potential for disturbance. The masking effect is also defined by the level of exposure and the proximity to the sound source (Clark et al. 2009; Erbe et al. 2016; Holt et al. 2017). Audibility of conspecific calls is a function of distance between both the interfering sound source to the caller and the source to the receiver, as well as the distance between the two conspecifics (see the "maskogram" by Erbe et al. (2016)).

## Behavioral Responses

The addition of anthropogenic sounds whereby they become a "pollutant" can induce modified swimming behaviors, including altered speed, direction, depth, altered diving patterns, either on the dive and/or on the surface, and evasive or avoidance behaviors away from the sound sources (Norris 1994; Gordon and Moscrop 1996; Frankel and Clark 1998; Croll et al. 2001; NRC 2003; 2005; Weilgart 2007; Erbe et al. 2019). Startle and aversion behaviors have also been noted, with the abandonment of the area around the source observed for short to prolonged time periods (e.g., dolphin species, Lusseau et al. 2006; fish species, Popper and Hastings 2009; Hawkins and Popper 2018; gray whales, Malme et al. 1983, 1984; killer whales, Morton and Symonds 2002; zooplankton species, Slotte et al. 2004).

The impact can be spatially far-reaching depending on the frequency of the sound source and temporally dependent on the duty cycle, if any, of the source. For example, sounds exceeding 120 dB re: 1 μPa initiated startle and avoidance responses in a continuous construction-based sound exposure experiment (gray whales, Malme et al. 1983, 1984, 1986, 1988; Richardson et al. 1995). Substantial area avoidance was noted when the sound level was increased to 160–170 dB re:

1μPa (Malme et al. 1983, 1984, 1986, 1988). These levels have become accepted thresholds for marine mammal behavioral responses. Displacement from migration routes and critical breeding, young-rearing or feeding areas, and the cessation of these behaviors have also been noted as a result of anthrophonic acoustic disturbance (Malme et al. 1983, 1984; Morton and Symonds 2002). However, a behavioral response is not only predicted by the received sound level. The conditions, timing and duration of exposures, animal activity, and its habituation to the sound all help determine the response. The animal's experience, motivation, and conditioning based on previous exposure to the sound may also play a role (Southall et al. 2018).

An acoustic response has also been noted in several species to anthropogenic additions to the soundscape. Calling behaviors are altered to help signal projection overcome increased sound levels. Animals may adjust their vocalizations, displaying Lombard-effect responses by calling louder, longer, or more repetitively, or by changing the energy or frequency of the vocalization to overcome the additions (Nowacek et al. 2007; Weilgart 2007; Tyack 2008; Holt et al. 2009; Rolland et al. 2012; Janik 2014). Increased call amplitude can match sound level increases (e.g., beluga whales, Scheifele et al. 2005; humpback whales, Dunlop et al. 2014; killer whales, Holt et al. 2009, 2011, 2015, 2021). Changes in call structure, including altering the frequency content of the call to minimize spectral overlap with the human-derived sound signal, have also been noted for several species (e.g., right whale, Parks et al. 2007; beluga whales, Lesage et al. 1998; common dolphins *Delphinus delphis*, Ansmann et al. 2007). Repetition of calls or call components also increases in elevated ambient sound levels and particularly with a masking sound present (e.g., beluga whales, Lesage et al. 1998; bottlenose dolphins, Buckstaff 2004; gray whales, Dahlheim and Castellote 2016; killer whales, Foote et al. 2004; Holt et al. 2009; harp seals *Pagophilus groenlandicus,* Serrano and Terhune 2001; humpback whales, Noad et al. 2017). In humpback whales, Dunlop et al. (2010) also noted that whales demonstrated more surface activity and breaching, pectoral slapping, and tail lobbing, which would result in acoustic but nonvocal signals in the presence of human-made sounds. This was a different response to that seen for wind-dependent ambient sound increases, where song source level was increased (Dunlop et al. 2014).

## Physiological Changes and Hearing Threshold Shifts

Discomfort, pain, stress, or injury can result for aquatic life from elevated sound exposure. The sound level may be enough to alter sensitivity in hearing acuity and cause a threshold shift. This acoustic trauma can be mild, where an individual suffers pain and recoverable hearing loss, also frequently referred to as a temporary threshold shift (TTS). The onset of TTS in hearing is the short-term elevation of hearing thresholds and can be described as auditory fatigue, with levels set for pulsive tones, non-impulsive and octave-band sound levels (Southall et al. 2017). Sounds causing TTS can affect the sensitivity of sensory hair cells in the inner ear, modifying the chemical environment or blood flow to these cells; displace or overstimulate inner

ear membranes; decrease sensory neural inputs; or induce metabolic exhaustion (Kryter 1994; Ward 1997; Nordmann et al. 2000; Hastie et al. 2003; Southall et al. 2007).

Moderate hearing loss results from damage in the middle ear, and finally severe damage to the hearing apparatus in the inner ear is seen for great acoustic traumas where permanent threshold shifts (PTS) would occur (Ketten 1995, 2002; Southall et al. 2007, 2018). The onset of PTS could be considered to be the point where tissue damage results from sound exposure (Southall et al. 2017). Permanent injury may be experienced as irreparable damage to sensory hair cells of the inner or outer cochlea, or swelling of the hair cells, neural connections, and vascular system of the cochlea leading to anatomical changes. In more extreme cases, loss of differentiation within the cochlea and degeneration of the auditory nerve may occur (Hastie et al. 2003). This is often followed by neuronal losses and persistent chemical and metabolic cochlear abnormalities (Saunders et al. 1991; Ward 1997; Yost 2000; Southall et al. 2007).

Much of what is known about TTS and PTS is from observation and study of short-term responses from acute exposure. Ketten (2002) considers the onset of PTS to be more general and less species-dependent than TTS, with signal rise time and duration of peak pressure being the more significant factors. PTS is also estimated from TTS-onset, whereby permanent loss is commonly thought to result from longer duration exposure or sudden, intense onset of a broadband source, particularly in the higher frequencies (Ketten 2002). However, the loss of hearing and progressive PTS in individuals is likely a complex nonlinear process, with little known about the physiological response of individuals or populations to long term or chronic elevation in ambient sound levels.

A stress response to elevated sound exposure has also been demonstrated in aquatic organisms. It has been observed through direct testing in the presence of a sound stimuli (e.g., humpback whales, Mingramm et al. 2020) and inferred from testing in periods when sound levels have been reduced. Rolland et al. (2012) demonstrated a reduction of the stress response in north Atlantic right whales with the decrease of commercial traffic by testing stress hormone levels opportunistically after September 11, 2011, when ocean commerce was completely halted. Similar responses have been noted during the COVID-19 pandemic "anthropause" (Rutz et al. 2020), where notable reductions in oceanic soundscape levels in some areas have been recorded (Gabriele et al. 2021; Notteboom et al. 2021; Ryan et al. 2021). During the pandemic, both regional and international movements of people and goods were altered (Baldwin and Tomiura 2020), with maritime trade reduced by approximately 7–10% (Baldwin and Tomiura 2020; Bates et al. 2020; Rutz et al. 2020). Recreational and tourism-based vessels were also reduced (Gabriele et al. 2021).

## Animal-Centric Risk Assessments

To better determine the potential impact of anthropogenic sound sources on individuals or species and, therefore, the most effective means of mitigation, it is not sufficient to consider the acuity or severity of the exposure in terms of changing

sound levels over time. More species-specific metrics should be considered and take a more animal-centered approach (see Popper et al. 2020). The focus under this ideal is first to determine the presence and level of adverse effects that an individual, group, or species will be subject to if they experience a certain sound source at a particular level over a given time. The risk of auditory disturbance and adverse impacts from human-made sound sources to an individual species would be determined by the characteristics of the sound and the level of exposure. This would include a need to measure the animals' presence and residency time in the area with elevated sound levels. The implications of this disturbance to the individual also needs to include the consideration of the importance of that area to the individual or species, and whether it is critical to important life history events like breeding or feeding.

## Auditory Sensitivity

Identifying areas and level of risk of sound exposure includes first distinguishing sound sources that might elicit a response, and then assessing the exposure and dose-response of individuals or groups to the sound (Popper et al. 2020). The audibility of a sound depends on both its amplitude and frequency spectrum. Defining the hearing abilities of an animal and its vocalization and hearing range is, therefore, the first means of describing the disturbance risk (Ellison et al. 2012). The hearing range of a species provides a contextual setting, where an individual is more likely to respond to a sound in that frequency range, along with the assumption that the higher the level above the described sensation level, the greater the potential response.

Auditory thresholds and audiograms have been estimated using behavioral or electrophysiological techniques, showing variation in functional frequency and absolute sensitivity on the species and individual level (Fay 1988; Richardson et al. 1995; Szymanski et al. 1999; Wartzok and Ketten 1999; Ketten 2002; Houser et al. 2008; Supin et al. 2003, 2004; Parks et al. 2007; Tubelli et al. 2012, 2018; Branstetter et al. 2017, 2021). However, this has been measured for only a few aquatic species (Rice 1998; Erbe et al. 2016; Southall et al. 2017). Work has so far focused on toothed whale and pinniped species (Erbe et al. 2016). However, even for these species, testing is still lacking in over 20 delphinid species, 20 beaked whale species, and 18 phocid species. Testing is lacking for all baleen whale species, and little knowledge of hearing sensitivity curves or anatomy and physiology is available for these species (Erbe et al. 2016). Where data for a species does not exist, data from surrogate species within the same functional hearing group are used to create an estimate (Hastie et al. 2003; NOAA 2013). Failing this, 1/3 octave bands are commonly used as an estimate of the acoustic energy within a signal (Payne and Webb 1971; Clark et al. 2009; Hildebrand 2009; Jensen et al. 2009). Giving priority to the frequency range that species-specific calls are made can also guide the animal-centric perspective in assessing disturbance risk and is especially relevant for evaluating the potential for masking (Clark et al. 2009; Hatch et al. 2012; Burnham et al. 2023).

Frequency weighting for aquatic animals based on audiograms has been suggested to tie the sound exposure back to the animal. Differences in hearing capabilities between species are accounted for through a weighting function based on their audiogram. A generalized frequency-weighting for marine mammals, called "M-weighting," for example, has been developed with refinements for mysticetes, odontocetes as mid- or high-frequency species, and pinnipeds listening in air or water. However, these nominal audiograms may not predict well how species will specifically be able to hear certain sounds or indeed their reaction to them. Additional audiometric methods can help determine the frequency discrimination, intensity discrimination, frequency selectivity, duration discrimination, stimulus generalization, and directional hearing of individuals, or an average of individuals to represent a species (McFadden et al. 2022). Also, the critical ratio, as the minimum signal-to-noise ratio for detecting a tone against the background ambient, represents the minimum level a sound needs to be present to just be detectable and so is the lowest level of an individual's hearing sensitivity.

## Active Space

The "active space" of an aquatic organism describes the furthest extent or area of its auditory detection and discrimination. This could be communication signals between conspecifics, where the acoustic range is defined by the area over which a signal may be projected from one animal, and be received and enacted on as intended by another. This may also be described as the communication range or distance (Clark et al. 2009). Active space can also be defined by auto-communication processes, described as the area over which an animal can send a signal and then receive its own echo as part of an echo- or electro-location process (Maynard-Smith and Harper, 2003). In the context of cetacean bio-sonar, this is the echolocation range (Au et al. 2004). However, the active space should also be considered as the area over which an animal is able to send and receive signals in a functional way; this may be the active use of acoustic signals through communication, or interpretation of echoes, but can also include "soundmarks" (Schoemann et al. 2022) and cues from the environment or conspecifics received passively or through "eavesdropping" which supports orientation, navigation, and habitat choices (Slabbekoorn and Bouton 2008; Allen 2013).

Active spaces are dynamic and reflect the variations in signals produced and the sound field they are projected into. The extent is defined by many variables. For example, signal production, transmission, and properties of the signal itself, including the frequency, amplitude, length, and modulation. As well, the signal modifying properties of the environment, and complexity of the acoustic surroundings are significant influences (Bradbury and Vehrencamp 2011).

An appreciation of the active space of an individual, and its dynamic nature, provides insight into how an animal associates with its habitat (Burnham 2017, 2020). Species sensitive to sounds in the lower frequencies have a greater active space due to the long-range propagation of these signals compared to those of higher

frequencies. It considers how an animal makes sense of its surroundings and is fundamental to taking a more animal-centric approach to its role and place in an ecosystem. This may be conceived of as a part of the "operational niche" (Parker and Turner 1961) of an organism. This is synonymous to the "realized niche" described by Hutchinson (1957), but with the influence of "operational environments" introduced by Mason and Langenheim (1957), where there is a time-space-organism concept of environment. However, here the space is centered around the organism and so active space could equally be its "dynamic spatio-spectral-temporal acoustic habitat" (Clark et al. 2009) or its operational ambisonic niche, describing the three-dimensional acoustic landscape it is actively engaged with and interpreting.

The risk and extent of masking can be estimated using the concept of active space. If signals or a signal return falls below background sound levels, calls or cues will become less discernable, and the active space will be reduced. One of the first descriptions of the potential for acoustic masking of calls by human-made sound sources was presented by Payne and Webb (1971) for fin whales. They demonstrated a hypothetical reduction of signaling range for 20-Hz calls to fall from 900 km in a quiet ocean to 90 km under moderate ambient sound conditions under spherical spreading conditions, and from a maximum range of 13,000 km in the sound fixing and ranging (SOFAR) channel to just over 1 km with the same elevation in ambient sound levels (Payne and Webb 1971). Further examples have been reported in the reduction of communication space for baleen whales (Richardson et al. 1995; Hatch et al. 2012), delphinids (Janik 2000; Williams et al. 2014; Burnham et al. 2023), seals (Southall et al. 2003), and fish species (yellowfin tuna *Thunnus albacares,* Finneran et al. 2000; cod *Gadus* spp. and haddock *Melanogrammus aeglefinus*, Stanley et al. 2017).

## Metrics to Assess Risk of Affect

Identifying areas and level of risk from sound exposure includes distinguishing sound sources that might elicit a response and then assessing the exposure level of the individuals or groups (Popper et al. 2020). Likening the presentation of a masking sound in a soundscape to a pollutant allows exposure-response or dose-response relationships to come to the fore. The relative impact as a function of dose can be defined by considering the sound level, exposure duration, and proximity to the source (Clark et al. 2009; Hatch et al. 2012; Erbe et al. 2016).

Metrics have been developed to quantify the level of exposure to assess the risk of sublethal effects such as masking or behavioral change. These include the root mean squared ($SPL_{rms}$) or peak sound pressure level ($SPL_{peak}$), sound exposure levels (SEL), and kurtosis. Few studies discern between the root mean square or peak SPL, or direct measures of the received sound levels, and none of these metrics account for the duration of exposure. Sound exposure levels (SEL) offer a first approximation of the sound levels experienced by an individual on variable amplitude and/or duration schedules (Southall et al. 2017). This is an "exposure summation" metric, whereby an intermittent sound source is expressed as a single continuous exposure (Finneran

2015a). The sound level is normalized to 1 s periods across the period of exposure, which allows time periods to be compared in terms of the total acoustic energy received. This is important to assess cumulative exposure from multiple sources or the same source repeated several times. The SEL can be adjusted to be a more species-specific metric by using frequency ranges representing functional hearing groups (Martin et al. 2019) or by applying auditory frequency weighting functions prior to summation (Finneran 2015b). When considering the potential for acoustic masking, where possible, the metrics should be considered in the frequencies relevant to the species of interest and, where audiograms are available, the frequency that the species has the most acute hearing (Tougaard and Dähne 2017). If there is little to no overlap in frequency ranges of the signal and the noise, then non-masking effects such as behavioral modifications should be considered (Erbe et al. 2016).

Vocal plasticity allows species to respond to varying sound exposure with Lombard-effect like responses. Masking release strategies may also be employed to overcome some of the risk of sound additions interfering with signals. Strategies that alter the structure and projection of the signal from that of the interfering and potentially masking sound additions might allow the signal to still be discerned. Here, signal alteration allows for a release by creating disparity between that and the soundscape additions. Spatial and temporal release in the location, direction, and timing of signal production can also be used. Spatial release occurs when the level of masking is decreased due to the signal and masking sound sources being located in different locations and/or being projected in different orientations (Erbe et al. 2016), and relies on the receivers' ability to localize sound (Penner et al. 1986; Erbe et al. 2016). Directionality in calls has been demonstrated in several low- to mid-frequency vocal projections (e.g., bowhead whale calls, Blackwell et al. 2012; whistles and stereotyped calls of killer whales, Miller 2002; Lammers and Au 2003) and echolocation signals (e.g., killer whales, Au 1993; Au et al. 1995, 2004; sperm whales, Beedholm and Mohl 2006). Temporal release strategies take advantage of periods of quiet or relief from noncontinuous sound sources (Erbe 2008; Erbe et al. 2016). In addition, co-modulation release describes the variation of the frequency of a signal if the sound additions are present in a predictable modulation pattern across its range of frequencies (Brainsetter and Finneran 2008; Erbe et al. 2016). Adaptation of the signal is used to make it discernable from the patterns in soundscape additions that would otherwise result in masking.

Sound source parameters, and variables defining an individual's sensitivity to varying sound exposure, influence the onset of changes in hearing capabilities. These criteria will differ based on the sound source and if it is a single pulse, multiple pulses, or continuous. Hearing threshold shifts occur when either the cumulative sound exposure or peak sound pressure level set per species is exceeded. However, pressure-based metrics should be applied conservatively in reference to this variation. Yet, at some point, sound levels can reach a point where injury will result from all sounds over all frequencies. Measures of kurtosis describe the abruptness of the onset of the sound source and can be used as one variable to quantify potential impact. Typically, a statistical measure used to describe the shape of a distribution, here a high negative platykurtic score, would indicate rapid onset

and high instantaneous peak pressure that could elicit a stronger behavioral or physiological response (Ketten 2002; Hamernik and Qiu 2003). This indicates the presence of a broadband, atonal, transient impulsive sound with a short rise time (Southall et al. 2007). Mammalian auditory systems are particularly vulnerable to damage from intense impulsive sounds (Finneran et al. 2000, 2002; Southall et al. 2007, 2019). Distance from the sound source can mitigate some of the effects of an impulsive signal. Indeed, Hastie et al. (2019) investigated the propagation of pile driving and seismic survey signals, demonstrating that range from the source was the defining factor in shaping the received signal duration, rise time, and crest factor, which defines the impulsive or non-impulsive nature of the sound signals. Over distances of several kilometers, only a small proportion of sounds emitted from pile driving, seismic surveys, or underwater explosives would be characterized as impulsive after propagation (Finneran et al. 2000; Hastie et al. 2019).

## The Use of TTS and PTS as Metrics of Risk

Exposure thresholds have been suggested as limits to mitigate the negative impact to organisms and constrain TTS and PTS responses. These thresholds could be used to assess the risk of hearing fatigue or physical injury following elevated sound exposure. They can also be used to understand the potential hazards to animals within the range that the TTS-causing sound is present. This can guide mitigation measures (Popper et al. 2020). However, care must be taken when applying these metrics as TTS can accumulate over multiple exposures or show a delayed onset (Erbe et al. 2022). The most comprehensive criteria have been outlined for marine mammals, with several reviews and refinements (NMFS 2005, 2013, 2018). To limit harm, these criteria state that received levels of impulsive sounds should not exceed 190 dB re: 1 μPa for pinnipeds and most odontocete species, and 180 dB re: 1 μPa for mysticetes and sperm whales (NOAA 2013). Continuous sound sources are deemed to elicit avoidance responses before injury, yet an onset level of 230 $dB_{peak}$ re: 1 μPa has been described for PTS as a result of continuous sound sources for all cetacean species. Thus, any sound with amplitude greater than this level would result in permanent hearing damage in all species and functional hearing groups. This absolute threshold is similar to the definition of the asymptotic threshold shift, which is thought to represent the upper bounds of PTS and results from sources of a specific sound pressure level regardless of duration (Mills 1976; Finneran 2015b).

Sound exposure criteria is increasingly being adopted into regulatory approaches aimed at reducing the risk of acoustic disturbance. Estimates of the onset of TTS and PTS are becoming an integral metric in this process. The applications of these thresholds, however, expect that there is a typical response and that it will be consistent across all individuals. While the use of these sound levels provides an approach for precautionary management to reduce the potential for acoustic disturbance or injury, they do not consider the duration or frequency distribution of sound levels, and so may underestimate the true risk of impact (Stober and Thomsen 2019).

## Assessing the Scale of Impact

The spatial scale of the impact of a sound source ostensibly can be determined by its frequency and magnitude, and the time that it is present. The impact can be far-reaching, depending on the spectrum characteristics, and temporally dependent on the duty cycle of the sound additions. However, this is a simplified approach for assessing disturbance to aquatic species. The scale of impact on an individual, population, or species also depends on the context of how the individuals are using the space, their behavioral state (Goldbogen et al. 2013), and their sensitization (Kastelein et al. 2011). Each of these factors refines the dose-response curve, adjusting the likelihood and implications of a response. This creates an exposure-response risk function (Miller et al. 2012; Southall et al. 2019). Considering this with the factors that influence audibility, different sound sources have different "potencies" for different species or indeed for different individuals.

Identifying high use regions where more individuals are exposed to elevated sound allows for prioritization of risk management and mitigation. The risk of disturbance, however, should take into account both the exposure level and the ecological importance of the area to the focal species. To take the animal-centric approach to acoustic impacts, both environmental factors and receiver variables ("enviroscape" and "psychscape," respectively, Job et al. 1999) should be considered. Mapping co-occurrence of species' presence and human activities might be the first step in establishing risk (e.g., gray whales, Silber et al. 2021; humpback whales, Dransfield et al. 2014). Maps like these are a precursor to aggregate sound level models such as those created by Erbe et al. (2012) until data availability make them possible. Using vessel presence data, Erbe et al. (2012) visualized the cumulative underwater acoustic energy from commercial shipping. These maps can be made more species-specific by considering the sound fields for frequency bands specific to a species of interest. Clark et al. (2009) show an example of this for a construction site and vessel transits. The propagation and potential for masking of communication calls by human-derived sound sources of the same energy levels differed spatially when considering representative ranges for fin (18–28 Hz), humpback (224–708 Hz), and right whales (71–224 Hz). This highlights the importance of mapping specific frequencies of interest when taking the animal-centric approach and not solely relying on the emissions focused around the source (Erbe et al. 2012; Aletta and Kang 2015).

If calling behaviors have temporal patterns, disturbance risk will differ based on the proximity of the signal of interest and the sound source in time. Diurnal patterns, for example, or those related to an activity state might be impacted by sound exposure if there was temporal overlap (e.g., New Zealand bigeye *Pemphersis adsperda,* van Oosterom et al. 2016).

Previous work, using either observations and/or models, have typically only considered the direct impact of sound sources on an individual. The level of response and impact is usually discussed using the dose-response curve on the individual level relating to acute exposures. This, however, limits the assessment of impacts significantly; it considers the response from only one exposure from one source and does not consider the impacts of individual exposures in relation to their group or species success.

A framework to understand the cumulative impacts of multiple exposures of the same sound and/or exposures to several sounds sources concurrently is lacking. It cannot be presumed that exposure is additive when determining the response (Ayres et al. 2012), or that a short-term response can be used to infer the longer-term or population wide implications (Tougaard et al. 2015). Also, the shift to link these to longer-term, population level impacts on a broader scale is more challenging.

However, broad scale ecosystem implications may result from the addition of sound sources and/or elevated sound levels, where the impact is felt across trophic layers (Popper et al. 2020). To consider this, the potential for the sound source to change prey distribution and abundance, or species richness and diversity of an area more broadly, should be estimated. Startle and avoidance behaviors have been noted for fish and zooplankton (Popper and Hastings 2009; Hawkins and Popper 2018). Less directly observable effects might also result, such as changes in swarming or aggregating dynamics or a decline in reproductive success, or increased risk of predation due to masking (Slotte et al. 2004).

The population consequences of acoustic disturbance (PCAD) framework was developed to quantify the population level disturbance of sound exposure (e.g., dolphin species, Noren and Holt 2010; elephant seals, Costa et al. 2016). A similar but more general model, the population consequences of disturbance (PCoD) has also been used to determine the implications of disturbance on a population (New et al. 2014; King et al. 2015). This model attempts to address the scaling issue from individuals to population (e.g., gray whales, Villegas-Amtmann et al. 2015, 2017; humpback whales, Dunlop et al., 2021), but additional information is needed on the dose-response curves of species to be able to provide a more definitive assessment of impact. The PCoD framework suggests a means to quantify the impact of multiple stressors. However, this considers that the relationship between stressors, in this case different sound sources, would be additive in nature and exposures would be consecutive. This does not yet allow for synergistic or antagonistic relationships between sound sources, or response to various ambient sound levels, to be quantified. Neither model has been fully parameterized for a species with empirical data. Data interpolation and expert judgment, or informed assessments are used to apply the model to species (Pirotta et al. 2018). These models could, however, with time, be useful to establish if a single or multiple sound sources represent a risk to population success and survival, which may develop more meaningful evidence-based mitigation measures.

## Assessment of the Cost of Acoustic Disturbance

The adverse effects from acoustic disturbance on aquatic animals can be far-reaching. Masking ecologically important signals can drive behavioral changes in vocalization and habitat use. Displacement from areas critical to feeding, breeding, or rearing of young, or cessation of these behaviors have implications on foraging and weaning success, and the energy balance of individuals.

Loss of communication and echolocation space through masking has significant implications to the health and survival of aquatic species (killer whales, Williams et al. 2014; right whales, Clark et al. 2009; Hatch et al. 2012). Also, a loss of "listening space" (Barber et al. 2010; Pine et al. 2018) reduces the ability to detect threats, to locate prey, or find a mate. There may be energetic implications from altered vocalizations, either calling louder, more repetitively or using nonoptimal frequencies (Bradbury and Vehrencamp 1998). However, this is considered one of the least severe outcomes of acoustic disturbance, with the cost to change calling or echolocation signals low to negligible compared to other behaviors that might result from exposure to sound sources (Noren et al. 2009, 2017). There may be limits for species or individuals to compete with the elevated sound levels, with the adaptation of calling possibly limited by physiology. The capacity of the acoustic apparatus can limit the calls that are able to be produced. Perhaps reaching this threshold instigates calling cessation or maybe even area abandonment.

Implications for foraging behaviors have been noted for aquatic animals in the presence of anthropogenic sound sources. For southern resident killer whales, for example, foraging efficiency was reduced by 38–100% in proximity to the source of vessel-based additions to the soundscape (Au et al. 2004; Holt et al. 2009). Elevated ambient sound levels may make prey less available (Sato et al. 2021) and hinder the location, capture, and sharing of prey (Ford and Ellis 2006). The cessation of foraging or spatial displacement can directly result in reduced reproductive success or survival. A behavioral shift from foraging to travelling, for example, (e.g., killer whales, Williams et al. 2006, 2014; Lusseau et al. 2009) reduces both energy intake and increases expenditure. Differing responses have been shown between individuals based on prior experience or exposure, sensitivity, age, gender, and health (Simmonds et al. 2004; Weilgart 2007). Differences between genders, with the female being more sensitive to the exposure (e.g., killer whales, Williams et al. 2014; Holt et al. 2021), suggest greater population level implications from the disturbance. The transition away from social or resting behaviors have also been noted in the presence of vessels (e.g., bottlenose dolphins, Lusseau 2003).

In elevated sound conditions, the altered use of surface-active behaviors has been noted in some species (dolphins, Henderson et al. 2014; humpback whales, Dunlop et al. 2010; Dunlop 2016; killer whales, Noren et al. 2009; right whales, Parks et al. 2019). As well, increased ventilation rate, swimming speed, and path sinuosity may be apparent with the proximity of a vessel as a sound source.

The behavioral context of sound exposure can explain the varying sensitivities between species or even individuals. Periods, like weaning, also represent a critical period of learning and development, shaping future foraging and acoustic behaviors (e.g., gray whales, Wisdom et al. 2001; Burnham and Duffus 2020). Elevated sound levels could hinder vocal learning from their mother and conspecifics, or reunion events after the cow has left the calf to feed (e.g., gray whales, Burnham and Duffus 2020; humpback whales, Indeck et al. 2020; sperm whales, Whitehead 2017).

There currently is no way to determine the relative impact of disturbance based on the behavioral or social context of the area, or the behaviors that are disturbed. The energetic cost of disturbance might be weighted to reflect the importance of these

areas or behaviors to individual or population success, once we can clearly estimate the cost of the stress or changes in vital rates. Stress responses can occur at low sound levels and far removed from the source, and could impact the immune response, reproductive success, and vigilance of an animal. Behavioral responses can be subtle, whereas the stress response may be unobservable and may be confounded by the presence of other stimuli. More nuanced biological relevance may also be established when considering the repetitiveness of the source and how long the presence of the sound persists. Assessing the cost to an animal with no observable change in behaviors can minimize the estimated impact. Observable changes of behavior could be absent due to increased habituation or, indeed, progressive deafness. However, it may also reflect limited dispersal abilities, for example, when foraging on patchy prey resources.

## Noise Pollution as a Competitor to Aquatic Species

To take the appreciation of human-made sound sources as a habitat level pollutant, a step further in an animal-centered approach, and regarding it as a competitor, may be useful. Competition is defined as two or more entities competing for the same resources in an ecosystem. This can be for the same prey resources or living space when these resources are limited. In this case, the presence of a sound source resulting in acoustic disturbance is in an amensalistic relationship with the individual, group, or species. Instead of using the same resources, the sound addition limits the availability or access to resources to produce the one-sided negative effect. This suggests a more active and direct impact than simply dose-response. Considering asymmetric competition traits may help understand how, as the dose or exposure of the sound increases, a decrease in abundance of a species is seen.

The strength of competition depends on the similarity of the traits of individuals; in this application, the similarity in frequency range of the signal and sound source describes first their sensitivity to the disturbance, and then forms part of the assessment of potential masking. Masking, expressed as proportional reduction of range, area, or volume, represents a reduced active space. To form a masking metric, this reduced range is compared to the range or space of acoustic signals under a minimum ambient sound level condition (Clark et al. 2009; Hatch et al. 2012; Burnham et al. 2023). This enables a proportional reduction of communication or echolocation space to be quantified. This metric is a useful comparator of effect over space and time but could also be considered akin to competition coefficients.

The competition between an individual and the masking sound for effective active space highlights the importance of the frequency and amplitude of the sound. Those individuals that utilize spatial or temporal co-modulation masking release mechanisms could be said to be taking advantage of the "vacuum of competitive release" (Van Den Elzen et al. 2017) or opportunistically making use of any declines or reductions in exposure. Sound sources as competitors have, in some instances, been shown to push species past a short-term response into a long-term adaptation in their acoustics use. Seasonal and longer-term changes in whale

calls have been noted, for example, in response to changes in the acoustic properties of the soundscape on both regional and global scales (e.g., blue whales *Balaenoptera musculus,* McDonald et al. 2009; Leroy et al. 2018).

Under the designation of a pollutant, elevated sound levels cause habitat degradation. It may, however, be more in keeping with the animal-centric approach to consider that the sound source has removed habitat from the realized niche of an individual as a result of avoidance behaviors. Anthropogenic sound sources displace aquatic life over a range of spatial and temporal scales. Gray whales changed their migration route when exposed to industrial (Malme et al. 1983, 1984) and vessel sound sources (Moore and Clarke 2002). Longer-term habitat displacement was seen as a result of construction noise in their breeding lagoons, abandoning a site for several years until construction ceased (Mate 1995). Also, humpback whales avoid air gun arrays at greater distances than the protective mitigation zone that industry would have allowed (Dunlop et al. 2015). Acoustic harassment devices deployed to displace seals from salmon fish farms have also halted killer whale use of an area (Morton and Symonds 2002).

For many species, however, the threshold of the introduction of a sound source that instigates habitat abandonment has yet to be established, and so more subtle behavioral responses are assessed. Startle and avoidance responses can change the ecosystem dynamics, making changes to predator-prey relationships (Francis and Barber 2013; Naguib 2013). Fish catches were reduced after exposure to seismic survey sounds (cod, *Gadus morhua*, haddock *Melanogrammus aeglefinus* and rockfish *Sebastes* spp., Skalski et al. 1992; Engås et al. 1996). Prey may become less available due to acoustic competition, by not being able to effectively locate prey (Sato et al. 2021). Prey displacement and altered habitat use of fish and invertebrate species have also been noted (Simpson et al. 2016). Together, this can alter the trophodynamics of a system (see Popper et al. 2020).

## Animal-Centric Mitigation Strategies and Future Actions

Mitigation strategies to lessen acoustic disturbance can be enacted at the source or through more operational and policy measures. Source-based measures are changes to the design or implementation of the activity generating elevated sound levels. Retrofitting the existing commercial fleet, propeller shields, and bubble curtains, for example, lessens the sound levels emitted from a source. The measures themselves are not species-orientated, but the efficacy of the measures can be assessed in a more animal-centric way by evaluating the change in sound levels in the frequencies pertinent to the focal species. An elevation in sound levels can be compared to estimates of hearing sensitivity and audiograms to better understand the relevance and effectiveness of the measures.

Operational measures may, however, be more targeted to populations or species by considering their temporal and/or spatial application. Animal-centric tools to directly mitigate elevated sound levels include “marine mammal safe zones,” during construction or sonar and seismic surveys, and vessel rerouting or slowdowns in

critical habitat. Policies linked to habitat conservation that include the soundscape, stating that acoustic emissions should not "destroy" habitat, are being developed (DFO 2011, 2021). These measures state that species using areas with this type of protection should be able to use signals to communicate and detect and capture prey. However, threshold sound levels that would constitute a violation of this principle have yet to be defined. The masking metric of proportional reduction in communication or echolocation range or space might go some way to quantify a maximum level of allowable acoustic addition or overall ambient sound level that should not be exceeded. Considering the impacts during important life history events or the presence of whales in areas of intense human use can be the first step to highlighting areas in need of more complex mitigation strategies. Soundscape mapping highlights regions that most need mitigation measures (Erbe et al. 2012, 2014, 2021; Schoemann et al. 2022), further refined by considering species-relevant frequencies.

Increased research effort is needed to clarify the sensitivity and response of animals to sound exposure. Hearing sensitivity curves and audiogram development methods should not be based solely on the response of individuals on narrow band artificial tones, as these might not accurately predict the audibility of complex sounds (Erbe and Farmer 1998; Cunningham and Mountain 2014; Erbe et al. 2016). Natural animal- or environment-derived signals and anthropogenic sound sources are usually more broadband than the signals used in the signal-response testing to establish acoustic capabilities. More studies like those conducted by Kastelein et al. (2011, 2012, 2013, 2014), where behavioral auditory testing was applied to more complex human-derived sources like sonars, construction, and pile driving are needed. Reflection, diffraction, and scattering of the sound signals, and potential multipath arrivals formed from the depth, range, and azimuth between the signal and receiver, reflecting a more natural setting, may need to be considered to refine the three-dimensional shape of an individual's active space (Erbe et al. 2016), before looking at the implications of elevated sound conditions or noise sources on it. Similarly, more data on the auditory filters and critical ratios and the integration time or temporal processing of signals by animals is needed for many aquatic species (Erbe et al. 2016). So far determination of these have been limited mostly to odontocetes, including bottlenose dolphin, harbor (*Phocoena phocoena*) and finless (*Neophocaena phocaenoides*) porpoise, false killer whales (*Pseudorca crassidens*) and beluga whales, and seal species including harbor (*Phoca vitulina*), ringed (*Pusa hispida*), northern elephant (*Mirounga angustirostris*), and fur (*Callorhinus ursinus*), as well as the Californian sealion (*Zalophus californianus*), western manatee (*Trichechus senegalensis*), and sea otters (*Enhydra lutris*) (Erbe et al. 2016).

Perceived loudness is a frequently employed metric to describe sound sources, with additions to a soundscape described in decibels (dB re 1 μPa) relative to ambient sound levels. However, perceived loudness is also tied to the signal duration and frequency content. A better predictor of behavioral response is derived when taking all these variables into account. The sound level threshold is attractive for initiatives designed to manage acoustic disturbance because of its simplicity, but it may not capture the complexities of the response (Tougaard and Beedholm 2018).

## Conclusion and Future Directions

Considering anthropogenic sound sources more as a competitor than a pollutant is a subtle mindset shift but highlights the potential impact to both the individual, group, or ecosystem more clearly. It can have greater implications than that of an additive pollutant and instead be seen as limiting resources and diminishing habitat. The concept of being a competitor also highlights the interaction between the animal, its acoustics use, and the various levels of sound exposure. That said, the analogy of noise as a pollutant has been useful in expressing the problem to managers and the lay public, and remains relevant. The term "pollutant" captures the pervasive nature of human-made sound additions to the soundscape. Although some sources of anthropogenic sounds are consistently present over long time periods, to date modeling efforts have not been able to fully capture the more persistent nature of this pollutants. Also, sound of any source is removed immediately as soon as the source is eliminated and does not linger in the habitat after source removal. This differs from other pollutant types that may be more persistent. However, recovery of animal habitat use before the sound source was present may take time (Mate 1995; Morton and Symonds 2002).

Increasingly, acoustic disturbance is being included as a key threat to the success and survival of threatened and endangered species. Also, with the growing concern around the impacts of human-made sound sources, it has become an expanding area of aquatic and marine environmental management (Popper et al. 2020). By taking the animal's perspective, a change in the appreciation of implications of elevated sound levels gives more weighting to their reliance on the acoustic sense for survival, and that interference in the reception of acoustic signals because of changes in the soundscape has the potential to create adverse effects. Concepts such as active space should be incorporated more readily in the assessments of the effects of acoustic disturbance to truly take a more species-specific and animal-focused approach. Also, a weighting towards mitigating the effects of increased sound levels in areas that represent ecologically important areas should be made, as well as targeting those areas where human activity and aquatic species overlap most.

**Abstract**

Underwater sounds produced from anthropogenic sources may pose risks to aquatic life, yet there is much uncertainty regarding the prediction of these impacts. A structured risk-based framework for identifying, assessing, and managing risks associated with underwater sounds has been previously proposed; however, real-world applications of the approach are lacking. Therefore, this

chapter describes a risk-based framework for evaluating underwater sounds from dredging operations and demonstrates the process using a real-world dredging scenario. The approach described was used to evaluate risks to aquatic biota from a dredging operation in the Port of Alaska, USA. Sound levels were recorded during dredging activities and used to evaluate the relative risk of hearing impairment to the species of concern, including marine mammals and fish. Demonstration of the screening-level approach was beneficial to inform the relative risk of dredging operations, eliminate species of concern from further evaluation, and provide a path forward for future refinements to decrease uncertainties. This approach provides a transparent and repeatable phased methodology to discern ecological risks associated with dredge-induced underwater sounds that is applicable to a wide range of sound sources and site-specific scenarios.

## Introduction

There is growing awareness on the impacts of anthropogenic underwater sounds on aquatic life (UN 2018). Yet, to inform current and future protective guidelines and regulations, there is a need to apply risk-based approaches (Popper et al. 2020). To achieve this, regulators and researchers need to collaboratively develop and implement strategies that bridge the gaps of knowledge so that ecosystems can be protected and the degree of regulation and mitigation is appropriately proportional to the risks (Hawkins et al. 2020; Popper et al. 2020). The importance of applying a risk-based assessment process to improve regulatory and mitigation decision-making for underwater sounds has been previously acknowledged (Faulkner et al. 2018; Merchant et al. 2018; Popper et al. 2020). Therefore, as more scientific understanding of ecological impacts (or risks) are developed, there is a corresponding need to develop risk-based approaches to integrate data (which are often disparate and complex) and utilize multiple lines of evidence to inform management of underwater sounds from anthropogenic sources.

The goal of a risk framework is to provide a widely accepted and applicable process and methodology that enable resource managers to systematically evaluate ecological risks associated with underwater sounds and to guide appropriate management solutions, if necessary. Specific to dredging operations, there has been substantial progress in the past decade documenting underwater sound exposures for various operational scenarios (Suedel et al., 2019), development of high-level risk frameworks specific to dredging (WODA 2013), and expansion of more detailed approaches and application of these risk-based methods (McQueen et al. 2020). Yet, there remains a need to provide pertinent examples from real-world case studies to apply a risk framework in practice. Therefore, the aim of this chapter is to further

define and demonstrate the utility of a risk-assessment process for evaluating ecological risks from dredging-associated underwater sounds. To achieve this aim, the specific objectives were to (1) apply a tiered risk assessment process for assessing underwater sounds produced from dredging, (2) use real-world data from a dredging project to demonstrate and evaluate the risk assessment approach, and (3) document lessons learned and areas of future research.

## Ecological Risk Framework for Dredging Sounds

A detailed risk framework process has been previously defined and discussed in detail (Fig. 1; McQueen et al. 2020). Prior work has acknowledged the benefits of using a risk-based framework for evaluating impacts of anthropogenic underwater sounds to aquatic life. For example, Boyd et al. (2008) proposed a stepwise framework for evaluating underwater sound risks which included hazard identification, characterizing exposure to hazard, characterizing dose-response relationships, risk characterization, and risk management. Additionally, a high-level description of a risk assessment framework was proposed for evaluating dredging sounds (WODA 2013). Yet, in the case for dredging sounds, such assessment processes have not been described in detail or evaluated using real-world data. Therefore, in this chapter, a tiered process including both a screening level and a detailed assessment process is described. Both assessment steps of the approach consist of three components: (1) define the risk problem (i.e., project formulation), (2) assess exposure and effects (i.e., analysis), and (3) characterize risk (Fig. 1).

## Case Study: Screening Assessment for Dredging Sounds

### Project Formulation

The study site is the Port of Alaska, USA, near the confluence of the Knik Arm and Turnagain Arm of Cook Inlet which connects to the Gulf of Alaska (Fig. 2). The Port of Alaska is the largest cargo port in the region, handling 74% of all in-bound nonpetroleum freight that enters south-central Alaska. Approximately five million tons of cargo (all commodities) passed through the port in 2021 which is also designated as a Military Surface Deployment and Distribution Command. Therefore, maintaining safe and navigable waterways for the Port of Alaska is critical to commerce and national security. To achieve this, the harbor basin requires an annual routine maintenance dredging cycle, and up to one million $m^3$ of sediments are annually removed using dredges. However, environmental consequences (risks) of dredging activities are addressed and managed (if necessary) prior to operations. A conceptual site model is a useful tool to describe the potential interactions between dredging sound sources (exposures) and species of concern (responses). In this case, the conceptual site model defines details of the underwater sound sources, sound

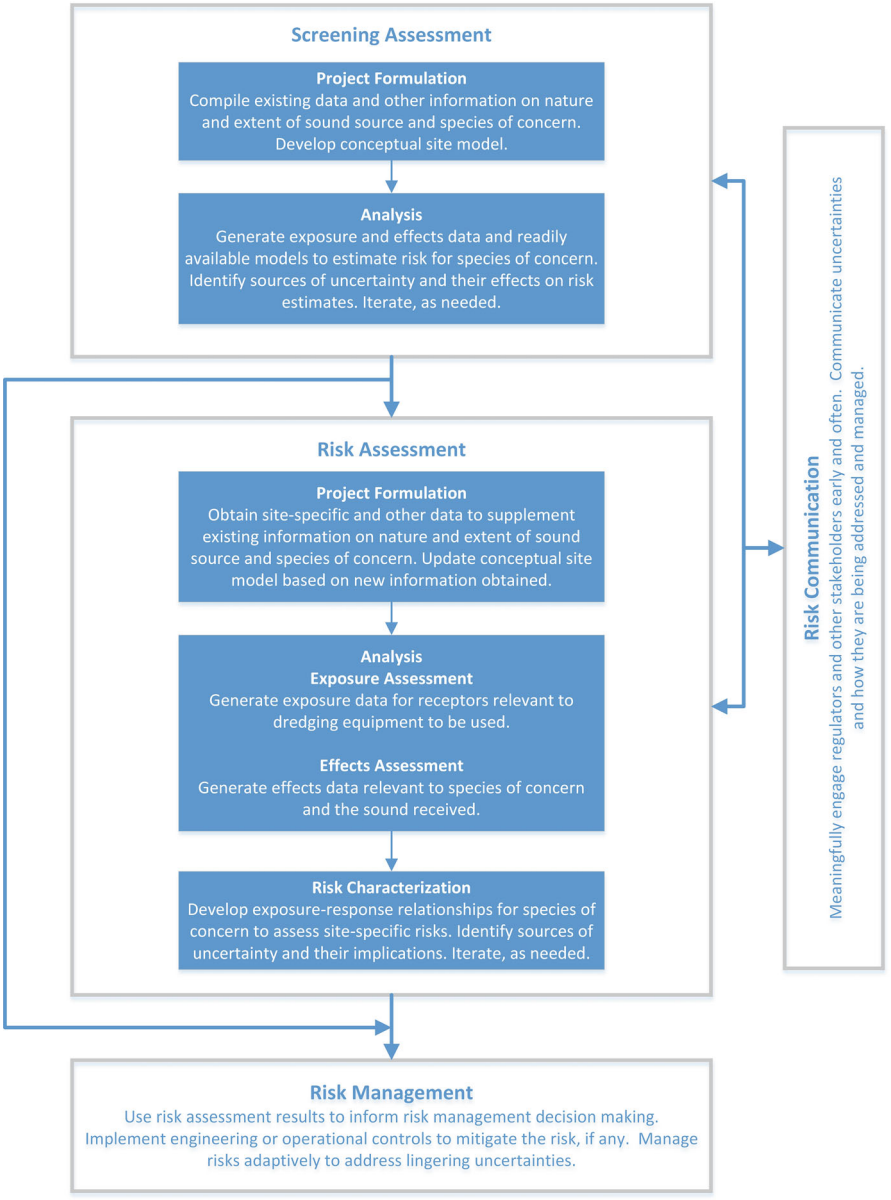

**Fig. 1** Overview of the risk-based approach for assessing and managing risks associated with underwater sound from dredging operations. (From McQueen et al. 2020)

exposure scenario (e.g., spatial and temporal scales, intensity, waveform), exposure metrics (e.g., sound pressure level [SPL], sound exposure level [SEL]), defined species of interest, and specific response measurement endpoints (Fig. 3).

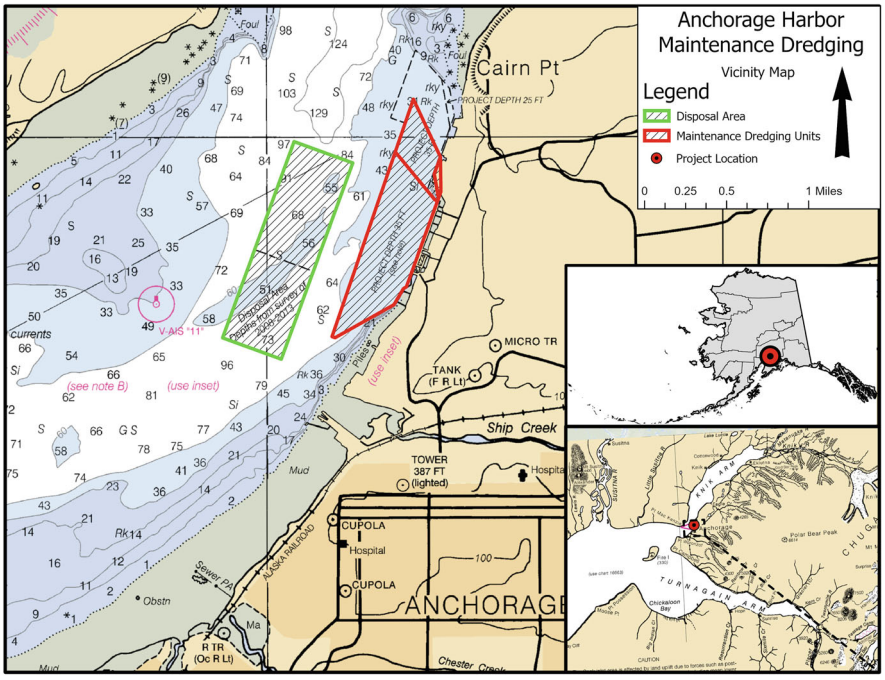

**Fig. 2** Study area located in Anchorage Harbor Alaska, USA

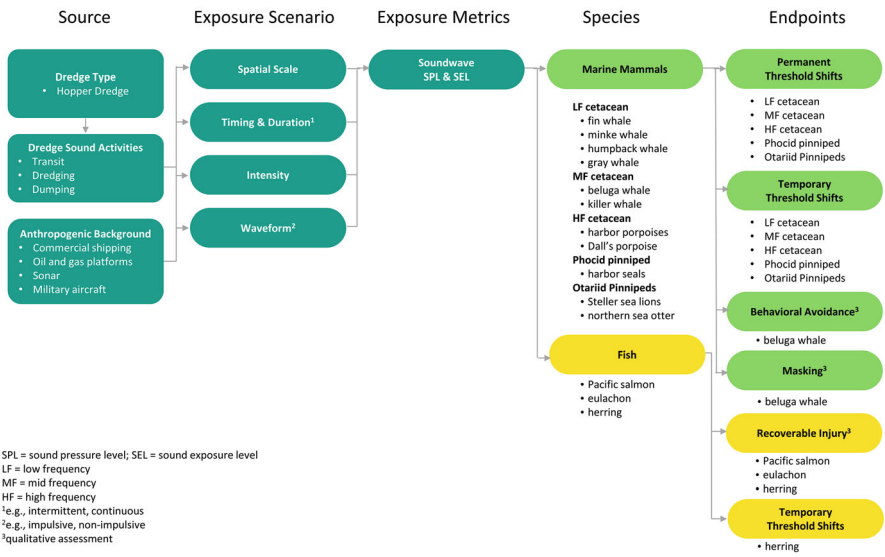

**Fig. 3** Conceptual site model showing sound sources, exposure scenarios, species, and endpoints for a hopper dredge scenario

## Sound Sources

The US Army Corps of Engineers (USACE) Alaska District recorded underwater dredging sounds produced by a hopper dredge with 1500 $m^3$ capacity during active dredging, transportation to disposal site, and placement in the water disposal area. The hydrophone was within the active dredging zone anchored approximately 1 m from the bottom seafloor. To minimize terrestrial sound interferences, closed-cell foam insulation was wrapped around the hydrophone cable between the cable reel and water surface. Unless otherwise noted, sounds were analyzed in one-third octave bands with a 1-sec interval averaging time. In this case study, a simplistic spherical spreading model was used to estimate propagation loss and to inform the sound source level (Eq. 1).

$$\mathrm{PL} = \left(\mathrm{A} + \mathrm{N}\log_{10}\left(\frac{\mathrm{R}}{\mathrm{r_{ref}}}\right)\right)\mathrm{dB} \tag{1}$$

where R is the distance from the measured sound source, $r_{ref} = 1$ m is the reference distance, N is 20 (i.e., spherical spreading), and A is a constant factor.

## Ambient Background

The ambient background soundscape in the Port of Alaska is complex and influenced by both natural and anthropogenic sources. Dominant natural sounds in this region include ice, tides, waves, and precipitation (Blackwell and Greene 2002). Nearby to the dredging project location, there are numerous potential contributors to the anthropogenic underwater soundscape from commercial and military activities the in the Port of Alaska, including shipping vessels, oil and gas platforms, sonar, and aircraft (study area is located near a military airport). Of these anthropogenic "background" sounds, military aircraft overflights were among the loudest measured, with underwater SPLs reaching 150–160 dB re 1 μPa with the peak spectral density levels in the 675–1500 Hertz (Hz) range. Additionally, the maximum SPLs recorded during positioning of cargo ships and associated tugboats at 50 m from the hydrophone were 154 dB re 1 μPa one-third octave band centered at 125 Hz. Assuming spherical spreading (N = 20 and A = 0 in Eq. 1), the source level of the shipping and cargo activity is estimated to reach 188 dB re 1 μPa-m. Yet, these recorded SPLs are intermittent and generally occur within short time periods (i.e., minutes). The most quiescent period recorded during the study period was at an SPL of 128 dB re 1 μPa one-third octave band centered at 125 Hz and represents the mean received ambient background. This background sound level is generally consistent within the range of ambient background sounds levels previously reported in the region (Austin et al. 2016; Denes et al. 2016), which described a mean SPL of 138.8 dB re 1 μPa during a 2016 study, within a range of L95 = 106.8 dB re 1 μPa (level exceeded for 95% of the time and representation of background level without any construction noise present) and a maximum SPL of 164.7 dB re 1 μPa (reached by a single aircraft event) (Austin et al. 2016; Denes et al. 2016).

## Dredging Sounds

Dredging sounds were monitored during operations and included three distinct activities: dredging (sediment removal), transit, and sediment placement on the seafloor. In general, dredging produces continuous, non-impulsive sounds that are low frequency (<1000 Hz) (WODA 2013). Hopper dredging sounds are generally discontinuous, cyclical sounds due to periodic operational changes as the dredging vessel shifts from sediment removal to transiting to the dredging placement site. During the active dredging process, continuous sounds are generated from the draghead movements along the seafloor below the vessel with additional sound sources from the engine, propeller, pumps, and generators. Therefore, the putative primary sources of sounds during hopper dredging activities are from propeller and engines, inboard pumps, and draghead (CEDA 2011; Heinis et al. 2013; McQueen et al. 2019; Suedel et al. 2019; Fig. 4).

In this study, the dredge approached within 28 m of the hydrophone while the dredge pumps were operating, and sediment was being excavated. The mean received SPL during dredging operations was 133 dB re 1 μPa one-third octave band at 500 Hz. Most of the sound energy was in the 160–175 Hz and 575–1500 Hz frequency ranges, with brief exposures around 10 kHz reaching 108 dB re 1 μPa. Therefore, based on a conservative propagation loss of 20 (assuming spherical spreading; Eq. 1), the maximum SPL observed during dredging (sediment removal) was 162 dB re 1 μPa at 1 m (one-third octave band at 500 Hz). The highest SPLs produced by the hopper dredged occurred during transit and maneuvering. The dredge was recorded approaching the harbor from the disposal site. As the tug increased power to swing the stern of the dredge vessel around to parallel the dock face, SPL equaling 139 dB re 1 μPa was recorded 30 m from the dredge, with an estimated source level of 168 dB re 1 μPa-m (N = 20, A = 0) one-third octave band

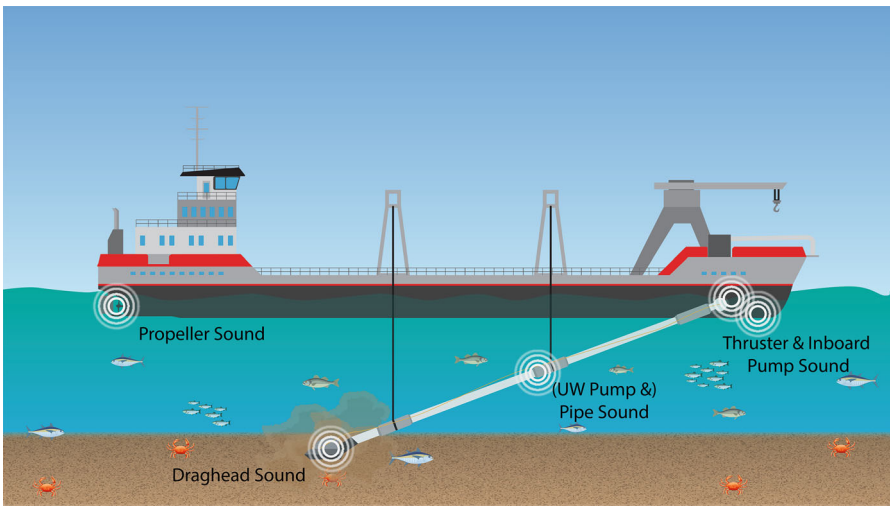

**Fig. 4** Diagram of potential sound sources from a hopper dredge

at 500 Hz. The maneuvering produced powerful sound for about a minute, after which, the dredge continued along parallel to the dock face producing a measured SPL around 128 dB re 1 μPa one-third octave band at 500 Hz as the pumps were turned on and dredging began. Therefore, as a conservative approach, the maximum SPL of 168 dB re 1 μPa was used for this risk assessment with the assumption that 95% of the energy was below 2.5 kHz.

## Species of Concern

The lower Cook Inlet supports a diverse group of marine mammals including whales, beluga (*Delphinapterus leucas*), fin (*Balaenoptera physalus*), humpback (*Megaptera novaeangliae*), minke (*Balaenoptera acutorostrata*), and killer (*Orcinus orca*); porpoises, Dall's porpoise (*Phocoenoides dalli*) and harbor porpoise (*Phocoena phocoena*); harbor seal (*Phoca vitulina*); Steller sea lion (*Eumetopias jubatus*); and northern sea otter (*Enhydra lutris kenyoni*) (Muto et al. 2019). Although these marine mammals have populations in the lower Cook Inlet, there is a lower probability that these species occur near the dredging area in the upper Cook Inlet; nonetheless, for conservative assumptions, they were retained for consideration in this screening-level assessment. The exception to this is the beluga whale, which has a well-documented small, isolated population present in upper Cook Inlet near the dredging area (O'Corry-Crowe et al. 1997; Laidre et al. 2000; Speckman and Piatt 2000; Rugh et al. 2000, 2005). For this assessment, marine mammal hearing impairment in terms of permanent threshold shifts (PTS) and temporary threshold shifts (TTS) were the endpoints of interest. Additionally, a qualitative assessment of behavioral avoidance and masking was conducted for beluga whales.

Beluga whales have been routinely observed near dredging operations in the past years. The population of beluga whales was estimated at 1300 in 1979 but declined by 47% in the 1980s primarily due to unrestrained subsistence hunting (Muto et al. 2020). Since that time, beluga whales were listed and endangered under US Federal Endangered Species Act (73 FR 62919 2008), and critical habitat for the stock was designated in Cook Inlet. Habitat ranges of belugas vary in the inlet based on seasonal patterns and food abundance. During migration of eulachon (*Thaleichthys pacificus*) and salmon, beluga whales occupy regions closer to the large rivers (Moore et al. 2000; Nemeth et al. 2007). During the winter they migrate toward deeper waters in lower Cook Inlet and shallow areas along the western Cook Inlet shoreline (76 FR 20179 2011). Additionally, sea otters and Steller sea lions have designated critical habitat in Cook Inlet.

Fish species of concern include five species of Pacific salmon (i.e., chinook (*Oncorhynchus tshawytscha*), chum (*Oncorhynchus keta*), coho (*Oncorhynchus kisutch*), pink (*Oncorhynchus gorbuscha*), sockeye (*Oncorhynchus nerka*)) (Nemeth et al. 2007). Additionally, herring (*Clupea harengus*) and eulachon (*Thaleichthys pacificus*) occupy regions within Cook Inlet and are of commercial and environmental importance (Nemeth et al. 2007). For this risk assessment, the response endpoints included recoverable injury for salmon, herring, and eulachon based on reported qualitative guidelines for shipping and continuous sounds (Popper et al. 2014). Additionally, TTS was considered for herring as they are relatively sensitive to underwater sound (Popper et al. 2014).

## Analysis

### Marine Mammals: PTS and TTS

For marine mammals, PTS and TTS were evaluated in the screening assessment using conservative maximum SPLs measured during the dredging operations. In this case, a maximum source level of 168 dB re 1 μPa-m was used to calculate SEL for "non-impulsive, continuous, mobile sources" using the National Oceanic and Atmospheric Administration (NOAA) National Marine Fisheries Service (NMFS) tool, which is a publicly available exposure model (NMFS 2018a, b). The model uses frequency-weighted exposures for groups of marine mammals for estimating an SEL using the "safe distance" concept (from Sivle et al. 2014) with exposure assumptions including source level, velocity, cycle, and weighting factor adjustment (NMFS 2018b). The model can be used to estimate risk isopleths (distances) from the sound source where risk of PTS- or TTS-onset thresholds is anticipated to occur. In this dredging scenario, the maximum source level was observed during dredging transit where vessel speeds were estimated at 1.5 m/s (Table 1). Using these stated assumptions, the estimated marine mammal PTS and TTS risk isopleths were $< 1$ m from the dredging sound source for all the marine mammals of concern (Table 1).

### Beluga Whales: Avoidance and Masking

A potential consequence of dredging sound in the underwater environment is masking (Todd et al. 2015), when loud dredging sound drowns out softer animal communication signals at the same frequency. Masking can impact an animal's communication ability with conspecifics or impair food foraging (Erbe et al. 2016; Pine et al. 2020). Beluga whales in the Anchorage Harbor vicinity generally occur in pods consisting of 2–35 individuals, with a median pod size of 8, according to USACE observation data. Beluga whales in the pod communicate and find prey using echolocation. Beluga whale vocalizations cover a broad range of frequencies; but social communication is generally lower frequency (below 10 kHz), and echolocation is much higher frequency (peaks at 40, 80, and 120 kHz) (Gurevich and Evans 1976). The mean frequency of beluga whale whistles is 2.0–5.9 kHz, while their broadband calls occupy a frequency range of 800 Hz to 9.4 kHz with a mean frequency of 3.4 kHz (Sjare and Smith 1986).

Dredging sound (70–1000 Hz) overlaps the lower end of the broadband call frequency range; however, this is below the frequency range of whistles and mean frequency of calls. Beluga whale fish predation is understood to be primarily enabled by echolocation in the highly turbid waters (~500 nephelometric turbidity units [NTUs]) of upper Cook Inlet. Peak beluga whale echolocation frequencies do not overlap with the frequencies produced by dredging sound, so it is unlikely that dredging sound would cause any direct impacts to beluga whale predation efficiency due to masking. Notably, anecdotal observational data suggests that annual dredging activities at the port are not affecting beluga whale use of Knik Arm as evidenced by the consistency of timing, location, and numbers of belugas (including calves) in the area each year (Prevel et al. 2006; Markowitz and McGuire 2007; Cornick and Kendall 2008). These qualitative data indicate a relatively low risk of behavioral avoidance of beluga whale due to dredging activities.

**Table 1** Estimation of PTS and TTS risks to marine mammals based on the maximum recorded source SPL from hopper dredges

| Parameter/assumption | Mobile dredge[a] Continuous operation | Unit |
|---|---|---|

## Fish: Recoverable Injury and TTS

Near the dredging operations, potential underwater sound impacts were qualitatively estimated for salmon, herring, and eulachon which occupy regions within Cook Inlet and are of commercial and environmental importance (Nemeth et al. 2007). There are very limited exposure response data or quantitative sound exposure guidelines available for fish species relative to low-frequency, intermittent sounds like dredging

(Popper et al. 2014, 2022). Fish sensitivity to underwater sound is dependent on the anatomical makeup (e.g., inner ear connectivity to tissues or organs), and therefore sensitivities vary greatly among species (Popper and Hawkins 2018; Popper et al. 2022). To date, sound exposure guidelines published by Popper et al. (2014) have subsequently taken into consideration these differences and have proposed qualitative guidelines for species with either no swim bladder or if the swim bladder is not involved in hearing. Though it is thought that metrics based on particle motion may be more predictive to inform responses to fish (Popper et al. 2022), quantitative guidelines for particle motion are still lacking. At sufficient distance from dredger, water surface, and seabed, sound pressure and sound particle velocity are proportional.

Salmoniformes (i.e., Pacific salmon) have swim bladders that are distant from the ear (Popper et al. 2022). Therefore, in this assessment, salmon were compared to qualitative fish guidelines from Popper et al. (2014) for non-impulsive sounds ("shipping and continuous sounds") where swim bladders are not involved in hearing. These comparisons indicate salmon have a "low" risks of mortality and recoverably injury (e.g., injuries, hair cell damage, hematoma, etc.) to dredging sounds.

Herring (*Clupea harengus*) have gas bubbles in the ear as well as swim bladders involved in hearing which are physiological adaptations making them more sensitive to sound (Popper et al. 2022). Therefore, herring were compared to quantitative risk thresholds available for "recoverable injury" (170 dB re 1 μPa for 48 h) and TTS (158 dB re 1 μPa for 12 h) developed for fish species which swim bladders are involved in hearing (Popper et al. 2014). Risk of herring "recoverable injury" was considered de minimis since the maximum source level (168 dB re 1 μPa-m) was below the "recoverable injury" threshold. For TTS, the maximum source level and propagation loss (Eq. 1) indicate that SPLs would be above the threshold at a distance of $<3$ m from the dredge. These distances were considered minimal and therefore were not considered as a significant source of risk. It should be noted that this screening-level risk assessment has conservative assumptions and fish avoidance was not considered. Fish avoidance to various underwater sound sources have been well-documented (e.g., Engås and Løkkeborg 2002) and therefore would be an important aspect of estimating exposures (e.g., duration, periodicity) if more detailed assessments were warranted.

## Risk Management

Based on the screening assessment, the risks of hearing impairment from underwater sound from dredging were determined to be de minimis. As a precautionary principle, a 50 m shutdown radius was established around dredging operations and informed by marine mammal observers which would prevent any auditory impacts to beluga whales or other marine species of concern (Fig. 5). Subsequently, a byproduct of the exclusion zone radius would result in marine mammal SPL exposures below $\sim$134 dB re 1 μPa (based on maximum observed source-level SPLs and spherical spreading assumptions; Eq. 1).

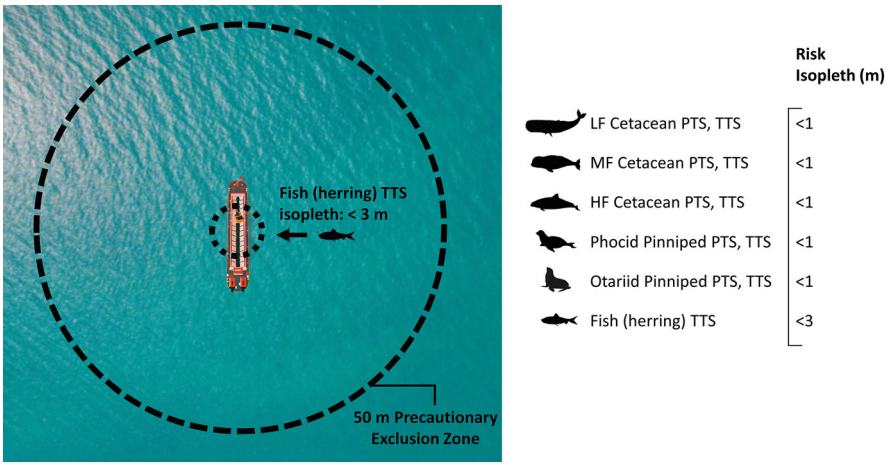

**Fig. 5** Hearing impairment response isopleths for species of concern based on maximum sound levels (168 dB re 1 μPa) from a hopper dredge in the screening assessment. PTS = permanent threshold shift; TTS = temporary threshold shift; LF = low frequency; MF = mid-frequency; HF = high frequency. Risk isopleths based on assumptions from NMFS (2018a,b) and fish risk thresholds based on Popper et al. (2014)

## Uncertainty

The primary sources of uncertainty identified in this case study include lack of site-specific exposure-response data and incomplete model assumptions. In this screening assessment, "worst-case" conservative assumptions were made regarding continuous operation of the dredge vessel and exposures of maximum observed SPLs (100% of time) and 100% site usage of marine mammal and fish. These assumptions therefore likely overestimate risk estimates. However, this assessment assumed a propagation loss of 20 logR (as used in the NMFS tool) which could potentially be less in Cook Inlet due to a variety of location conditions (water depth, sediment characteristics, etc.) and would subsequently underestimate underwater sound ranges.

It is pointed out that in this study only the risk of hearing impairment was quantitatively assessed. Masking was discussed concerning one species. As Todd et al. (2015) point out, at least in theory, dredging noise can lead to chronic impacts due to stress, and there is the possibility that marine mammals and fish are displaced from important habitat due to avoidance reactions. Behavioral reactions to dredging sound have been shown in harbor porpoises (see review by Todd et al. 2015). Yet, for behavioral assessments, there remain significant data gaps that contribute to the uncertainty. Sources of uncertainty for behavioral impacts for both marine mammals are clear exposure-response relationships and also the biological significance of those responses (Erbe et al. 2019). For fish, there remain significant gaps of information (Popper et al. 2020). For example, many fish species only detect particle motion (Popper and Hawkins 2018), and therefore SPLs are likely irrelevant as sound exposure metrics for predicting hearing (PTS, TTS) or other physiological responses (stress hormones) (Popper et al. 2022).

## Lessons Learned and Areas of Future Research

Benefits of this risk assessment approach include the flexibility of the framework to include new data as it becomes available and the adaptability to site-specific scenarios. As the scientific understanding of underwater bioacoustics rapidly evolves, it is particularly beneficial to have an assessment process that can readily adapt to the emergence of new data. The tiered process incorporates an efficient use of time and resources to apply appropriate level of detail to reach informed (actionable) risk management decisions. Future research opportunities include the continued development and refinement of standards and terminology for underwater sound measurements (e.g., ISO 2017). Additionally, lacking exposure-response data as discussed above remains a key data gap in future risk assessments and offers a pathway for identifying future research.

## Conclusions

This chapter describes an existing risk-based framework applied to assess potential biological impacts associated with anthropogenic underwater sounds. This tiered and iterative framework allows a transparent and repeatable process for evaluating and communicating ecological risks in order to efficiently reach actionable risk management decisions. The present case study demonstrated that a screening-level assessment was achievable using publicly available sound exposure modeling tools (i.e., NMFS 2018b), user spreadsheet, and qualitative threshold guidelines (Popper et al. 2014). Results indicated that using conservative exposure assumptions, dredging sounds in the Port of Alaska do not pose an adverse risk to the hearing of marine mammal or fish species of concern. Sounds generated by dredging and related activities are similar in intensity and waveform to those associated with other harbor activities.

**Abstract**

An underwater sound modeling assessment was performed of fishing boats in the Jabuka/Pomo Pit Fisheries Restricted Area (FRA) in the Adriatic Sea, offshore of Italy and Croatia. Underwater sound fields were modeled for two types of fishing vessels employing either longlines (LLS) or otter-bottom trawls (OTB).

Estimated broadband source levels ranged between 149 and 153 dB re 1 μPa m for LLS vessels and 171 and 175 dB re 1 μPa m for OTB vessels. Sound fields were calculated for sound pressure levels (SPL) to compare with available impact criteria. The SPL thresholds for recoverable barotrauma injury and temporary hearing threshold shift (TTS) pressure-sensitive fish from Popper et al. (2014) of 170 and 158 dB re 1 μPa, respectively, were not reached for any vessel at any location. The modeled levels considered only the sound generated from fishing vessels and did not account for other sound sources. The maximum modeled range to the behavioral response threshold for marine mammals from NOAA (ESA Section 7 consultation tools for marine mammals on the west coast (webpage), 2019) of 120 dB re 1 μPa was 0.91 km. Modeling results indicate that underwater noise produced by LLS and OTB on marine fauna do not represent a threat to biodiversity.

## Introduction

This chapter presents an underwater noise modeling assessment of fishing activities in the Jabuka/Pomo Pit Fisheries Restricted Area (FRA) established by the General Fisheries Commission for the Mediterranean Sea (GFCM) in 2017 (GFCM 2021) in the Adriatic Sea offshore of Italy and Croatia (GFCM Geographical Subarea, GSA, 17). The demersal fisheries in this area target valuable species such as the European hake (*Merluccius merluccius*) and the Norway lobster (*Nephrops norvegicus*), among others.

The Adriatic Sea is one of the most productive seas of the Mediterranean. Promoting the recovery of essential fish habitats and ecosystems is a key priority for rebuilding fish stocks and supporting sustainable fisheries. With this aim, GFCM established the FRA in 2017 (Fig. 1). The area was clearly identified as (1) a site of unique physical features influencing the dynamics of water circulation in the whole Mediterranean basin; (2) hosting important essential fish habitats (EFHs) for European hake and other valuable species such as horned octopus (*Eledone cirrhosa*), monkfish (*Lophius budegassa*), and Norway lobster; (3) a key area for cetaceans, sea turtles, and seabirds; and (4) hosting vulnerable marine ecosystems (VMEs) that might be impacted by bottom-trawling fishing.

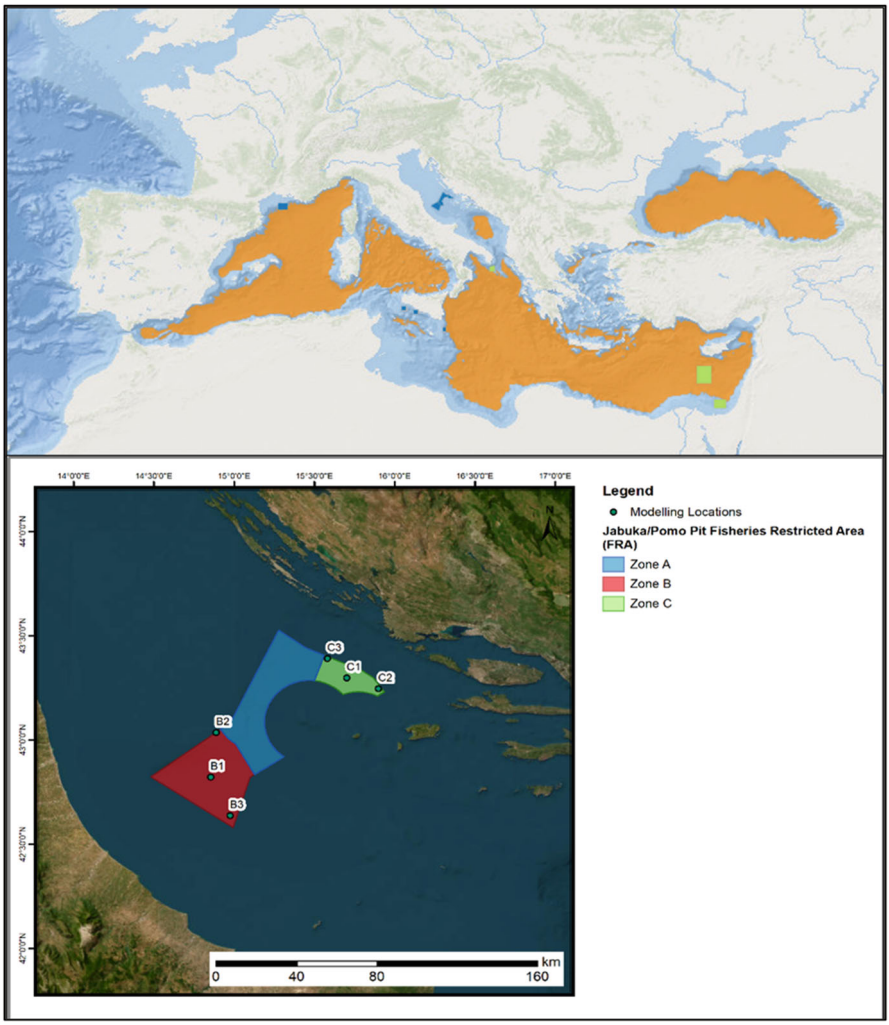

**Fig. 1** The Jabuka/Pomo Pit GFCM Fisheries Restricted Area (FRA) and its zoning (Zone A: No fishing permitted; Zones B and Z: demersal fishing permitted and regulated by GFCM) (top). Selected sites for modeling are depicted by the green dots and labels for each zone (marked by different shading, bottom panel)

The Jabuka/Pomo Pit FRA is divided into three Zones: A, B, and C (Fig. 1). No fishing is permitted in Zone A at any time, while fishing is permitted in Zones B and C subject to restrictions imposed by GFCM.

Modeling of underwater sound emissions from two specific fishing activities (i.e., bottom trawling, longlining) was therefore assessed for the two areas where fishing is permitted (i.e., Zones B and C) to understand whether the underwater noise

generated by these activities could have indirect detrimental effects on those demersal fish and invertebrate stocks that the FRA aims at rebuilding.

The study considered realistic scenarios for the fishing activities, as much as possible, according to the permitted schedule for fishing activity.

## Modeled Scenarios

Three modeled sites shown in Fig. 1 (bottom) were selected in each of Zones B and C corresponding to the geometric center of each zone and two others based on geography and bathymetry. No sources were modeled in Zone A since fishing is prohibited in that area. GFCM provided a spreadsheet containing details of Italian and Croatian fishing vessels, specifically set longlines (LLS) and otter-board bottom trawlers (OTB). Both vessel types were separated by size into small (S), medium (M), and large (L) categories, and each vessel type and size combination was modeled at each modeling location to produce 36 single vessel sound fields.

The likely fishing schedule in each zone was considered when assessing the multiple vessel sound fields. In Zone B, authorized Italian fishing vessels are allowed to operate on any day of the week, with any single vessel entitled to no more than two fishing days per week. In Zone C, authorized Croatian vessels are only allowed to operate on specific days based on fishing gear; LLS vessels are only entitled to fish Monday to Thursday, while OTB vessels are only entitled to fish Saturday and Sunday. Two scenarios were therefore modeled considering sound fields from multiple vessels:

- Croatian OTB vessels operating in Zone C and a mixture of Italian vessels in Zone B, representing Saturday to Sunday
- Croatian LLS vessels operating in Zone C and a mixture of Italian vessels in Zone B, representing Monday to Thursday

These two scenarios were chosen to represent the worst-case scenario for the maximum number of vessels operating in the region simultaneously. Since neither vessel type considered is entitled to fish in Zone C on Fridays, this day is not represented in either scenario.

## Sound Impacts on Fish and Invertebrates

While the impact of ocean noise pollution on marine mammals has long been the focus of scientific studies and research, the impacts of underwater noise on fish have only recently started to be investigated to a greater extent. Studies on invertebrates and noise are still in their infancy (Popper and Hawkins 2012, 2016). Findings suggest that ocean noise may have adverse impacts on fish and invertebrate development. These include the appearance of body malformations, increased mortality of eggs and juveniles, and delays in growth and/or development (Aguilar de Soto et al. 2013;

Nedelec et al. 2014; McCauley et al. 2017). Furthermore, the anatomy (André et al. 2011; Solé et al. 2013b; André et al. 2016) and the physiology of fish and invertebrates (Day et al. 2017) may be impacted by sound, depending on its level, frequency, and duration of the source.

Research is ongoing into the relationship between sound and its effects on marine invertebrates, including the relevant metrics for both effect and impact. The literature suggests invertebrate hearing happens primarily through particle motion detection via the statocyst (a sensory organ providing orientation cues) (Solé et al. 2013a; Tidau and Briffa 2016).

There remains limited real-world data on absolute levels of sound pressure or particle motion from nonimpulsive sources inducing adverse effects in benthic invertebrates (Hawkins et al. 2015; Popper and Hawkins 2018); hence, there are no current widely accepted criteria for assessing the impact of this type of noise on these animals. Some studies identified short-term behavioral and physiological effects on invertebrates exposed to vessel noise. For example, Solan et al. (2016) found that Norway lobster repressed burying behavior and bioirrigation, and reduced locomotion when exposed to broadband continuous noise between Sound Pressure Levels (Lp) of 135–140 dB re 1 μPa (in tank experiment). Other behavioral effects have been observed in crustaceans exposed to vessel noise; these include disruption in feeding in the common shore crab (*Carcinus maenas*), increase in distance and velocity traveled by groups of European spiny lobster (*Palinurus elephas*), and a rise in resting behavior for individual common prawn (*Palaemon serratus*) (Tidau and Briffa 2016; Weilgart 2018). Furthermore, a meta-analysis study on various taxonomic groups of marine invertebrates (Murchy et al. 2019) showed a statistically significant impact on the behavior and physiology (e.g., reduction in foraging and predator response) of cephalopods and gastropods exposed to shipping noise.

## Fishing Vessels Underwater Sound Emissions

The sound signature of a vessel depends on its size, power output, and the characteristics of its propulsion system. Vessels generate broadband acoustic energy. Most energy is in the low frequencies; sound below 200 Hz from onboard machinery dominates the sound spectrum before cavitation begins (Spence et al. 2007). The underwater sound that radiates from a vessel (Underwater Radiated Noise; URN) is produced mainly by propeller and thruster cavitation (Ross 1976, §8.6), with a smaller fraction of noise produced by sound transmitted through the hull, such as by engines, gearing, and other mechanical systems. Sound levels thus tend to be highest when propulsion systems are used at high power, for example, during dynamic positioning or transiting at high speeds.

URN from fishing vessels has received little attention thus far, likely because a wide variety of techniques and types of vessels are used for these activities. A few studies are available in peer-reviewed literature that characterize fishing vessels as an underwater sound source. Recent studies have focused on small fishing vessels that are used for local fisheries and on describing the sound that is generated during the

transit of such vessels (Amron et al. 2021; Picciulin et al. 2022). The authors are not aware of any studies that characterize the sound emitted by vessels during fishing activities or describe the tools and machinery involved with different fishing methods.

Characterizing the URN from fishing vessels presents similar challenges to those described for dredging activity in that the noise-generating activities not only include the standard sources of transiting vessels but also the machinery and activities of dredging (CEDA 2011; WODA 2013; Thomsen et al. 2016).

Daly and White (2021) recorded two trawlers in two locations and calculated decidecade source levels using propagation loss modeling. There is no size information for one of the vessels measured, but the other is listed as 17–20 m long with a calculated broadband source level between 170 and 173 dB re 1 μPa m. With the exception of the studies by Picciulin et al. (2022) and MacGillivray and de Jong (2021), measurement standards, such as (ISO 17208-1:2016; ANSI and ASA S12.64-2009), were not followed.

## Modeling Methods

A combined range-dependent parabolic equation and Gaussian beam acoustic ray-trace model (the Marine Operations Noise Model MONM-BELLHOP, a proprietary model developed by JASCO Applied Sciences) was used to predict the acoustic field around the vessels for frequencies from 10 Hz to 25 kHz.

The acoustic source spectrum of each vessel was used in the propagation modeling to calculate the $L_p$ field in the modeled area. The modeled $L_p$ only consider the generated noise field from fishing activities and do not account for the existing ambient noise levels in the area.

Each ship's sound field is modeled at a distance of at least 85 km from the source location, with a horizontal spacing of 10 m between receivers. The horizontal angular resolution was 2.5° for a total of 144 radials. Receiver depths each 1 m up to 270 m were modeled to cover the entire water column, with step sizes increasing with depth.

### Source Levels

Based on the list of vessels provided by GFCM, the vessels in each category (OTB and LLS) were split evenly into three subcategories by length overall (LOA): small, medium, and large. The median vessel in each size category was used as a proxy for that category. Where available, draft information was obtained from an online vessel database service (VesselFinder 2021). For the small and large LLS proxy vessels where no information on vessel draft was available, the draft was estimated by multiplying each LOA by the draft to LOA ratio of the medium LLS proxy vessel. Table 1 presents a summary of the proxy vessel properties for each category.

Estimated source level spectra were calculated using the JOMOPANS-ECHO model developed by MacGillivray and de Jong (2021). The model calculates a ship source level spectrum based on vessel size and speed, while also incorporating specific reference speeds and spectrum coefficients based on AIS ship type.

Source spectra for each vessel category were calculated using the vessel lengths as specified in Table 1 and the appropriate parameters for the fishing vessel category. The vessel speed for LLS vessels was set as 6 knots, based on a realistic worst-case speed for this type of vessel as determined by AIS data for a single vessel provided by GFCM. Trawlers typically travel at lower speeds than this when actively trawling, around 3–4 knots. There is evidence to suggest, however, that noise levels are higher when trawling than transiting at similar speeds. De Robertis and Wilson (2006) determined that a vessel pulling a pelagic trawl at 3.3 knots produced similar spectrum levels to the same vessel free running at 11.2 knots. Similarly, Hovem et al. (2015) presented measurements showing that a vessel bottom trawling at 4 knots produced slightly higher noise levels than the same vessel transiting at 12.4 knots. The speed for OTB vessels was therefore approximated as 12 knots to represent the trawling condition. Table 2 and Fig. 2 present the resulting source levels and spectra, respectively, for all vessel types.

Typically, the acoustic source depth of a vessel can be estimated from the vessel draft and the diameter of the propeller (Gray and Greeley 1980); however, in the absence of propeller diameter information, the source depth was approximated as two-thirds of the vessel draft.

Since set longlines are static in the water, the fishing gear for the LLS vessels is unlikely to generate noise at any substantial level compared to the vessel-generated

**Table 1** A summary of proxy vessel properties for the modeled vessel categories

| Vessel category | | *Vessel* | LOA (m) | Draft (m) | Total power (kW) | Source depth (m) | Broadband source level (dB re 1 µPa m) |
|---|---|---|---|---|---|---|---|
| LLS | S | *215-KŽ* | 9.9 | Unknown | 55 | 1.5 | 149.2 |
| | M | *Ariete I* | 12.8 | 3.0 | 81 | 2.0 | 151.4 |
| | L | *Vitoantonia* | 14.8 | Unknown | 169 | 2.3 | 152.6 |
| OTB | S | *Indomita* | 15.9 | 2.3 | 220 | 1.5 | 171.3 |
| | M | *Princeza Grejn* | 20.2 | 3.2 | 276 | 2.1 | 173.4 |
| | L | *Marc* | 24.8 | 4.0 | 445 | 2.7 | 175.2 |

**Table 2** Broadband monopole source levels (MSL; dB re 1 µPa·m) for the modeled vessel categories

| Vessel category | | Broadband MSL (dB re 1 µPa m) |
|---|---|---|
| LLS | S | 149.2 |
| | M | 151.4 |
| | L | 152.6 |
| OTB | S | 171.3 |
| | M | 173.4 |
| | L | 175.2 |

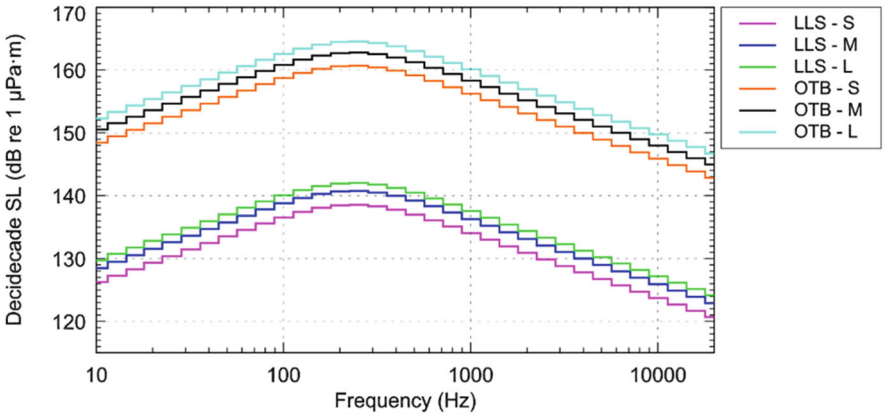

**Fig. 2** Modeled source spectra for the three modeled sizes of OTB and LLS fishing vessels

noise. Conversely, the trawl gear used by the OTB vessels is mobile and hence more likely to generate additional noise on a more consistent basis through humming in trawl cables under tension, rattling chains and shackles, and noise related to the otter boards contacting the seabed (Daly and White 2021). Several studies measured the noise from demersal trawl gear, and in all cases the vessel-generated noise was considered to dominate, particularly in the case of soft sediment (Chapman and Hawkins 1969; Buerkle 1977). For these reasons, the vessel has been considered the primary noise source, and the source depth has been chosen accordingly in this study (Table 1).

## Environmental Parameters

Water depths throughout the modeled area were extracted from the EMODnet European bathymetry grid, a 1/16 arc minute resolution (approximately 115 × 115 m) grid rendered for European sea basins (EMODnet Bathymetry Consortium 2020).

The sound speed profiles (SSP) of the modeled locations were derived from the temperature and salinity profiles of the US Naval Ocean Service's Generalized Digital Environment Model V 3.0 (GDEM; Teague et al. 1990; Carnes 2009) (monthly temporal resolution). The climate profile contains 78 fixed depth points up to a maximum depth of 6800 m; the Mediterranean sea does not reach this depth (in any part). The GDEM temperature-salinity profiles were converted to sound speed profiles according to Coppens (1981). GFCM requested the SSP for June to be modeled. Figure 3 shows the modeled SSP.

In a shallow environment, interactions between the acoustic field and the seabed are important, and accurate geoacoustic profiles are needed for proper acoustic modeling. Since the modeled area is large and geoacoustic information is limited,

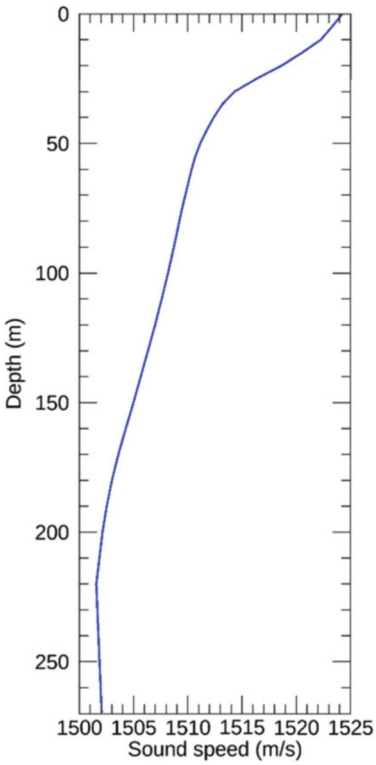

**Fig. 3** Mean monthly sound speed profile for June, derived from data obtained from GDEM V 3.0 (Teague et al. 1990, Carnes 2009)

two simplified geoacoustic profiles were constructed to represent the major features of the sediment at the modeled sites.

The modeled sites were divided into two geoacoustic areas based on the water depth at the source. Sites with a water depth greater than 150 m were categorized as an organic clay-loam substrate (here modeled as calcareous silt-clay), while sites with a water depth shallower than 150 m were categorized as a terrigenous sand-silt-clay, based on information provided by GFCM and the EMODnet Seabed Substrate map (Correggiari et al. in press). The EMODnet Seabed Substrate map is made available by the EMODnet Geology project (http://www.emodnet-geology.eu) funded by the European Commission Directorate General for Maritime Affairs and Fisheries. Well logs available through the *Visibilità dei Dati afferenti all'attività di Esplorazione Petrolifera in Italia* (ViDEPI; Società Geologica Italiana 2021) project indicate that sediment is likely quite thick in the region of interest, and, in the absence of more detailed information, no other subsurface layers were modeled.

The depth-dependent geoacoustic profiles presented in Tables 3 and 4 were calculated from the values of Hamilton (1980) for water depths greater than 150 m and shallower than 150 m, respectively. MONM-BELLHOP only considers shear

**Table 3** Estimated geoacoustic profile for Sites B1, B3, and C3, which have a water depth at source of greater than 150 m. Within each depth range, each parameter varies linearly within the specified range. The compressional (P) wave is the primary wave. The shear (S) wave is the secondary wave

| Depth below seafloor (m) | Material | Density ($g/cm^3$) | Compressional wave | | Shear wave | |

wave properties of the surficial layer; hence, these values are constant throughout the seabed.

## Estimating Impact Ranges

The noise footprint for multiple vessels operating simultaneously within the FRA zones was analyzed by modeling the $L_p$ for each vessel type at the individual transmission loss modeling sites and by transposing and summing these footprints at various other locations within the FRA zones. This method acceptably reflects large-scale sound propagation features, primarily dependent on water depth, which dominate the multiple source field, and is thus considered to provide a meaningful estimate of the sound field.

Two multiple vessel scenarios were determined based on the local fishing regulations in Zones B and C, set by Italy and Croatia, respectively. Scenario 1 represents a day where only OTB vessels are allowed to fish in Zone C, and Scenario 2 represents a day where only LLS are allowed to fish in Zone C. As a conservative estimate of the number of vessels in both scenarios, it was assumed that all authorized Croatian vessels using the relevant fishing gear type were present in Zone C. Since vessels are only allowed to fish for 2 days in any given week in Zone B, it was assumed that approximately one-quarter of the authorized Italian vessels using each fishing gear type were present. Table 5 presents a breakdown of the number of the vessels modeled in each FRA zone.

Source locations for each scenario were generated by using Geographic Information System (GIS) software to randomly distribute the correct number of source locations in each FRA zone. The minimum point separation parameter of the GIS tool was adjusted to ensure the points were approximately evenly distributed throughout the area. The source locations within each zone were then arbitrarily ordered, and a list randomizer was used to assign vessel categories to each location as appropriate for the zone and scenario. The modeled single vessel sound field within the relevant zone (either B or C) with the closest water depth at source was selected to represent the sound field at each source location.

Sound level contours are based on the underwater sound field predicted by the propagation model sampled at both the seafloor and represent the maxima of all modeled depths above the seafloor for each location. From these contours, predicted distances to specific planes were calculated. Two distances to the sound source are given for each noise level, i.e., (1) $R_{max}$, the maximum range at a specified sound level in all directions; (2) $R_{95,}$ the range at a specified sound level after excluding the 5% of the furthest point.

The $R_{95}$ value is used because sound field footprints are often irregularly shaped. Occasionally, noise level contours may show small ridges or unusual isolated fringes. $R_{95}$ ignores important projection considerations in floor plans. In such

**Table 5** A summary of the vessel types modeled in each FRA zone for each multiple vessel scenario

| FRA zone | Vessel category | | Number of modeled vessels | |
|---|---|---|---|---|
| | | | Scenario 1 | Scenario 2 |
| B | LLS | S | 0 | 0 |
| | | M | 2 | 2 |
| | | L | 3 | 3 |
| | OTB | S | 2 | 2 |
| | | M | 6 | 6 |
| | | L | 6 | 6 |
| C | LLS | S | – | 11 |
| | | M | – | 1 |
| | | L | – | 0 |
| | OTB | S | 26 | – |
| | | M | 13 | – |
| | | L | 12 | – |

cases, $R_{max}$ may better represent the range of motion in a particular direction. Such cases are usually associated with bathymetric topography that affects propagation. The difference between $R_{max}$ and $R_{95}$ depends on the directivity of the sound source and the heterogeneity of the acoustic environment.

## Results

This section presents results for the modeled scenarios involving single vessels and multiple vessels in sections "Single Vessel" and "Multiple Vessel," respectively. The tabulated results present the maximum and 95% distances to specified isopleths and impact criteria. Results are presented at the seafloor and as maximum-over-depth, meaning that the specified threshold is reached at some point in the water column at the distance presented.

## Single Vessel

Table 6 presents received SPLs near the seabed at 750, 1500, and 3000 m from the source for the six vessel types at the six modeled locations. Results are the maximum

**Table 6** Modeled $L_p$ at three distances (750, 1500, and 3000 m) from each modeled source at all modeled locations. Levels are given near the seabed and are the maximum along any radial around the source

| Vessel category | | Distance from source (m) | $L_p$ (dB re 1 μPa) near seabed | | | | | |
|---|---|---|---|---|---|---|---|---|
| | | | Site | | | | | |

| | | 1500 | 108.7 | 109.6 | 106.6 | 108.0 | 109.6 | 104.8 |
| | | 3000 | 94.4 | 107.1 | 93.8 | 106.9 | 107.4 | 93.6 |
| | L | 750 | 120.5 | 122.9 | 120.3 | 123.2 | 122.7 | 120.2 |
| | | 1500 | 111.8 | 112.2 | 109.8 | 110.6 | 112.3 | 108.1 |
| | | 3000 | 97.5 | 110.1 | 97.2 | 110.0 | 110.3 | 97.1 |

level modeled along any radial around the source at the specified distance, and hence may not be along the same radial for different distances. Tables 7, 8, 9, 10, 11, and 12 list ranges to various $L_p$ isopleths from each of the six vessel types. Table 13 presents ranges to the $L_p$ thresholds for fish from Popper et al. (2014).

Note that, in Tables 7, 8, 9, 10, 11, and 12, an $L_p$ of 120 dB re 1 μPa is the behavioral response threshold for marine mammals (NOAA 2019), and in all results tables, dashes indicate that the stated level was not reached within the minimum horizontal range step of the modeling.

### Multiple Vessels

This section presents results for multiple vessel Scenario 1 (a day where only OTB vessels are allowed to fish in Zone C) and Scenario 2 (a day where only LLS vessels are allowed to fish in Zone C). Figures 4 and 5 show the results. In Fig. 4, it appears as if the modeled sound field passes through some island land masses where this would not happen. This a result of the methodology where sound fields modeled elsewhere were transposed to the new modeling locations and effectively overlapping the land.

As no reference could be found in the public literature for the ambient sound levels in the study area, the results are not presented as exceedance maps; however, levels below SPL of 100 dB re 1 μPa are typically meeting background level conditions in the Mediterranean Sea (Picciulin et al. 2019).

## Discussion and Conclusion

This modeling study predicted noise levels associated with fishing activities in the Jabuka/Pomo Pit FRA. The underwater sound field was modeled at six different locations for two vessel types employing different fishing gear each split into three size categories and for two scenarios involving multiple vessels operating simultaneously based on realistic fishing schedules. A sound speed profile for June was selected considering the fishing behavior peaks and weather conditions and the model also accounted for site-specific bathymetric and local geoacoustic properties.

### Modeled Sound Levels

Modeled broadband MSLs ranged from 149 to 153 dB re 1 μPa m for LLS vessels and 171–175 dB re 1 μPa m for OTB vessels. Source levels were significantly higher for the OTB vessels than the LLS vessels since OTB were larger and more powerful in all modeled size categories (see Table 1). Additionally, the effective speed used in the source model for the OTB vessels was double the speed used for the LLS vessels to account for the increase in source levels during trawl noise. Daly and White (2021) recorded two trawlers in two locations and calculated decidecade source

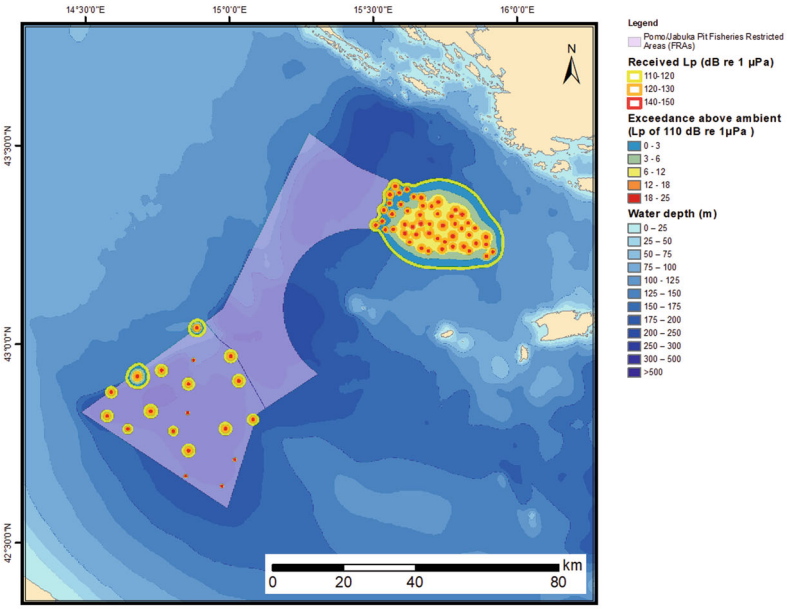

**Fig. 4** Scenario 1, $L_p$: Sound level contour map showing unweighted maximum-over-depth results. Modeled vessels are Croatian OTB vessels operating in Zone C and a mixture of Italian LLS and OTB vessels in Zone B representing Saturday to Sunday. The 120 dB re 1 µPa behavioral response threshold for marine mammals (NOAA 2019) is outlined in gray. (©JASCO Applied Sciences)

levels using propagation loss modeling. There is no size information for one of the vessels measured, but the other is listed as 17–20 m long with a calculated broadband source level between 170 and 173 dB re 1 µPa m. The small OTB vessel modeled in this study was 15.9 m LOA with a broadband source level of 171.3 dB re 1 µPa m, and the medium OTB vessel was 17.1 m LOA with a broadband source level of 173.4 dB re 1 µPa m. While the modeled broadband levels are similar to those measured by Daly and White (2021), the spectrum was different, which is expected when comparing measured data to a generalized source model. It should also be noted that the source levels determined by Daly and White (2021) appear to have been calculated opportunistically rather than according to ISO 17208 (Part 1: 2016, Part 2: 2019).

Predicted $L_p$ near the seabed was extracted at three distances (750, 1500, and 3000 m) from the modeled single-vessel source locations to assess the impact on the demersal fauna of the lowest, and highest predicted levels at all distances were observed for the small LLS and large OTB vessels, respectively. The predicted levels at 750 m ranged from 92 to 123 dB re 1 µPa (at C3 and C1, respectively); levels at 1500 m ranged from 79 to 112 dB re 1 µPa (at C3 and C2, respectively); and levels at 3000 m ranged from 67 to 110 dB re 1 µPa (at C3 and C2, respectively). The SPL thresholds for recoverable injury and TTS in pressure-sensitive fishes from Popper

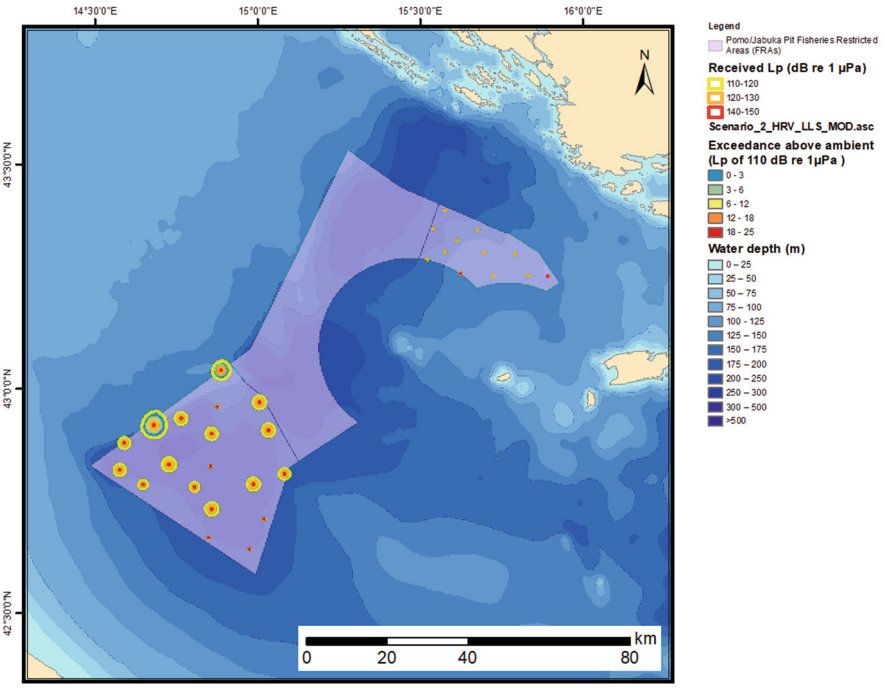

**Fig. 5** Scenario 2, $L_p$: Sound level contour map showing unweighted maximum-over-depth results. Modeled vessels are Croatian LLS vessels operating in Zone C and a mixture of Italian LLS and OTB vessels in Zone B representing Monday to Thursday. The 120 dB re 1 µPa behavioral response threshold for marine mammals (NOAA 2019) is outlined in gray. (©JASCO Applied Sciences)

et al. (2014) of 170 and 158 dB re 1 µPa, respectively, were not reached for any vessel at any location within the resolution of the modeling (20 m), although source levels for all sizes of OTB vessels exceeded these values. The ranges to these thresholds for OTB vessels can therefore be considered to lie at some distance within 20 m of the source (Table 13). Ranges to the behavioral response threshold for marine mammals from NOAA (2019) of 120 dB re 1 µPa varied between 0.03 and 0.05 km for LLS vessels and between 0.44 and 0.91 km for OTB vessels. Ranges to levels below approximately 110 dB re 1 µPa are significantly longer at the shallower sites (B2, C1, and C2) compared to the deeper sites (B1, B3, and C3). This is likely due to the complex interactions of the sound emanating from the source with the sea surface and seabed, which is further exaggerated by the difference in geoacoustics between the different groups of sites; the coarser-grained sediment at the shallower sites is more reflective than the softer sediment in the deeper waters, and hence sound propagates farther.

Results of the multiple vessel scenarios indicated that with vessels operating in close proximity, there is some coalescing of the individual sound fields into a single

larger sound field, which is largely dominated by the noise from OTB vessels (see the difference between Figs. 4 and 5). In Scenario 1 with OTB vessels only operating in Zone C (representing Saturday to Sunday), the entirety of Zone C is ensonified above 110 dB re 1 μPa, and there are some coalesced areas ensonified above 120 dB re 1 μPa where several large and medium OTB vessels are near each other. In Scenario 2 with LLS vessels only operating in Zone C (representing Monday to Thursday), the overall ensonified area is much smaller since the overall number of vessels is lower, and no OTB vessels are operating in Zone C.

**Comparing the modeled levels to the subjective assessment of relative risk for fishes from Popper et al. (2014), there is unlikely to be any risk of mortality for any fish species, eggs, or larvae due to noise from fishing vessels in the Jabuka/Pomo Pit area.** The guidelines also consider there to be a low risk for nonpressure sensitive fish of recoverable barotrauma injury at any distance and a moderate risk of TTS at close range to the source only. These relative risk scores may be reasonable considering the limited coalescing of sound fields at high levels, even when multiple vessels are closely located. **There may be a greater risk of masking and behavioral effects than stated by Popper et al. (2014), considering the large predicted ensonified region caused by multiple vessels, though this does not consider the relative levels caused by the fishing vessels compared to the broader soundscape of the Adriatic Sea** (see section "Modelled Levels in Context"). Caution should be emphasized when comparing to the stated values of relative risk as these are highly subjective and make no reference to source or received levels.

## Modeled Levels in Context

**The modeled levels consider only the noise generated from fishing activities and do not account for the existing ambient noise in the area or other transient sources of noise.** The ambient sound levels that define the ocean soundscape are composed of many natural and anthropogenic sources. The most important sources of environmental noise are wind, precipitation, and sea ice. Wind-generated noise in the ocean has been well documented (e.g., Wenz 1962; Ross 1976), and surf sound is known to be an important component of the coastal noise soundscape (Deane 2000). Precipitation is a common sound source, and its contribution is usually concentrated at frequencies above 500 Hz. Below 100 Hz, earthquakes and other geological phenomena contribute to the soundscape.

Anthropogenic (human-generated) can be a by-product of ship operations, or produced by active acoustic data collection (e.g., seismic surveys, military sonar, and depth sounding). The presence of oil and gas exploration by air guns, offshore piling, and oil and gas production platforms can increase sound levels at distances of 10–1000 km (Bailey et al. 2010; Miksis-Olds and Nichols 2016; Delarue et al. 2018).

**The Adriatic Sea is a busy area for commercial shipping, and small vessels such as fishing vessels do not typically generate a large noise footprint compared to large ships with high source levels.** A modeling study investigating the

change in the soundscape of the northern Adriatic due to the COVID-19 pandemic by **Sertlek (2021) concluded that, while the largest proportion of vessels in the area comprised fishing vessels, the contribution to the overall sound energy density was considerably smaller than that from cargo vessels and tankers.** The Adriatic is also an established area for oil and gas exploration and exploitation (AZU 2021), and the effect of impulsive noise from seismic sources on fish, marine mammals, and (to a lesser extent) marine invertebrates is well studied and documented with established thresholds for injury (Payne et al. 2008; Popper et al. 2014; Day et al. 2016; NMFS 2018; Day et al. 2019; Southall et al. 2019). It is recommended that any further investigation into the effect of noise on sensitive receptors in the area should consider these additional sources.

## Future Work

A knowledge gap currently exists in the characterization of the underwater-radiated sound from fishing vessels. In particular, while a few studies determined the source levels for transiting of these vessels, no dedicated study has looked at the different noise-generating sources and contextualized the sound emissions during the regular operations of these vessels. While vessels transiting at high speed from their base port to a fishing area may be the operation that results in the highest instantaneous sound emissions, the fishing operation should be assessed as it takes up most of the time, with the potential for sound to accumulate over several hours, and it involves not only the movement of the vessel using its engines but actively using tools and equipment onboard that may have implications on the signature of the emitted acoustic signals. For instance, a long liner that is carrying heavy nets that are scraping the seafloor will use more power than an equivalent vessel using a different fishing method that is likely to lead to higher URN. Furthermore, the nets being dragged are likely to generate additional noise that has yet to be described and characterized.

Future work should aim at undertaking detailed measurements of various fishing vessels according to international measurement standards while transiting but also while using the dedicated gear and at the typical fishing speed.

## Regulatory Implications

This chapter indicates that the modeled levels of generated noise from vessels undertaking demersal fishing in the study area do not exceed the auditory injury thresholds for marine fauna. However, the study did not account for other sources of noise that may be present in the area and likely to substantially contribute to the soundscape. Underwater sound from commercial vessels (e.g., cargo ships, tankers) and seismic exploration activity, for example, should be considered, in combination with fishing, in any further investigation into the effect of noise on sensitive

receptors in the area. This would be necessary to decide what regulation is needed and in which sector.

**Abstract**

The pivot from offshore oil to offshore wind has ushered in the advancement and development of offshore wind farms. While wind energy generation is an environmental improvement with regards to decreasing atmospheric carbon associated with fossil fuel energy generation, it does not come without environmental costs. Siting, construction, installation, operation, and maintenance are all accompanied by noise, including benthic substrate vibration, mechanical impulse propagation of pile driving, and other installation activities, airborne and underwater sound transmission of operational noise. Operational noises include transmission of gearbox noise (on legacy turbines) and propeller noises down the masts into the water and benthic substrate, but also infrasonic noise from propeller and mast interactions creating torsional and mast resonances, and microbarometric noise propagated into the barometric "soundscape." These noises will affect the soundscapes of large areas of our Outer Continental Shelf habitats, both above and below the waterline, and into the benthos with known and unknown impacts on marine and avian biota.

## Introduction

As the world shifts our energy strategies toward decarbonization, offshore wind may provide one of the more dependable sources of energy conversion due to the near-constant barometric gradient between land and sea. But converting wind energy into electrical energy is not without environmental costs (Bailey et al. 2014). As with any large-scale industrialization efforts, building wind power to scale will rapidly transform large areas of marine habitat that has been open water for millions of years, providing evolutionary context to the current marine biota.

Many of the transformations will be structural – with the introduction of vertical and horizontal structures into what is now open ocean. These structures will serve as new habitat and environment for marine life (Bolser et al. 2020) with unpredictable outcomes (Page et al. 2006).

In addition to the structural and mechanical transformations, the entire process of siting, surveying, locating, constructing, operating, and servicing offshore wind turbines is accompanied by acoustical, barometric, and vibrational artifacts, illustrated herein.

## Site Selection

Wind patterns and variability have been mapped since the beginning of maritime navigation, so areas with the highest density of reliable wind energy are well known (Pike 2018). Intersecting these areas with shore-side needs and distribution infrastructure establishes wind farm site suitability.

Once a site is selected, it needs to be surveyed to determine the most suitable mechanics of the farm in terms of how the turbine mast will be fixed or anchored to the sea floor. Gravity bases, monopiles, "jacket bases," and tripods are all options for shallow water (up to ~60 m in depth). Deeper locations require floating structures tethered to the sea floor (Bhattacharya 2019). In all cases, the sea floor and subsea bottom characteristics need to be determined – predominantly through acoustical probing.

Multibeam and side-scan sonars scan swaths of the sea floor, profiling the topography of the benthic habitat. Frequency selection is correlated to the desired resolution, but ranges from 2 kHz to 3.5 MHz (Smith and Rumohr 2008).

Pingers and Chirpers: The Pinger-type subbottom profiler transmits single-frequency "pings" every few seconds (10–50 m, with vertical resolution of 0.2 m). Chirper systems sweep, giving a more detailed resolution (<100 m, vertical resolution ~0.05 m). Both systems operate typically between 2 and 100 kHz and are generally used to detect substrata geological horizons in upper to mid-range strata depths (Geoscience Australia).

Sparkers and boomers emit seismic pulses reflecting off the subsea bottom geological structure that have bearing on long-term site stability, and substrate variations that have bearing on anchoring and pile driving strategies. Impulse acoustical energy is predominantly <2 kHz. These systems operate with an energy

source of between 50 and 300 J with typical penetration depths of up to 50 m when penetrating fine-grain sediments (e.g. sand) and a penetration depth of up to 25 m when penetrating coarse grain sediments (e.g., gravel).

## Construction

Shallow water turbine base construction – with the exception of gravity bases, and "suction bucket" caissons, require pile driving – using hydraulic hammers on the tops of 1 m to greater than 12 m diameter hollow steel piles. Some larger hammers can deliver up to 4.4 MJ, either as single strikes or as impulse vibration. Noise propagates away from the walls of the pile into the surrounding water, and vibration propagates through the sea floor impacting benthic biota and transmitting noise into the surrounding sea (Tsouvalas 2020).

Common noise mitigation strategies include bubble curtains (which are not without their own noise) that create an acoustical impedance variable in the propagation path of the noise source, and resonator systems, which convert acoustical energy into mechanical energy. Putting this into perspective, 30 wind farm projects are proposed on the Atlantic Outer Continental Shelf – installing hundreds of turbines, thousands of piles, and millions of pile strikes. Regardless of base type, all turbine bases require high concentrations of construction vessels and construction/deployment noise during installation.

## Operation

Once put in service, all turbines introduce a suite of chronic noises into the environment: gearbox noise from some turbines, and torsional and mast resonances transmitting down the mast and into the water (Edwards 2015). (Larger turbines are migrating away from gear box-driven generators.) Turbulence from the blades includes rotating noise of the collapsing tip vortices and blade-mast transect noise, which is largely infrasonic (Edwards 2015), and thus less attenuated by the air/water interface, and likely to propagate far into the surrounding aquatic environment. Permeability of the air/water boundary is correlated with wavelength such that:

$$TL_{\mathrm{dB}} = 20 \log_{10} (k_a h)$$

Transmission loss ($TL$) equals "$k_a$" which is the acoustic wave number, and "$h$" is the height of the sound source. This illustrates how the air/water boundary becomes much more permeable at lower frequencies. At 0.1 Hz, the transmission loss is theoretically −24 dB (nonexistent). Selecting "$h$" for 220 m as the hub height is arbitrary given the wavelengths of concern.

This infrasonic noise also propagates into the above-water environment, interfering with barometric cues that some birds use to navigate (Kreithen and Keeton 1974). This may account for avoidance of wind turbines by procellariiformes

(Dierschke et al. 2016), Anseriformes (Desholm and Kahlert 2005), and Gannets (Peschko et al. 2021).

The evidentiary question remains as to whether mysticetes use low-frequency acoustical energy for navigation cues as well – given that they navigate across vast distances. As underwater visual input is limited by turbidity and marine light conditions, low-frequency acoustical energy remains the best candidate for mysticete navigation cues (Clark and Gagnon 2022). If this is the case, infrasonic noise generated by fields of large wind turbines may interfere with mysticete migration.

## Service and Maintenance

Once a wind farm is in operation, there will be a continuous fleet of maintenance vessels over the course of operation and through decommissioning – tending to the bases, masts, spars, turbines, infrastructure, and instruments deployed around the wind farm structures with their inherent propeller and equipment noises.

## Conclusion

We are advising thorough acoustical baselining before commencing wind-farm development, and acoustical soundscape monitoring throughout the installation and operation – with hopes that we will learn something from the acoustical changes that the energy industry will have on the ocean and its inhabitants. These observations should also be biologically tracked in terms of baselining and monitoring species and population densities of marine organisms.

**Abstract**

The clearance of mines and other unexploded ordnance is known to pose the utmost danger to marine life, causing injuries and even mortality (Lewis, Effects of underwater explosions on life in the sea. Defence Science and Technology Organization, Canberra, 1996). The EU Marine Strategy Framework Directive requires the spatial distribution, temporal extent of noise levels produced by the explosions do not exceed levels that adversely affect populations of marine animals. For achieving this aim, the data about the explosions have to be collected and reported to the impulsive noise registries, as is the ICES impulsive noise register (ICES, Impulsive noise events registry in support of OSPAR and HELCOM, ICES, 2022). Reporting impulsive noise data can be quite challenging, as data collection methods vary by country and are subject to local legislative restrictions (Merchant et al., Mar Pollut Bull 152:110951, 2020). One way to facilitate reporting is to use publicly available seismic data. This study aims to analyze the feasibility of using national seismic data for this task. The correspondence between the national seismic data and a dataset provided by the authority responsible for the mine clearance operations is studied. Case studies of individual explosions that have been recorded during passive acoustic monitoring are additionally used for further analysis.

## Introduction

Among the various man-made underwater impulsive sound sources, explosions produce the highest peak level sound that may cause injuries or death to the animals in the vicinity (Lewis 1996; Koschinski 2011). In some cases, the aim for creating the explosion is to remove material on the seabed during offshore construction. More often, explosions are created upon disposal of unexploded ordnances (UXOs). For example, during the two world wars ~175,000 naval mines were laid in the Baltic Sea, of which 10–30% are estimated to remain (Möller 2011). Besides mines, other UXOs like torpedoes, anti-submarine rockets, aircraft bombs, and depth charges are still discovered each year and disposed of.

Due to the potential environmental impact, data about the explosions in the European seas have to be collected. This data has to be reported to the impulsive noise registries, as is the ICES hosted impulsive noise register. Among the data reported, the value code indicating the radiated sound intensity of the explosion is the most difficult to determine. Although before disposal the UXO is usually identified, the explosion's TNT equivalent weight of the energy released by the actual explosion is not usually estimated in situ. Therefore, we investigated the viability of using other available sources for acquiring this information.

The earthquake activity in Estonia and surrounding areas is known to be relatively modest (Grünthal et al. 2009). Regular measurement by seismometers has been ongoing here since 1987 and has been part of the national environmental survey since 2001. The aim for collecting the seismic data has been to register and analyze both the man-made and the natural seismic events in the Estonian and neighboring territories (KESE 2023). The seismic events data used in this study were from the processed recordings by three permanent and eight temporary seismometer stations with additions from the neighboring stations from Finland, Latvia, and Sweden (Soosalu 2022). This data contains time stamps of the events, location coordinates, location error estimates, type of seismic event, and their magnitude estimates. The magnitude listed is the Helsinki University local magnitude $M_{HEL}$ (Uski and Tuppurainen 1996). Of the recorded and located events, the overwhelming majority were man-made and identified principally as signals from routine blasting operations in local mines.

We were interested in the man-made seismic events within this registry that were located in the Baltic Sea. Also for reporting to the ICES registry we considered the events (1) listed as explosions and (2) located within the Estonian EEZ. All the 229 seismic events in the registry from 2017 until 2021 that fit these criteria are shown on a map in Fig. 1 with blue plusses and red crosses.

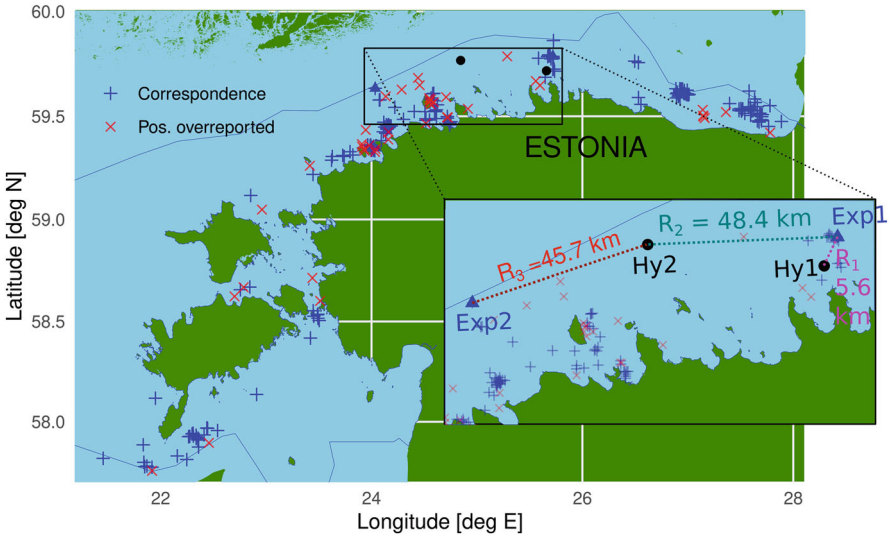

**Fig. 1** Locations of 229 explosions from the national seismic events data from 2017 to 2021, located in the Estonian EEZ. Blue plusses show locations of all the seismic events with corresponding records in the UXO disposal data. The red crosses mark the locations of the seismic events that have no correspondence (possibly overreported). The inset shows the case study locations for the three recordings of two explosions Exp1 and Exp2 (blue triangles) with hydrophones Hy1 and Hy2 (black circles) and ranges $R$ between the explosions and hydrophones

## The Correspondence

The explosions in the Estonian EEZ from the national seismic data were checked against the data acquired from the Estonian Navy about their UXO disposals for correspondence. Among other information, the disposal data listed the geographical coordinates, date of disposal, and type of the UXO. Most of the UXOs were naval mines of various types along with some anti-submarine rockets, torpedoes, depth charges, and aircraft bombs.

A record in the seismic data was considered to correspond to the data in UXO disposal data when there exists at least one record for which two following criteria are satisfied simultaneously:

- Difference in time is less than 2 days: $t_d < 2$ days
- Geographical distance between the points is less than 10 km: $d_g < 10$ km

These criteria were selected to account for the human errors that might occur in manually writing down dates and coordinates during disposal. Altogether, 192 explosions from the seismic data met these criteria and their locations are shown in Fig. 1 with blue pluses. In total, 30 seismic events did not fit the criteria $t_d < 2$ days and

$d_g < 10$ km. As previously only the seismic data has been used for reporting to the ICES registry, these can be considered possibly overreported and are depicted with red crosses in Fig. 1. The UXO disposal data also contained 28 records of explosions with no counterpart in the seismic data that might be considered as possibly underreported. Although there is also a possibility that in these cases the intensity of the blast was so low that they would not have to be reported to the registry. In the end, the overall number of the reported explosions coincided with the number of listed UXO disposals.

## TNT Charge and Magnitude Relation

For assessing the risk proposed by the explosions, their intensity has to be known. The seismic data gives the local seismic magnitude $M_{HEL}$ for every listed event. For reporting explosions, the ICES hosted impulsive noise events registry provides a vocabulary that divides their intensity according to TNT-equivalent charge weights in kilograms. Although some tables for converting between local seismic magnitude and charge weight exist (Mymathtables 2022), the corresponding data from the UXO disposal and seismic data sets enable to give a very rough estimate for their relationship.

The TNT-equivalent charge weights in kilograms of each disposed UXO was considered to be its historic TNT weight listed in online (NavWeaps 2023) or other sources (Коршунов and Дьяконов 1995; A Bureau of Ordnance Publication 1946). The resulting estimate is shown in Fig. 2. Due to uncertainties in the actual amount of explosives within sometimes over 100-year-old ordnance the error estimated for

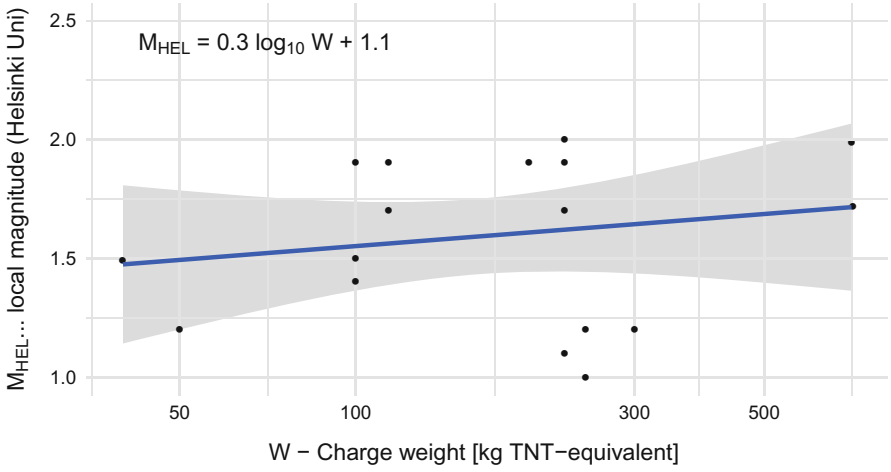

**Fig. 2** Estimate for a relationship between charge weight W extracted through UXO disposal data by finding the UXO's historic weight and its corresponding seismic magnitude $M_{HEL}$ from the national seismic data

the slope and the intercept are quite large. Nevertheless, the result shown in Fig. 2 coincides with a recent result from a controlled experiment (Favretto-Cristini et al. 2022).

## Case Studies

Some of the explosions took place in locations where their radiated sound could also be recorded by long-term monitoring hydrophones. Two of the hydrophones were the SM2Ms by Wildlife Acoustics and one the ST500 by the Ocean Instruments. Here we look at recordings of two explosions that were created when disposing of the same type of naval mines. One explosion was recorded by a single hydrophone and the other by two hydrophones at different ranges. The hydrophone locations Hy1 and Hy2 in relation to the explosions Exp1 and Exp2 are shown in the inset of Fig. 1. The time series of the calculated sound pressure from the recorded received levels are shown in Fig. 3. The lower two time series in Fig. 3 correspond to the disposal of naval mines of the same type with same listed charge weight recorded at relatively similar distances. It can be seen that the recorded peak sound pressures of these two

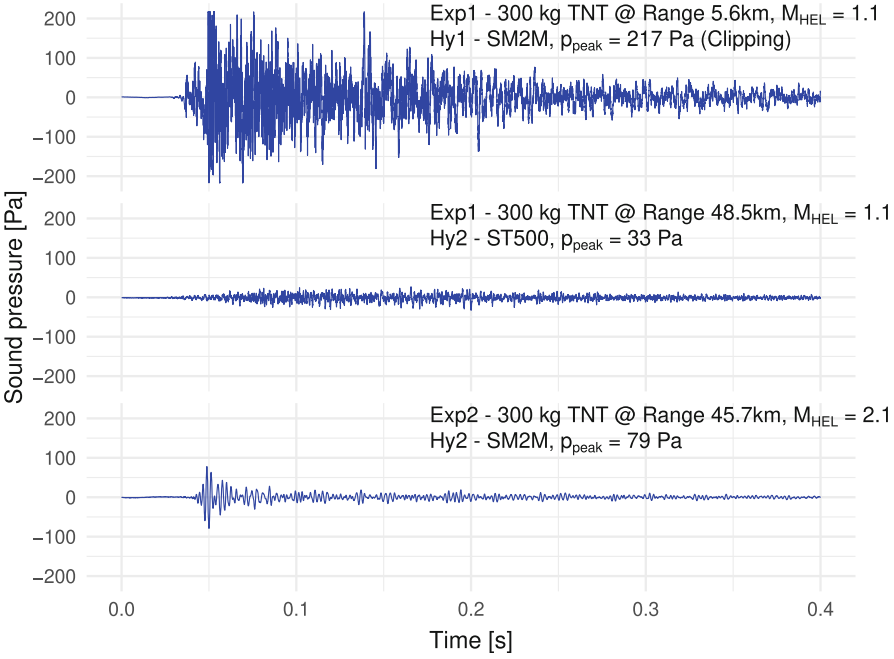

**Fig. 3** Time series of sound pressures calculated from recordings of two separate explosions of same type of mine with TNT equivalent charge weight of 300 kg. One of the explosions denoted Exp1 was recorded by two hydrophones at ranges 5.6 km and 48.5 km. The other explosion Exp2 was recorded with a single hydrophone at range 45.7 km. The seismic magnitude created by the first explosion was 1.1 and second explosion had a listed magnitude of 2.1

explosions $p_{peak}$ were significantly different. Simultaneously, the listed seismic magnitude was also higher for the explosion with higher $p_{peak}$. This indicates that when reporting the explosions to the ICES registry, a good estimate about the actual intensity of the explosion could be acquired from the seismometers' data.

## Conclusions

- In case data from the authority performing the UXO disposals is not available, the seismic data is indeed an invaluable resource for estimating the pressure that underwater explosions pose for the marine animals as the correspondence between the seismic data and the UXO disposals were reasonably satisfactory.
- If records about UXO disposals exist, the seismic magnitude is extremely helpful for determining the actual intensity of the explosion by using the magnitude-charge relation from (Favretto-Cristini et al. 2022).

**Abstract**

The level of noise in the ocean has been increasing in the last decades, putting at risk a wide variety of marine species that rely on sound for their daily life. An important tool for assessing, and eventually mitigating, the potentially harmful effects of ocean noise on marine species is the so-called risk map. Noise risk maps result from the combination of noise pressure-level distribution and species density in the same time-space framework. A known drawback of the existing risk map methodologies is that they do not allow for direct comparison of the

degree of risk between different periods of time, or locations, or between different species. The present study proposes a Bayesian inference-based technique, as an alternative for determining risk maps that return comparable and quantifiable absolute quantities. A simulation of a shallow water seismic survey along the southwest coast of Portugal is used to illustrate the proposed methodology. The test case considered two periods of the year (winter and summer), using as an example the common dolphin (*Delphinus delphis*) species. The results show that risk maps obtained with the proposed method favorably compare with those obtained with existing methods with, however, the advantage of being based on mean absolute values. These results encourage its use in future studies, targeting different species and/or different areas in order to give some hints for the production of indicators to support ocean protection policies.

## Introduction

Ocean noise produced by human activities has been continuously increasing in the past decades due to globalization that uses the ocean as the main route for shipping goods around the world (Redfern et al. 2017; Frisk 2012). This increase of ship traffic is accompanied by the corresponding increase of the global ocean noise level with direct implications in many marine organisms, in particular on cetaceans, as they depend on sound to forage, to interact in their community, to orientate, and to perceive the surrounding environment (Nowacek et al. 2007, 2016).

The potential impact of noise generated by human activities in the ocean drove scientists, governments, and policymakers to design policies, to set thresholds, and to monitor the good environmental status including ocean noise (DIRECTIVE 2008/56/EC 2008). Modeling is a possible way to assess the state of the soundscape that results in spatial- and temporal-level distribution of sound/noise, the so-called sound/noise maps (Soares et al. 2020; Neenan et al. 2016; Maglio et al. 2015; Nicolas et al. 2016). However, sound maps are of little use for policymakers and governments since they do not take into account sensitive species distribution. In fact, policymakers and governments are more interested in the estimation of the level of risk to which a specific species is exposed, as caused by a specific noise level, in a specific area and period of time.

Noise risk maps combine, for the same period of time and area, predicted noise maps with biological distributions. Consequently, noise risk maps may be used to implement and/or support some of the decisions at an institutional level regarding the protection of most exposed areas.

In this specific context, risk can be defined, as proposed by Verling et al. (2021), as the possibility of loss or injury inflicted by ocean noise in marine species described as

$$Risk = Likelihood \times Consequence \quad (1)$$

where "Likelihood" defines the points in space and time where a given sound pressure "overlaps" with the distribution/habitat of a particular species and the "Consequence" defines what exactly might happen in case of some likelihood. Assessing the "Consequence" is challenging and entails several particularities related to biological and physiological aspects of the species. For this chapter, it will be considered that Risk = Likelihood.

In line with this definition, several methods to produce risk maps have been proposed, combining noise prediction maps and species maps (Verling et al. 2021; Erbe et al. 2014; Merchant et al. 2018).

Even though species distribution and noise maps modeling are relatively well accepted and defined, the combination of the two is quite debatable. For example, Erbe et al. (2014) used an example with the Dall's porpoise, where risk maps are obtained through multiplying species density maps by noise maps both provided in normalized scales and re-normalizing the final result. Merchant et al. (2018) follow the same methodology, with slight differences. Nevertheless, a major limitation of these methods is the fact that they preclude comparisons in time, in space, or between different species due to the normalization, so the resulting risk map becomes specific only for the considered area, time period, and species.

The present study proposes an alternative to produce risk maps based on the Bayes estimator which will make it possible to quantify risk areas while overcoming the drawbacks of current methodologies. It is believed that the alternative methodology presented in this chapter will help have a wider perception of the risk resulting from anthropogenic sources of noise and consequently promote the adoption of balanced regulations and legislation to protect marine species.

To illustrate the proposed methodology, a typical test case scenario of a light seismic survey off Setúbal on the southwest coast of Portugal was selected. This test case scenario was focused on two periods of the year, January and June, as representatives of winter and summer seasons. The selected geographic area is known to have a rich biodiversity and to host different species of cetaceans as, for example, the common dolphin that may be consequently affected by such impacting surveys.

This chapter is organized as follows: section "Materials and Methods" describes the materials and methods defining the target area, the target species, the noise source, the modeling inputs (noise and habitat suitability (HS) maps), and the Bayes estimator proposed method. Section "Results and Discussion" presents the results obtained with the proposed method and discusses its comparison with currently established methods. Finally, section "Conclusions" draws conclusions pointing out the main advantages and drawbacks of the proposed method and anticipates future work.

## Materials and Methods

Producing risk maps passes through several well-described stages until obtaining the risk map itself. These steps are summarized in the diagram of Fig. 1. Usually, the process starts by defining the target area and then separating it in two parallel

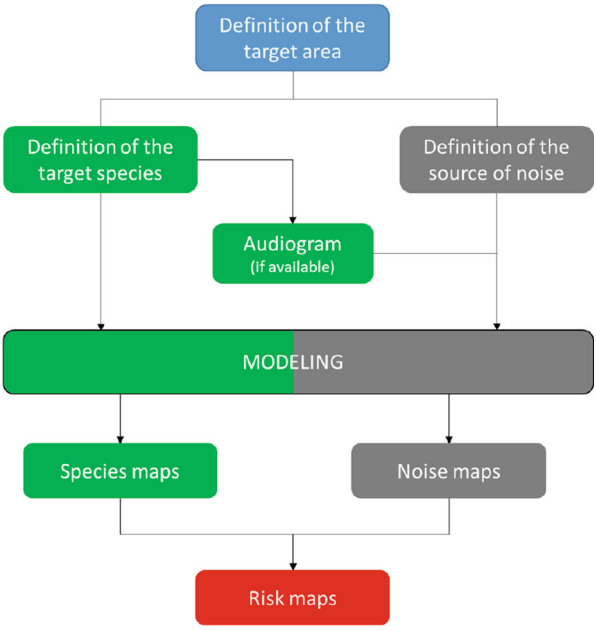

**Fig. 1** Generic noise risk map methodology flowchart

branches: the branch on the left (in green) leading to the habitat suitability (HS) map and the branch on the right (in gray) leading to the noise map. The only link between the two branches is the audiogram that is applied to the perceived noise field and depends on the selected species. Modeling is obviously different for the two branches. On the "biological branch," modelling the temporal and spatial distribution of the species may follow two approaches: through ecological niche models or through species density models depending on the available data (Fernandez et al. 2021). On the "noise branch," modeling the temporal and spatial distribution of noise is usually performed through the combination of several datasets such as bathymetry, sound speed profiles (SSP), Automatic Identification System (AIS) data, and bottom properties that are fed into acoustic propagation models for sound pressure-level (SPL) estimation (Soares et al. 2020; Neenan et al. 2016; Maglio et al. 2015; Nicolas et al. 2016). The last step consists on the combination of the HS map and noise maps to produce the risk map that will be, of course, conditioned on the specific area, the target species, and the source of noise.

To illustrate the proposed methodology, a hypothetical light seismic survey scenario taking place in the southwest coast of Portugal was designed. Shallow water (also called light) seismic surveys aim at superficial bottom sediment structure identification and are typically used in the initial area assessment for wind farms, bridges, breakwaters, wave energy generators, or cabling infrastructure development. This technique involves lower noise levels than classical deep water oil and gas seismic surveys and covers shallower areas when the required bottom

penetration is on the order of only a few tens of meters which consequently involve higher-resolution and relatively lower-energy sources.

The choice of this area was based on the fact that the Portuguese southwest coast is well known for its rich biodiversity and because a few years ago the Portuguese Government had provided concessions for oil and gas exploration in that area (Offshore Magazzine 2007; Almeida and Khalip 2018; Tavares Pires et al. 2019; Castro-Santos et al. 2020; Silva et al. 2018; Salvação and Soares 2017).

Thus, the Portuguese coast is an important spot for marine biodiversity, hosting a large number of fish species, invertebrates, sea turtles, and a variety of cetaceans that visit this coast throughout the year. Species of whales and dolphins are frequently sighted in the central part of the country, in the waters near the region of Setúbal (Correia et al. 2015; Castro 2010). Among them, the common dolphin (*Delphinus delphis*) is notably abundant, and it may, therefore, be at risk due to the plans for extensive offshore seismic surveying.

## Target Area

The area of interest was limited to −9.3° and −8.5° longitude west and 38.2° and 38.6° latitude north, with a spatial resolution of 1 × 1 km, as shown in Fig. 2. The bathymetry shows a slowly varying water depth over the continental platform extending up to approximately 45 km from the coastline, where it reaches the border of the continental shelf at approximately 250 m and then rapidly increases to deeper waters to the west. An interesting feature of this region is the Setúbal canyon, an

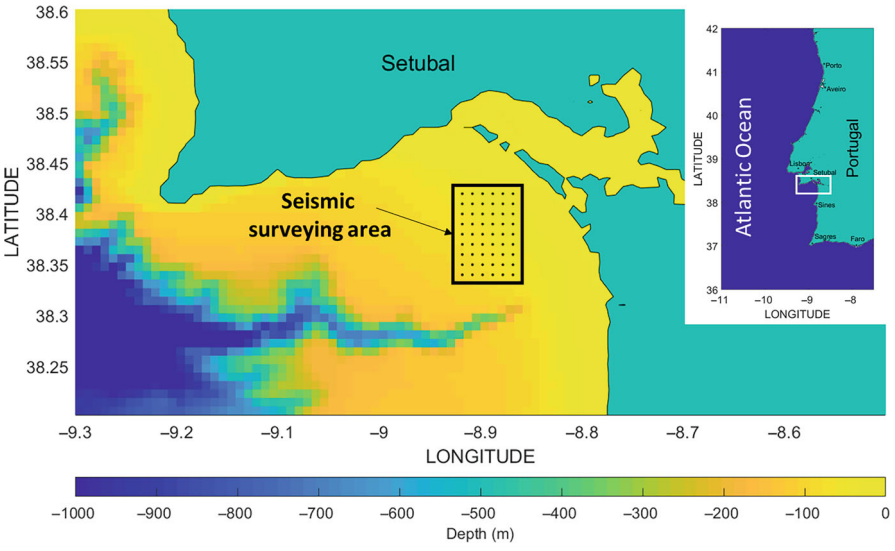

**Fig. 2** Bathymetry of the test case geographical region and the seismic surveying area (black-dotted rectangle)

east-west oriented steep-sided valley at approximately 38.3° latitude north, that entails the platform with depths reaching 1000 m. For simulation purpose, the seismic survey event was centered on a relatively small rectangular area of 50 $km^2$ delimited by the following coordinates, longitude −8.92° and −8.87° and latitude 38.34° and 38.42°, shown as a black-dotted rectangle in Fig. 2. The water depth of the surveying area varies from 30 to 150 m depth which is appropriate for the installation of offshore wind farms (Oliveira et al. 2021).

## Target Species

The selected species for this study (common dolphin) is one of the most abundant species in this region, being in fact one of the species with the highest number of records in dedicated databases. According to the Sociedade Portuguesa para o Estudo das Aves (SPEA), there are more than 3000 records of sightings for this species in 2019. The other reason that drove the selection of this species was the fact that common dolphins may be included in both the small cetacean group and high-frequency cetaceans group which allow future extrapolation regarding the effect of noise in different cetacean groups and gives more relevance for the study (Southall et al. 2019).

## Noise Source

A commonly used apparatus for light seismic surveys is the "sparker." These seismic sources are specially designed for shallow water usage that require less energy and higher bottom resolution. Sparkers operate by sudden discharge (spark) of a high-voltage electrical current between submerged arrays of electrodes. Modern sparker systems use several electrodes, which produce a seismic energy pulse typically between 300 and 20,000 Joules (Trabant 1995). A Geo-Source 200 sparker with two arrays of 100 electrode tips each was modeled as an example. (Developed and commercialized by GEO Marine Survey Systems, the Netherlands.) This system may reach a peak source level of 223 dB at 1 m depth, suitable for water depths from 2 to 500 m.

For the simulation purpose, the sparker source was placed at 1 m depth with a 5 s firing interval considering a ship moving at 5 knot in a traditional lawn mower pattern, which gives rise to a regular set of emission positions along the area (Fig. 2). A total duration of 1 month was considered with a time resolution of 10 min for the estimated SPL field.

## Modeling

As shown in the flowchart of Fig. 1, risk maps require two inputs: species maps and noise maps. Considering that the focus of the present work is to present an alternative methodology for producing risk maps, the modeling aspects will be omitted, and the interested reader is referred to Spadoni et al. (▶ Chap. 127, "Seismic Survey Risk Assessment on Common Dolphins in the South-western Coast of Portugal") for details.

## Species Maps: Common Dolphin Habitat Suitability Maps

Habitat suitability (HS) maps for the *Delphinus delphis* (i.e., common dolphin) population were developed by Spadoni et al. (▶ Chap. 127, "Seismic Survey Risk Assessment on Common Dolphins in the South-western Coast of Portugal") for the months of January and June as representatives of winter and summer seasons (Fig. 3).

HS maps present a higher quality of the habitat in coastal areas, until the bathymetric line of 200 m, especially during the month of June. This observation was expected due to the better feeding conditions in summer than in winter which creates a more suitable habitat for the species. Note that Cabo Espichel and Comporta represent high-quality areas for the common dolphin species in both cases.

## Noise Maps: Seismic Survey

Sound pressure level (SPL) is a representative metric for the noise produced by a seismic source. The propagation of noise resulting from seismic surveys is shown in Fig. 4 (see ▶ Chap. 127, "Seismic Survey Risk Assessment on Common Dolphins in

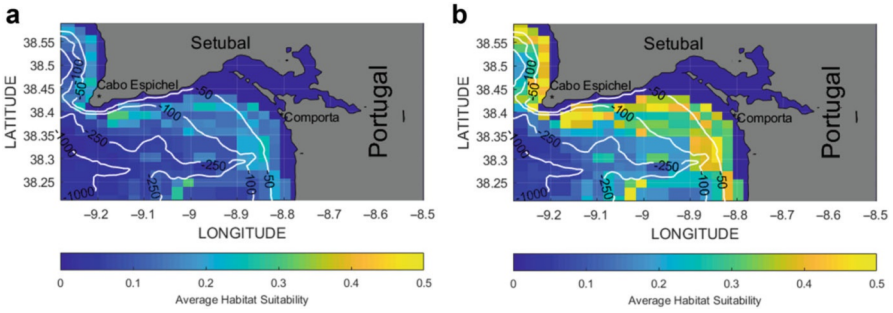

**Fig. 3** Common dolphin habitat suitability for the months of January (**a**) and June (**b**). HS maps were extracted from Spadoni et al. (▶ Chap. 127, "Seismic Survey Risk Assessment on Common Dolphins in the South-western Coast of Portugal")

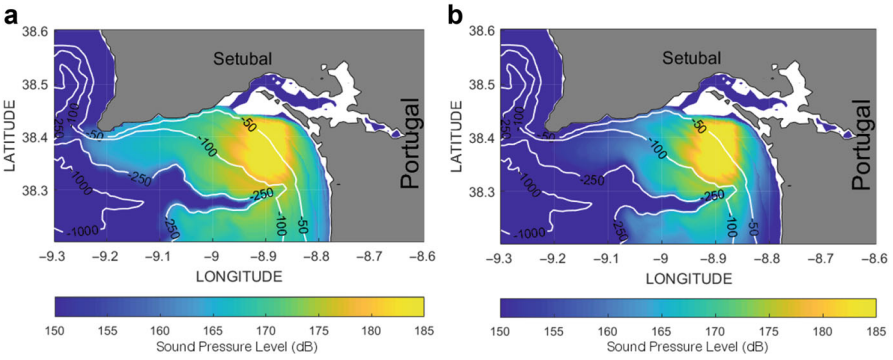

**Fig. 4** Sound pressure-level distribution for the months of January (**a**) and June (**b**). SPL maps were extracted from Spadoni et al. (▶ Chap. 127, "Seismic Survey Risk Assessment on Common Dolphins in the South-western Coast of Portugal")

the South-western Coast of Portugal"). An important influence of the environmental characteristics of the area can be noticed, as, for example, that of the bathymetry, when sound travels to the platform border and of the water column temperature variation, registering higher levels in January than in June. Significant sound pressure levels may be attained in large swaths of the considered area. A larger spread is particularly clear in January. The survey area registered SPL levels in excess of 185 dB re 1$\mu$Pa, for both months. In both cases, it is observed that noise levels may reach exceptionally high values which according to Spadoni et al. (▶ Chap. 127, "Seismic Survey Risk Assessment on Common Dolphins in the South-western Coast of Portugal") may have an impact on the temporary and permanent threshold shifts of species' hearing perception, in a range of about 40 km around the surveying zone.

## Risk Assessment Using the Bayes Estimator

The proposed approach to produce risk maps and estimate risk areas is based on Bayesian inference considering that biological and anthropogenic variables are somehow correlated, if the same location and time period are considered.

To facilitate the explanation throughout this section, one may consider the common dolphin HS as a random variable $A$ and anthropogenic noise denoted by random variable $B$ with an empirical probability density functions (pdf) $p(a)$ and $p(b)$, respectively. Then, if variable $A$ is represented by a prior distribution of the HS ($p(a)$), then the conditional density of $b|a$ (spelled as $b$ when $a$) will be given by the distribution of noise. It follows that the posterior distribution of variable $A$, after noise observation, denoted as the random event $a|b$, will be given by the classical Bayes theorem (2):

$$p(a|b) = \frac{p(b|a)p(a)}{p(b)}, \tag{2}$$

where the denominator is the normalizing factor $p(b) = \int p(b|a)p(a)da$. This normalizing factor fulfils the crucial role of a proper probability density normalization.

Estimation theory indicates that an estimator that minimizes the Bayesian mean square error is given by the conditional mean of the posterior distribution (after observation) or the mathematical expectation $E[A|B]$ written as:

$$\widehat{\mathrm{A}} = E[A|B] = \int ap(a|b)da. \tag{3}$$

Although in many cases the species distribution/habitat suitability is represented by an index which may be assimilated to a probability, in practice, sample sizes may be insufficient (or not available at all) which may prevent us from obtaining a truthful prior pdf estimate $p(a)$ making the usage of (2) and thus of estimator (3) impossible. This limitation may be overcome if one assumes that variables $A$ and $B$ follow

Gaussian distributions which, in fact, are quite acceptable in many applications involving real data (Fisher 2021). If the prior and the observation densities are both Gaussian, then the posterior is also Gaussian, which simply states the fact that the product of two Gaussian functions is also a Gaussian function. So, under the Gaussian assumption (and only under that assumption) if $A : \mathcal{N}\left(m_A, \sigma_A^2\right)$ and $B|A : \mathcal{N}\left(m_{B|A}, \sigma_{B|A}^2\right)$, the posterior density $p(a|b)$ of a random variable $A|B$ is still $\mathcal{N}\left(m_{A|B}, \sigma_{A|B}^2\right)$ in which mean and variance are given by:

$$m_{A|B} = \frac{m_A \sigma_{B|A}^2 + m_{B|A} \sigma_A^2}{\sigma_A^2 + \sigma_{B|A}^2}, \tag{4}$$

and

$$\sigma_{A|B}^2 = \sqrt{\frac{\sigma_A^2 \sigma_{B|A}^2}{\sigma_A^2 + \sigma_{B|A}^2}}, \tag{5}$$

respectively. Therefore, if the prior densities on the right-hand side of (2) are approximately Gaussian and their means and variances are known or can be estimated, the maximum a posterior Bayes estimator (3) can be calculated using expression (4). The variance of the resulting distribution is given by (5), which is not the variance of the estimator but is a measure of performance since it represents the Bayesian mean square error, i.e., the smaller the better.

## Results and Discussion

This section presents first the resulting risk maps obtained using the Bayes estimator, and second, it compares these results with those obtained using a classical method to estimate risk (Erbe et al. 2014). This comparison will be used to validate the results obtained and the assumptions made, for the proposed alternative noise risk map estimation method.

### Bayes Estimator Results

Figure 5 shows the risk distribution maps using the proposed Bayes-based mean estimator for the months of January (a) and June (c) and their variances (b) and (d), respectively. According to the mean estimator which, in fact, represents the simulated risk resulting from the exposure of the common dolphin population to a seismic survey, a higher sensitivity was observed in coastal areas, until the bathymetric line of approximately 200 m, specially near Comporta and Cabo Espichel. The higher- and lower-risk spatial distribution areas are similar in both months, albeit in June the

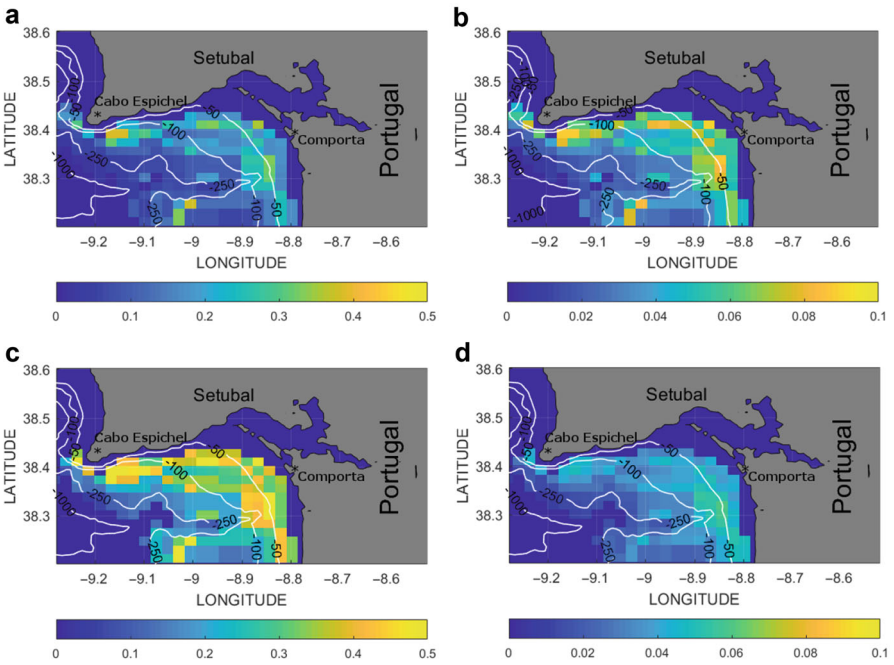

**Fig. 5** Risk maps estimated with the Bayes-based mean estimator for January (**a**) and June (**c**) and their respective variance (**b**) and (**d**), respectively (according to (4) for mean and (5) for variance)

risk levels are, overall, considerably higher than in January. The estimated risk levels show that a seismic survey in June is potentially more risky, for this species, than in January due to the higher species HS and also by the fact that the propagation is more condensed in the areas where the population's HS is higher. These results were expected since, first, the seismic survey was assigned to a coastal area which in fact is the most visited area for this particular species and, second, because the habitat suitability is higher during June than in January, as it was shown in Fig. 3.

A sub-product of the proposed method is that it gives additional information on the variance, providing an indication of the quality of the estimate, since it represents the Bayesian mean square error (Bmse). Smaller variance means a better estimate and a label of higher confidence. In our simulated example, it points out for a better estimate in June than in January, as shown in Fig. 5b, d, respectively.

## Comparison with a Classical Method

As stated in Erbe et al. (2014), normalizing the input maps (noise and species maps) makes it impossible for comparing the resulting risk maps. However, considering the same period of time, same location, and same species, it is possible to perform a spatial distribution comparison of the two methods which will allow to test the

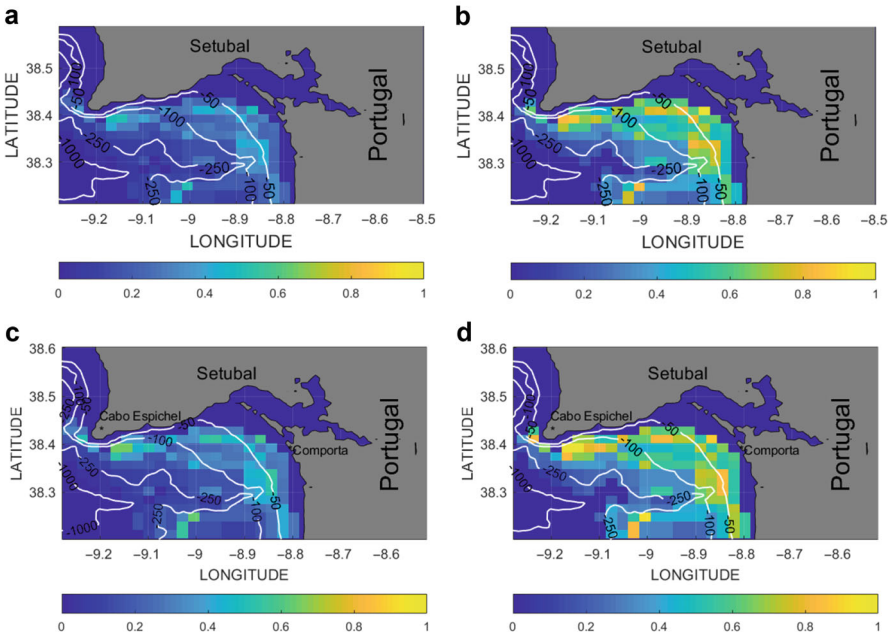

**Fig. 6** Comparison between the classical method of Erbe et al. (2014) (top) and Bayes estimator method (bottom) for January (left) and June (right)

validity of the method proposed in this study (and assert of the assumptions made). To facilitate this comparison, it was decided to set both maps color bars between 0 and 1. Figure 6 shows the risk maps produced using the classical method (top) for the months of January and June (right and left, respectively) and the risk maps produced with the Bayes estimator method for the same months (bottom). Noise risk maps estimated with the proposed method (Fig. 6c, d) look quite coherent with those obtained with the "classical method" (Fig. 6a, b). It can be observed that the spatial distribution of lows and highs follows the same pattern and the overall behavior between the 2 months is also similar. This sustains the validity of this alternative to produce risk maps.

## Conclusions

It is of major importance to assess the impact of anthropogenic noise in the ocean-living organisms, in order to develop effective protection measures. A way to predict the most impacted areas is through the production of the so-called noise risk maps, which combine the biological and anthropogenic distributions with a single time-space map. The current limitation associated with the production of noise risk maps is the fact that the existing methods preclude comparisons between different locations, at different periods of time or between different species. This limitation, at

some point, may prevent the development and the adoption of protection measures for specific areas.

The present work proposes an alternative method to produce/calculate noise risk maps which results in quantifiable maps that can be compared between them. To illustrate this methodology, a case study was designed modeling a seismic survey and its impact in the population of common dolphins in the southwest coast of Portugal. The test case results show that there is a higher seismic survey noise impact if the survey is to be carried in June than in January, specially near coastal areas. This suggests that there are periods of the year that are "better suited" for seismic surveying than others. Although this is only a simulated exercise, it shows that comparability not only in time but also in space and between species is determinant for a previous evaluation of environmental factors of the target area to support environmental management policies or to support political decisions. The contributions of the present work may be summarized as follows: (1) offers a sound theoretical framework to the ad hoc noise risk likelihood estimation used in the literature, allowing for a clear normalization of the result and its absolute comparability; (2) in case the statistic is insufficient for probability density estimation, the proposed method allows to still obtain a data coherent noise risk map estimate in case the statistics are Gaussian distributed, which is often the case whenever substantial real data is involved; and finally (3) the proposed Bayes-based methodology may be adapted to risk assessment maps, other than ocean noise.

**Acknowledgments** The authors gratefully acknowledge the funding of the EAPA 52/2018 – JONAS project and the collaboration of the Portuguese Society for the Study of Birds (SPEA) for giving access to their dataset of cetaceans and seabirds along all the Portuguese coast as well as to the whale-watching companies Mar Ilimitado and SeaEo tours for providing cetacean observation records for the region of Sagres and Setúbal, respectively. MF had the support of the Portuguese Foundation for Science and Technology (FCT) throughout the strategic projects UIDB/04292/2020 and UIDP/04292/2020 granted to MARE.

**Abstract**

While ship traffic is the primary source of anthropogenic underwater noise worldwide, locally, other sources may have a higher impact on marine life, such as seismic surveys. Although the impacts of this practice conducted in deep waters are widely investigated, less is known about the risk to biodiversity when such surveys are undertaken in shallow waters using light seismic techniques, such as for offshore wind development. The objective of this study is to assess at-risk areas by combining habitat suitability maps for the common dolphin (*Delphinus delphis*), selected as the target species, and noise maps from a light seismic survey simulation in the region of Setúbal (Portugal), an area of high marine biodiversity. Noise maps indicate that sound levels may reach up to 190 dB re 1$\mu$Pa, impacting the species' hearing perception in a range of approximately 40 km around the surveying zone. Habitat suitability maps showed high values in low-depth areas of the abovementioned region. Risk maps, obtained by overlapping seismic survey noise and habitat suitability maps, showed the particular sensitivity of coastal areas, especially until the bathymetric line of 250 m and higher levels of risk in a broader area in summer than in winter. The relevance of risk maps as a powerful tool for supporting environmental and marine life management policies is emphasized.

## Introduction

The ruthless search for sustainable energy led us to explore the ocean and the wind as potential energy sources (Rocha 2016; Salvação and Soares 2017). Compared to conventional oil and gas, wave and wind energy is cleaner and greener, but it also has significant disadvantages. These consist of the impact of the necessary infrastructures during their installation and operation. Prior to installing infrastructure at sea, the bottom structure must be assessed for platform fixing or anchoring and cable lay down. This is routinely carried out using light seismic surveying, a low power/high resolution version of traditional oil and gas seismic survey (Duarte et al. 2021; Jesus and Miller 2009). Light seismic surveying relies on the emission of high or very high-energy impulsive sound waves that reflect in the bottom and are received on towed streamers of hydrophones. Its effects on marine species, at short term and for those areas where these activities take place, have already been studied (Hastie et al. 2019; Read 1995).

Portugal, as well as other countries with an important seafront, has made plans for building several offshore wind farms along the Portuguese coastline, as referred in

the Portugal's National Strategy for the Sea 2013–2020 (Salvação and Soares 2017; Castro-Santos et al. 2020; Silva et al. 2018; Oliveira et al. 2021).

Besides that, the Portuguese coast is of great relevance in terms of marine biodiversity, partly due to the highly dynamic and complex topographic-oceanographic features of the coast and to the natural upwelling, which favors a great biodiversity richness and a countless number of cetacean occurrences every year (Correia et al. 2015). In particular, the region between Sines and Setúbal, in the SW coast of Portugal, is known to host many different species of cetaceans (Correia et al. 2015; de Castro 2010).

The lack of knowledge on light seismic survey noise emissions and the potential threat it represents for cetaceans and biodiversity led us to design a simulated typical test case scenario for a seismic survey event taking place in the SW coast of Portugal, near the region of Setúbal. The common dolphin (*Delphinus delphis*) was selected as representative species, commonly present in the test area.

A prediction tool was developed to estimate: a) the sound pressure level (SPL) field on the target area due to a typical light seismic survey, b) the common dolphin habitat suitability (HS) through Ecological Niche Modeling (ENM), and c) the potential at-risk areas for this particular species due to a seismic event in two periods of the year (January and June). Habitat can be defined as "an area with a combination of resources and environmental conditions that promotes occupancy by a given species (or population) and allows those individuals to survive and reproduce" (Darracq and Tandy 2019). Suitability indicates the quality of these conditions and resources.

Results on noise modeling showed the importance of bathymetry on the attenuation of the noise field along the continental shelf, while attaining significant sound pressure levels in large swaths of the study area, that also have a high HS for the common dolphin. The deduced potential risk is consistent, in space and time, with the HS distribution and the propagation of noise from the simulated seismic survey. These results give hints to produce indicators and to support management, conservation, and biodiversity monitoring.

This chapter is structured as follows: section "Materials and Methods" gives a description of the physical and biological characteristics of the area as well as the methodology used for seismic survey noise and habitat suitability modeling, and a description of the risk estimation technique. section "Results and Discussion" shows and discusses the obtained results. Finally, Section "Conclusions" points out some conclusions regarding the risk assessment for this study area.

## Materials and Methods

This section describes the environmental and biological properties of the Setúbal test case area used as a hypothetical scenario to estimate risk resulting from seismic survey for the common dolphin population.

## Definition of the Target Area

The study area was limited to −9.3° to −8.5° longitude west and 38.2° to 38.6° latitude north, as shown in Fig. 1. The area reveals a relatively flat continental platform extending up to approximately 45 km from the coastline where the water depth reaches 250 m and then rapidly deepens to the west. In addition, the presence of an east-west oriented steep-sided valley (known as the Setúbal submarine canyon) at approximately 38.2° latitude north, which reaches approximately 1000 m depth, is considered an interesting feature of the area. The seismic surveying area, represented by the black rectangle in Fig. 1, is characterized by a relatively small bathymetric slope and water depths varying between 30 and 100 m, which are suitable for the installation of offshore wind farm structures (pylons, anchors, cables, etc.).

## Definition of the Target Species

The entire coast of Portugal is known to be a rich ecosystem in terms of marine biodiversity, covering a variety of groups from fish to marine invertebrates and sea turtles (Gomes et al. 2018). The cetacean occurrence is one of the most studied aspect as well as one of the highlights of the coast (Correia et al. 2015; de Castro 2010). The common dolphin (*Delphinus delphis*) is one of the most abundant species of cetacean in the Northeast (NE) Atlantic in general and in this region of the Portuguese coast in particular (Murphy et al. 2013). This species has, in fact, the

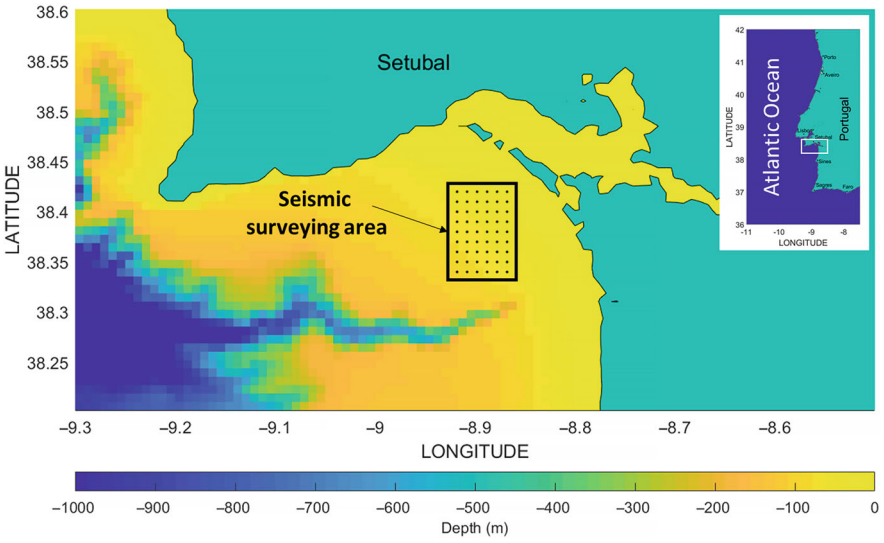

**Fig. 1** Bathymetry of the Setúbal region obtained from GEBCO database (Weatherall et al. 2015). The rectangular box of 50 km$^2$ was defined for seismic surveying simulation (longitude −8.92° and −8.87°, and latitude 38.34° and 38.42°)

highest number of records in dedicated databases (Silva 1999). Additionally, common dolphins belong to both the small cetacean group and to the mid-/high-frequency cetacean group (Southall et al. 2019; Finneran 2016). Therefore, due to their hearing sensitivity, they may be impacted by seismic surveying.

## Noise Source Definition

For modeling purposes, a Geo-Source 200 sparker (developed and commercialized by GEO Marine Survey Systems, The Netherlands geomarinesurveysystems.com) with two arrays of 100 electrode tips each was used as reference for seismic source. This type of seismic source is suitable for water depths from 2 to 500 m with a penetration in the order of dozens of meters below the seabed (depending on seabed type), which is commonly used in wind farms seabed prospecting and is characterized by a peak source level of 223 dB re 1$\mu$Pa.

## Seismic Surveying Modeling

The bathymetric data of the target area was obtained from the General Bathymetric Chart of Oceans (GEBCO, www.gebco.net) database (Weatherall et al. 2015), with a 1 km $\times$ 1 km spatial resolution (see Fig. 1).

In accordance with the description given by (Soares et al. 2015; Maglio et al. 2015) and outlined in Table 1, the bottom and sub-bottom acoustic properties were configured as a two-layer bottom model made up of a fluid sandy sediment layer over a rocky semi-infinite sub-bottom.

Water columns' physical properties (temperature and salinity) of the target area were obtained for the months of January and June 2019 from the Copernicus – CMEMS database (https://marine.copernicus.eu/). Figure 2 shows the superposition of profiles for the total area and for the months of January (upper row) and June 2019 (lower row), for temperature ((a) and (d)), salinity ((b) and (e)), and estimated sound speed ((c) and (f)). For each dataset, the black line represents the mean profile. As expected, temperatures in January are lower than in June. In January, a 50 m thick mixed layer develops, followed by a gradient till the depth of 500 m both in January and in June. A similar behavior is shown by salinity between January (see plot (b))

**Table 1** Assumed seabed parameters. (Adapted from (Soares et al. 2015; Maglio et al. 2015))

| Model Parameter (units) | Value |
|---|---|
| Sediment speed (m/s) | 1650 |
| Sediment density (g/cm$^3$) | 1.9 |
| Sediment attenuation (dB/$\lambda$) | 0.8 |
| Sediment thickness (m) | 10 |
| Sub-bottom speed (m/s) | 1800 |
| Sub-bottom density (g/cm$^3$) | 2.8 |
| Sub-bottom attenuation (dB/$\lambda$) | 0.2 |

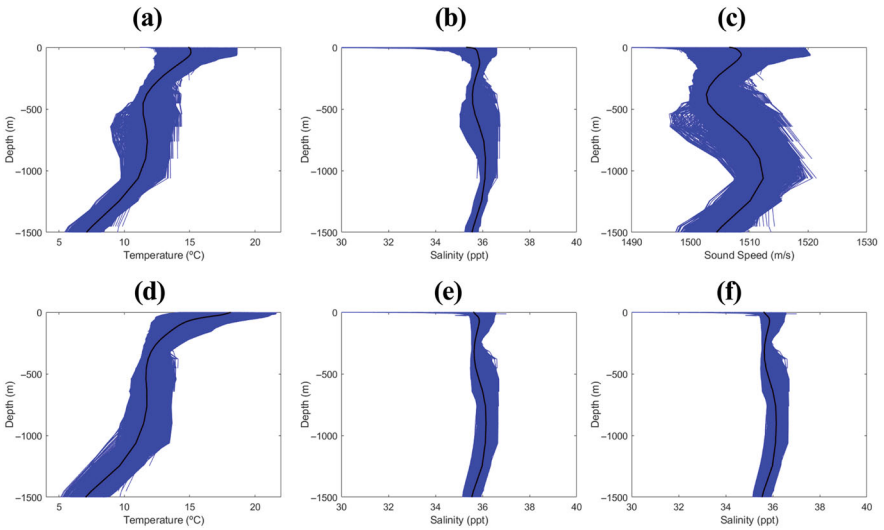

**Fig. 2** January (top row) and June (bottom row) 2019 variations for: temperature (**a** and **d**), salinity (**b** and **e**), and sound speed profiles (**d** and **f**). The mean profile is represented by the black lines. (Source: CMEMS-Copernicus Marine Service)

and June (see plot (d)), with higher variations in the mid water column in January compared to June, with characteristic values ranging from 35 to 37 parts per thousand (ppt). The nine-term Mackenzie approximate equation was used to estimate the sound speed profile: plots (c) resulting from January and plot (f) from June. The sound speed profiles of these 2 months follow, as expected, approximately the same shape as the temperature profiles of the respective months. The sound speed profiles in the deeper area result to have a double minima, which is typical of this area.

For simulation purpose, the seismic survey was centered on a relatively small rectangular area of 50 $km^2$ (see box in Fig. 1) with a spatial resolution of 1 km $\times$ 1 km. The previously described sparker seismic source was set to a source level of 223 dB re 1$\mu$Pa at 1 m, placed at 1 m depth with a 5 s firing interval considering a tow ship moving at 5 knot in a traditional lawn-mower pattern resulting in a regular set of emission positions along the area of Fig. 1. A total duration of 1 month was considered with a time resolution of 10 min.

The range of audible frequencies of cetaceans may extend far beyond 1000 Hz. In order to maintain the noise calculation computationally manageable, in this study only the frequency range 300–1000 Hz in 1/3-octave (10 base) bands was taken into account, which corresponds to the seismic source maximum level frequency band.

The acoustic receivers were placed at 5, 15, 30, 50, 75, and 100 m depth and the final noise map sound pressure level was evaluated as the mean field over depth. The statistical indicator percentile 50 (p50), which describes the percentage of time that a

specific value sound pressure level is exceeded, was adopted for sound map estimates and for the production of risk maps.

The normal mode propagation model Kraken (Porter and Reiss 1984) was used in combination with bathymetry, seafloor parameters, and sound speed profile (SSP) to estimate the transmission loss (TL), and thus the sound pressure level (SPL) was calculated according to Soares et al. (2015).

Since the assumptions for 1/3-octave bands may not be valid when dealing with impulsive noise that is emitted only at given time intervals, the estimation of a correction factor was deemed necessary. Since the seismic exploration implies a succession of periodic pulses at a given time rate, the concept of sound pressure level (SPL) was used in order to include transmission time. In a $T_0 = 5$ s cycle only $T = 1$ s is active. Thus, if one uses the standard definition of SPL as:

$$\mathrm{SPL}_{\mathrm{cycle}} = \mathrm{SPL}_{\mathrm{emitted}} - 10\log_{10}(T/T_0) \tag{1}$$

this gives a correction factor of approximately −7 dB relative to $\mathrm{SPL}_{\mathrm{emitted}}$. $\mathrm{SPL}_{\mathrm{emitted}}$ corresponds to the SPL in 1 s of emission. Nevertheless, this does not consider the time spreading nature of acoustic channels, which may make appear much longer at the receiver the short emitted pulse. Actually, the quantities of interest are the emitted and especially the received energy, rather than the frequency band power based only on 1/3-octave bands, as normally used for SPL definition. To highlight the difference, a test was performed following these steps:

- In the study area, two points, A and B, were selected representing the source and the receiver, spaced 2 km apart. To determine the channel impulse response (CIR), KRAKEN was used calculating modes for all frequencies between 300 and 1000 Hz.
- To obtain the received signal, the input signal was convolved with the CIR.
- A duty cycle of one pulse every 5 s was used to calculate the SPL for a duration of 10 min.
- The obtained SPL was then compared with the one obtained considering 1/3-octave band levels. A 4 dB correction factor was determined to be used in the subsequent simulations.

## Habitat Suitability Modeling

The common dolphin's HS was modeled through an ENM taking into account observation records of the common dolphin and environmental characteristics of the study area using a maximum entropy algorithm. The output of this model are, on one side, habitat suitability maps of the species and on the other side, the percentage of contribution of each environmental predictor to the model (see Fig. 3).

Maxent modeling (Phillips et al. 2006) was chosen among other methods essentially because of the few input data required, the availability of these data for the

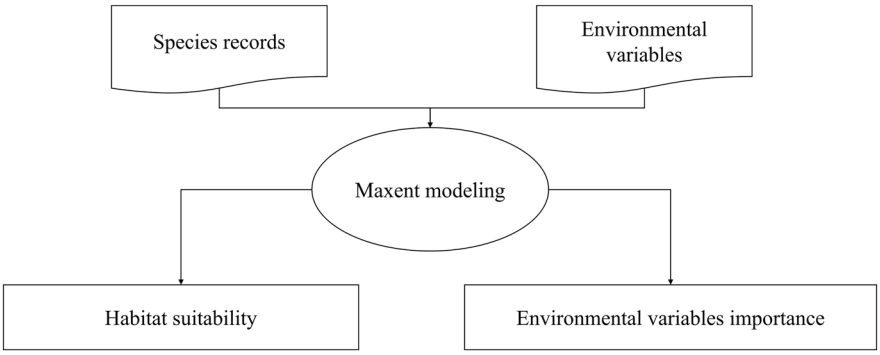

**Fig. 3** Methodological framework of Maxent modeling. (Adapted from (Wang et al. 2020))

**Table 2** Cetacean occurrences' datasets characteristics

| Observations' source | Code | Region | Coordinates lon × lat | Period of time | Background points creation method |
|---|---|---|---|---|---|
| **SPEA** | SPEA | Portuguese coast | [−10.5–7.5] × [36 42.5] | 2005–2020 | Using the transects of boat trips for all the species |
| **SeaEO tours** | SeaEO | Setúbal | [−9.6–8.7] × [38.3 38.8] | 2019–2020 | Minimum Sampled Area (MSA) |
| **MarIlimitado** | MI | Sagres | [−9.3–8.5] × [36.7 37.2] | 2005–2020 | Minimum Sampled Area (MSA) |

present case study and for being proven to give better predictions than other methods for small data amounts, such as those employed in this study (Ng and Jordan 2001). Additionally, following the definition given by Phillips and Dudík (2008), it was supposed that, for one specific species, habitat suitability can be interpreted as an estimate of the probability of species occurrence conditioned on environmental variables as it indicates the quality of the habitat for that single species (Phillips and Dudík 2008).

Cetacean occurrences (top left box of Fig. 3) were obtained over a period of 15 years (from 2005 to 2020) from three different opportunity platforms, as described in Table 2: SPEA, the Portuguese Society for the Study of Birds and two whale-watching companies, SeaEO Tours and MarIlimitado.

SPEA dataset that goes from 2005 to 2020, and SeaEO tours observations, from 2019 to 2020, were collected all year round, while Mar Ilimitado dataset, from 2005 to 2020, was mostly concentrated on the months between April and October.

Five environmental variables (see Table 3), already proven to affect the habitat suitability of small cetaceans and already adopted for the same purpose and same species in the literature (see for example Moura et al. (2012)), were selected as

**Table 3** Selected environmental variables

| Environmental variable | ACR | Unit | Source | Data setup |
|---|---|---|---|---|
| **Depth** | DEPTH | m | NOAA, ETOPO 1 Global Relief Model | Resampled to the selected resolution and extent |
| **Slope** | SLOPE | ° | Calculated on QGIS3.18 | Resampled to the selected resolution and extent |
| **Sea surface temperature** | SST | K | Copernicus Marine System | Scaled to the selected temporal and spatial resolution |
| **Chlorophyll-a** | CHL | $mg.m^{-3}$ | Copernicus Marine System | Scaled to the selected temporal and spatial resolution |
| **Chlorophyll-a standard deviation** | SD_CHL | $mg.m^{-3}$ | Calculated from the CHL layer | Scaled to the selected temporal and spatial resolution |

potential explanatory variables to calibrate HS models for the common dolphin (top right box of Fig. 3). The collinearity among the environmental variables, a challenging issue in ENM (Feng et al. 2019), was evaluated taking into account the variance inflation factor (VIF) approach, revealing no dependency among them.

This data were then pulled together into a temporal resolution of 8 days and 2 × 2 km spatial resolution in the World Geodetic System 1984 zone UTM 29 N projection.

The biggest issue facing presence-only and presence-background ENMs is accounting for sampling bias. The possibility of mapping sampling effort rather than the underlying HS exists when no sampling correction is implemented in the model (Barber et al. 2022). Therefore, in order to avoid this issue, a filtering approach was applied to remove potentially related sightings (Fernandez et al. 2021; Aiello-Lammens et al. 2015; Fourcade et al. 2014; Bystriakova et al. 2012). Moreover, two different target-background methods were applied according to the different nature of the selected dataset:

- **SPEA dataset:** transects between all the points with records for all species of cetaceans were considered over a 8-days-long period, generating the background data and providing a measure of the potential sampled area.
- **Whale Watching datasets:** a Minimum Sampled Area (MSA) technique, as in Fernandez et al. (2017), was used due to the opportunistic character of the sampling. A Minimum Convex Polygon, adding a 1 km buffer, was used to put together all the sightings for all species and for each distinct temporal scale. Grids crossing the polygon were classified as potentially sampled areas and thus considered as background.

The number of sea trips performed during a specific period determined the total amount of effort per temporal unit (8 days). From both datasets, occurrences and the

selected background grids were put together to proceed with the MaxEnt analysis. Random background datasets ($n = 10{,}000$) were generated for each analysis.

The common dolphin's habitat suitability maps along the Portuguese coast were obtained using Maximum Entropy modeling, as described in (Phillips et al. 2006). The HS maps resulting from this modeling, for the selected months of January and June, were then cropped for the detailed study area of Setúbal.

### Risk Maps

The risk maps presented in this chapter were produced taking into account the overlapping between sound pressure level and the biological distribution. In this particular case, this overlapping was performed between the SPL 50th percentile (or median) and the HS maps, for each point in space and time. According to the methodology proposed by Erbe et al. (Erbe et al. 2014), noise maps and habitat maps were normalized between 0 and 1 and then point wise multiplied. The result of this multiplication was then normalized again. As a result of these successive normalization, the resulting risk maps cannot be used for comparison between species, but gives a relatively good assessment of areas at high noise risk for the considered species. The risk maps were produced with a 2 km $\times$ 2 km spatial resolution.

## Results and Discussion

The results obtained for the Setúbal area test case are presented as: a) seismic survey simulation results, b) habitat suitability results, and c) risk assessment results.

### Seismic Survey Simulation Results

The SPL resulting from seismic surveying noise prediction modeling during the months of January and June 2019 is presented in Fig. 4a, b, respectively.

For a matter of comparison between the two cases, the color-coded noise level scale is presented between 150 and 185 dB which means that values lower than 150 are considered in blue and higher levels than 185 dB in yellow. It can be observed that noise propagation is significantly influenced by the bathymetry of the area which is attenuated over the entire platform till it reaches its edge. That's when the signal becomes dispersed over a much wider water column, so the sound level suddenly drops. It is also noticed that the pressure levels computed in January are higher and have a lager spatial spread than those estimated in June. This result can be explained by the sound speed profiles of both months, as described in section "Seismic Surveying Modeling." In both cases, the generated noise widely exceeds the usual mean ambient noise, resulting from the noise produced by continuous

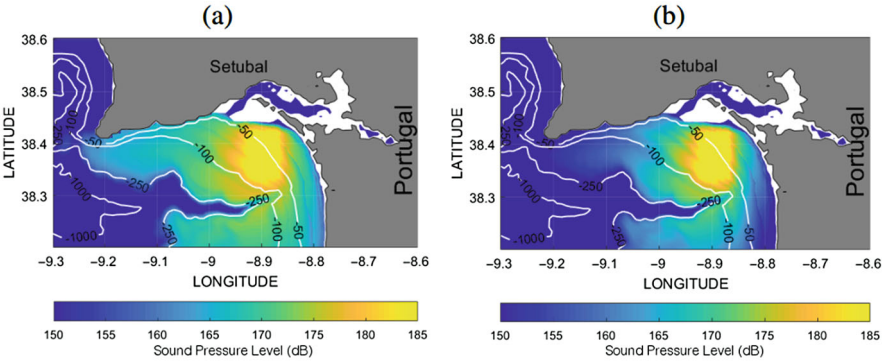

**Fig. 4** Percentile 50 of the Sound Pressure Level due to a seismic survey simulation for the months of January (**a**) and June (**b**)

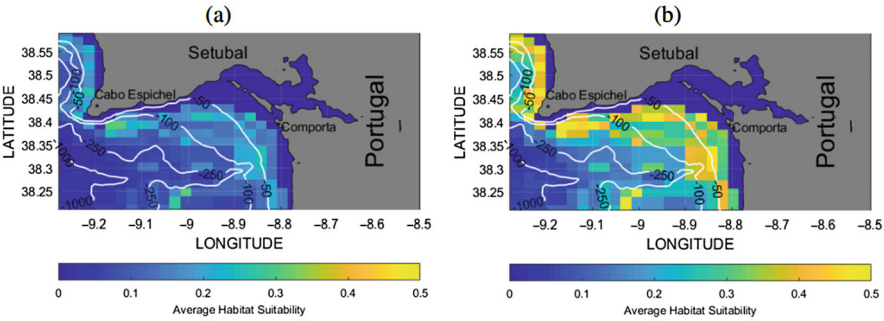

**Fig. 5** Common dolphin habitat suitability for the months of January (**a**) and June (**b**)

sources such as ships (120 dB according to Soares et al. (2015)) and from natural sources such as the wind (65–75 dB). Therefore, noise may represent, on species sensitive in this frequency band, a potential harmful impact.

## Habitat Suitability Results

HS resulting from the ENM for the common dolphin in the area of Setúbal was obtained for the months of January and June as shown in Fig. 5a, b, respectively.

The results are in accordance with a higher habitat quality for the common dolphin in the summer season rather than in winter. Nevertheless, in both seasons, the most favorable conditions are in the region delimited by the bathymetric line of 50 m and in the region delimited by the bathymetric lines between 100 and 200 m near Cabo Espichel, where the platform shortens. The areas where habitat suitability presents the greatest values are those near Cabo Espichel and Comporta.

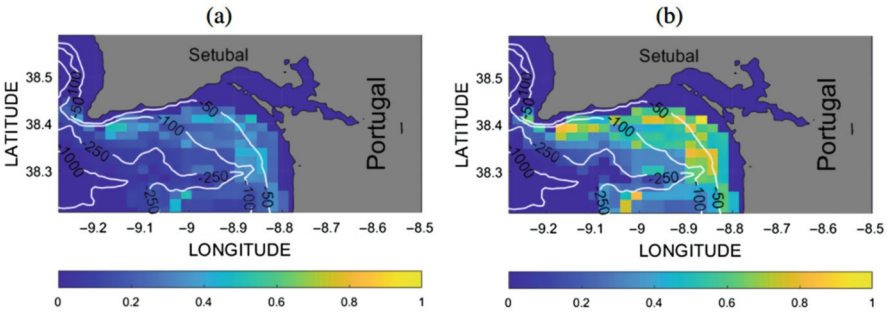

**Fig. 6** Risk maps for: January (**a**) and June (**b**) 2019

## Risk Assessment Results

Figure 6 shows the regions of predicted risk, estimated in the region of Setúbal, for the population of common dolphins for the months of January (a) and June 2019 (b), using the methodology outlined in the previous section.

It can be observed that even though the "affected area" has a much larger extension in January than in June, the former shows lower risk levels than the latter. In both cases, the highest risk areas result to be located near the shore, especially till the 100 m bathymetric line. The region near Comporta shows the highest risk levels, due to the highest HS of common dolphins in this area as described in section "Habitat Suitability Results."

In general, both the risk spatial distribution and its seasonality, reflect the combination of the HS distribution and the noise propagation. The areas with higher risk are those where: (1) HS values were higher (near shore) and (2) noise from the simulated seismic survey reached higher SPL values (near the area where the seismic survey took place). Summer presents higher risk levels because: (1) HS was higher in this season and (2) the highest values of SPL are more concentrated in this season. Additionally, risk maps reveal how regions that showed very high levels of HS, such as the northern coast of Cabo Espichel (between latitude 38.45 and 38.6, and longitude −9.3 and −9.2), but that were protected from the noise dispersion, present levels of risk very close or equal to zero. These findings confirm that risk is consistent with both the habitat suitability of the common dolphin and the propagation of the simulated noise from a seismic survey.

## Conclusions

This chapter presents a risk simulation for the common dolphin population in the region of Setúbal when exposed to a light seismic survey to assess the viability of offshore wind farm structures.

Habitat suitability results show that the highest habitat quality area follows the coastline configuration. This is particularly evident if considering the bathymetric

line of 100 m, which is known to correspond to an area with high productivity (Yen et al. 2004). Furthermore, the lower HS in January may result from a winter decrease in upwelling and subsequently to a decrease of the common dolphins' most important preys such as sardines (Silva 1999; Jefferson et al. 2009). This shows that the seasonality in habitat suitability is mainly related to water productivity and prey biomass (Danil and Chivers 2006).

Seismic surveys inject important quantities of energy into the ocean and consequently put at risk marine species in the surrounding area. Installing offshore wind farms occurs usually in shallow water, between 30 and 50 m depth, even though, as shown in the results, noise levels spread out for many kilometers. However, the coastal bathymetry induces an attenuation of the signal over the entire platform. Since light seismic surveys occur at such low depths which, as previously stated, are known for their high productivity, it is clear that it may potentially impact a higher number of individuals than typical seismic survey that occur in deep water.

The results confirm the important impact that seismic surveys may have on marine species, suggesting that, if they cannot be avoided, then periods and areas at lower risk should be chosen, whenever possible, in order to diminish the impact of these practices on marine species.

**Acknowledgments** The authors gratefully acknowledge the funding of the EAPA 52/2018 – JONAS project and the collaboration of the Portuguese Society for the Study of Birds (SPEA) for giving us access to their dataset of cetaceans along all the Portuguese coast as well as the whale-watching companies MarIlimitado and SeaEo tours for providing us with cetaceans observation records for the region of Sagres and Setúbal, respectively.

**Abstract**

Categorizing the effects of anthropogenic noise on aquatic life according to the mechanisms of effects could help regulators with their decision-making. This chapter proposes categorizing effects into those that likely scale directly with sound level and those that are influenced by many other factors and thus may scale inconsistently with sound level. The first proposed category of mechanisms is physical (direct effects of sound waves on biological tissues or interference of sound during detection). Physical mechanisms could lead to injuries, temporary hearing loss, and masking. The severity of responses with physical mechanisms is likely to scale with received sound level. The second proposed category of mechanisms is perceptual (following sensory experience of sound waves). Perceptual mechanisms, such as stress and distraction, could lead to changes in physiology, cognition, and behavior. The severity of responses with perceptual mechanisms depends on the receiver's external context (e.g., other environmental stressors), current behavioral context (e.g., feeding or breeding), and internal state (e.g., hungry, distressed), as well as the received sound level. Threshold values for noise criteria where effects are driven by perceptual mechanisms will be challenging to establish due to the large number of interacting factors. However,

regulating noise is an urgent priority as mortality can arise from effects with perceptual mechanisms, for example from a failure to exhibit a normal anti-predator response. Pragmatic policymaking for anthropogenic noise could consider area-based and time-based limits until sufficient information for effective level-based limits is available.

## Introduction

The effects of anthropogenic noise on aquatic life have been categorized according to the proximity to the source and assumed corresponding sound level in relation to the hearing abilities of the animal (Popper and Hawkins 2019). The "Zone of Influence" is considered as the area where the animal can detect a sound and is divided into four sub-zones: Zone of Audibility, Zone of Responsiveness, Zone of Masking, and Zone of Hearing Loss, Discomfort, and Injury (Richardson et al. 1995). Assumed to occur with increasing distance from the source within the Zone of Influence, effects have been categorized by some authors as: death, physical injury and physiological changes, hearing threshold shifts, masking, behavioral responses, and no obvious behavioral responses (Popper and Hawkins 2019). Additionally, a "dose-response" relationship has been assumed between the received noise level and the magnitude of effects within each category. However, several papers have recognized the importance of context to behavioral responses (e.g., (Bruintjes and Radford 2013; Ellison et al. 2012; Harding et al. 2019; Merchant et al. 2022)), the link between physiological responses and behavioral responses (e.g., Mills et al. 2020), and the potential for mortality as a result of behavioral responses (e.g., Bernaldo De Quirós et al. 2019; Simpson et al. 2016). While it is logical that some types of effect are expected to consistently scale with sound level, for other types of effect other factors could influence the degree of impact. This chapter proposes categorization of the effects of noise according to the mechanisms by which effects may occur, in the hope that this could help to target policy decisions to maximize the potential benefits of regulating underwater anthropogenic noise (see Fig. 1). It is hoped that this paper will stimulate discussions about the nature and naming of new categories, and the effects that belong within them.

## Physical Effects

The first proposed category of effects is physical. Physical effects are considered here as effects of a sound wave either directly on the tissues of the body (which could cause injury) or interfering with another sound wave during detection by the animal (which could cause masking). Sound levels for both "continuous" noise (measured by averaging over time, e.g., root-mean-square sound pressure or particle

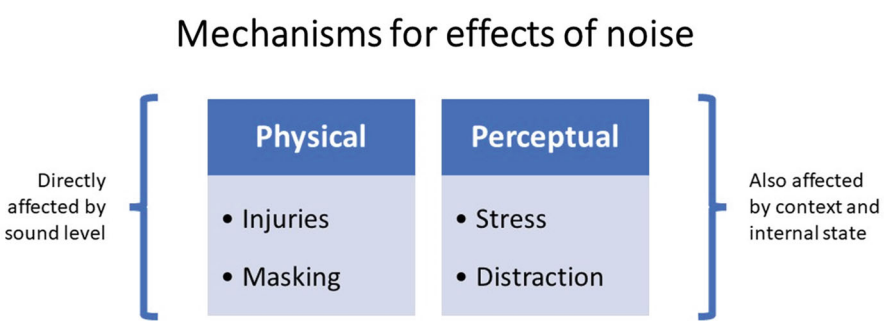

**Fig. 1** A schematic representation of suggested categories for the mechanisms for effects of noise. Any dose-response relationships may be inconsistent for effects with perceptual mechanisms and thus these effects may not necessarily scale directly with distance from the source or sound level

acceleration level) and impulses (e.g., 0-peak sound pressure or particle acceleration level) need to be considered. Due to relatively consistent dose-response relationships, physical effects are expected to be simple to mitigate using measured and predicted sound levels and criteria.

Injuries include barotrauma (tearing of tissues due to extreme fluctuations in pressure of gas bubbles such as swim bladders (Halvorsen et al. 2011; Popper and Hawkins 2019)) and tearing of tissues due to mechanical strain (possibly due to extreme fluctuations in particle displacement (Nedelec et al. 2021)), which may lead to death in the most severe cases, damage to organs, or hearing loss (via damage to auditory hair cells). For example, in a controlled experiment using plane waves in a specialized tank, Chinook salmon (*Oncorhynchus tshawytscha*) exposed to impulsive sounds mimicking pile driving strikes 1–1200 Hz at a range of sound levels experienced a corresponding range of severity of barotrauma injuries; from mild hematomas of fins at the lowest sound exposure levels (960 strikes single strike sound exposure level $SEL_{SS}$ (re 1 μPa) = 171 dB, cumulative sound exposure level $SEL_{cum}$ (re 1 μPa) = 204 dB), to mortal hemorrhage of the heart at the highest sound exposure levels (1920 strikes $SEL_{SS}$ (re 1 μPa) = 187 dB, $SEL_{cum}$ (re 1 μPa) = 220 dB) (Halvorsen et al. 2011). Further work in the same specialized tank established that the number of strikes as well as the $SEL_{ss}$ and the $SEL_{cum}$ influenced the probability of injury in hybrid striped bass (white bass *Morone chrysops* x striped bass *Morone saxatilis*) (Casper et al. 2017). Injuries could impact fitness via immediate mortality, shortening lifespan, or impacting reproduction. Immediate mortality has been observed in several cases, e.g., Halvorsen et al. 2011. Injuries could also impact physiology and behavior, e.g., digestion could be impacted by barotrauma to the gut or swimming could be impacted by hematoma to fins and muscles. The animal does not necessarily need to be able to hear the sound for injuries to occur; therefore, it is relevant to consider frequencies that are beyond the hearing range of the species concerned. Reducing the received sound level of anthropogenic noise (also described as noise abatement (Merchant 2019)) is expected to decrease the severity of injuries in a predictable way.

Masking occurs when the ability to detect or recognize a sound of interest is degraded by the presence of another sound (the masker) (Erbe et al. 2016). Masking is defined by the International Organization for Standardization for humans as a property of the auditory system by which an audio signal cannot be perceived in the presence of another audio signal (ISO/IEC 13818-7:2006). Quantitatively, masking refers to the amount in decibels by which an auditory detection threshold is raised in the presence of a masker (Acoustical Society of America 2013). Masking can occur when noise overlaps signals in the receiving sensory organ or in the central nervous system in time, frequency, and particularly for fishes and invertebrates who detect particle motion vectors, direction (Rogers et al. 2021). Masking is referred to as a physical effect here because it happens as a direct result of the physical properties of the sound present in the medium and inhibits the ability of the animal to detect, recognize, or perceive a signal.

Masking has been experimentally observed in marine mammals (recently reviewed in (Branstetter and Sills 2022)). Models depicting sound pressure levels within the acoustic communication range of marine mammals can be effective at demonstrating risk to marine mammal communication, for example, an assessment of vessel slowdown showed increases in effective listening space for a variety of marine mammals in the western Canadian Arctic (Pine et al. 2018). Masking has also been experimentally observed in fishes (e.g., Hawkins and Chapman 1975; Maiditsch and Ladich 2022); however, generating models that can predict masking in fishes is currently limited by the lack of understanding and measurement of particle motion levels and the potential for directional unmasking (Rogers et al. 2021), also termed spatial release from masking (Erbe et al. 2016).

Particle motion is inherent to sound waves at all frequencies and is detected by all fishes within their hearing range, thus in situations where particle motion is higher than would be predicted from sound pressure measurements (e.g., within the near field of a source), masking could be underestimated if only pressure is considered. Hearing thresholds measured only in sound pressure omit key information about the stimulus and background noise sound particle motion levels that the fish were exposed to during a hearing test, limiting the application of these data to any contexts outside of the tank used for the experiment. Conversely, as particle motion has directionality due to its nature as a vector, fishes are capable of directional unmasking using particle motion when noise is coming from a different direction to the signal (Rogers et al. 2021; Sisneros and Rogers 2016), meaning that masking may be overestimated if only omnidirectional sound pressure is considered. Despite the knowledge gaps and current limitations to our ability to predict masking, the degree of masking relates directly to the levels of noise in the environment and thus noise abatement ought to decrease the impacts of masking in a predictable way.

## Perceptual Effects

The second category of effects could be called “perceptual” (of, relating to, or involving perception, especially in relation to immediate sensory experience;

Merriam-Webster Online Dictionary 2023). Perceptual effects are proposed to be those where anthropogenic noise is detected by the animal, perception of the acoustic signal occurs, and a response arises as a result. The main two mechanisms by which perceptual effects might manifest considered here are stress and distraction. Two observable types of response that may be driven by these mechanisms are physiological and behavioral. Both stress and distraction may occur at the same time or independently. It is not always simple to determine which mechanism is leading to an observed physiological or behavioral response. However, if mechanisms can be established this could help regulators to target more effective mitigation.

Organisms evolve stress responses that are beneficial to fitness under normal environmental variability, for example, stress responses can help animals to survive danger by preparing the body for "fight, flight, or freeze." Stress responses can be maladaptive when the severity or duration of the stressors reaches a point where homeostasis cannot be maintained. If the severity of the stressor is too high the stress response may be inadequate, for example if the temperature in the environment becomes too hot for thermoregulation to effectively reduce an endothermic animal's body temperature to within a safe range. Alternatively, if the intensity of the stressor is overly severe or long-lasting, overactive physiological stress response mechanisms may themselves become harmful to the individual, a state associated with the term "distress" (Wuertz et al. 2023).

Stress responses are mediated by hormones, for example via stimulation of the hypothalamic-pituitary-interrenal or "HPI" axis culminating in the release of corticosteroid hormones in fish (Barton 2002). The observable indicators of a stress response to anthropogenic noise include primary (hormonal), secondary (physiological), and tertiary (behavioral) responses. Experimental evidence of these include: increased plasma cortisol in orangefin anemonefish (*Amphiprion chrysopterus*) in response to motorboat noise playback on coral reefs (Mills et al. 2020); increased heart rate in staghorn anemonefish (*Amblyglyphidodon curacao*) embryos in response to motorboats driving near coral reefs (Jain-Schlaepfer et al. 2018); and increased hiding in threespot dascyllus (*Dascyllus trimaculatus*) in response to motorboat noise playback near anemones (Nedelec et al. 2016). We may infer that stress is at least one of the mechanisms for changes in behavior if changes in plasma hormone levels correlate with changes in behavior, with a temporal pattern that allows for the mechanism to enact. For example, in orangefin anemonefish exposed to playbacks of motorboat noise, an increase in testosterone circulating in blood plasma was followed by an increase in aggressive social interactions (Mills et al. 2020). All aquatic life exists in a multi-stressor environment where the contexts of climate change, over-exploitation of resources and anthropogenic noise must be considered in concert. Stress responses may also scale with perceived risk as well as or instead of the intensity of the stressor measured in the environment. Therefore, where stress is one of the mechanisms for impacts of noise, the sound level in the environment could be a poor predictor of the threat imposed. On the other hand, where stress is a mechanism for impacts, reducing stress via noise mitigation and abatement could increase resilience to other environmental stressors (Nedelec et al. 2022).

Animals need to pay attention to relevant stimuli in order to perform vital life functions such as feeding, finding mates, and avoiding predators but animals may have a limited capacity to attend simultaneously to multiple stimuli (Dukas 2004; Purser and Radford 2011). Distraction is the reallocation of finite attention away from relevant stimuli (Chan et al. 2010; Purser and Radford 2011). The observable impacts of distraction by anthropogenic noise include failure to perform normal behaviors effectively such as feeding (Purser and Radford 2011) and anti-predator responses (Chan et al. 2010; Simpson et al. 2016). Stress could interact with distraction via effects on cognition (Salena et al. 2021). The severity of perceptual effects therefore not only depends on the received level of the sound but also the external context (other stimuli in the environment), current activity (e.g., feeding or avoiding predators), prior opportunity to habituate to the noise, and the internal state of the animal (e.g., impacts of other stressors, level of hunger) (Bruintjes and Radford 2013; Harding et al. 2019; Merchant et al. 2022). Therefore, dose-response relationships for effects with perceptual mechanisms may not scale directly with sound level or may appear inconsistent across contexts. Noise pollution thus presents a regulatory challenge. Experiments where contexts and internal states are tightly controlled are needed to determine dose response relationships for effects with perceptual mechanisms. The relationships revealed may then offer general principles (such as providing evidence that abatement can reduce impacts of noise) but specific sound exposure levels may not necessarily translate to other contexts.

## Considerations for Noise Criteria and Threshold Values

The categorization described here feeds into the need for noise criteria and threshold values for the regulation of anthropogenic noise pollution. Stress and distraction can both be mechanisms for behavioral and physiological effects, behavioral effects can lead to immediate mortality (e.g., via impacts on anti-predator responses (Simpson et al. 2016), or delayed mortality (e.g., via impacts on parental care behavior (Nedelec et al. 2017)), and physiological effects can lead to a state of distress which may be detrimental to fitness. Distress due to physiological effects may be detrimental to fitness without apparent behavioral responses, meaning that the boundary between the zone of audibility and the zone of responsiveness may depend on the animal's internal state, current activity, prior opportunity for habituation, and external context.

The European Union's (EU) Marine Strategy Framework Directive (MSFD) requires member states to develop marine strategies for maintaining Good Environmental Status of European waters. The EU Commission Decision 2017/848 of 17 May 2017 defines two criteria for anthropogenic noise; impulsive noise and low frequency continuous noise. Member States are required to establish threshold values for these two criteria where spatial distribution, temporal extent, and sound levels do not exceed levels that adversely affect populations of marine animals. The Technical Group on Underwater Noise has published advice and guidance for EU Member States developing threshold values (Borsani et al. 2023; Sigray et al. 2023).

The proposed approach is to use the concept of a level of onset of biologically adverse effects ("LOBE") in combination with the spatial distribution exceeding LOBE for an amount of time. The LOBE is a sound level above which an adverse biological effect on an indicator species is expected to occur, i.e., an effect that may affect the comfort, survival, and vital functions of individual animals (Sigray et al. 2023). For impulsive noise, behavioral avoidance is proposed for calculating habitat loss and thus reductions in carrying capacity (Sigray et al. 2023) and for continuous noise, effects on masking, behavior, and physiology are considered as options for defining a LOBE (Borsani et al. 2023). There remain however, significant practical challenges to establishing evidence-based LOBEs for the relevant indicator species.

The strictest noise criteria, particularly in the presence of multiple species and the absence of good data on other factors such as those species' hearing abilities and influence of other stressors, would be any noise level that is detectable among background ambient noise. Avoiding any anthropogenic noise being detectable among background ambient noise is an unrealistic target on a global scale in the near future. Some industrial activity is required for a just transition away from a fossil fuel-based economy and some noise pollution from this activity is unavoidable. However, it may be possible to apply this as a criterion at restricted spatial or temporal scales for where and when there is a high need for protection according to the context, such as breeding fish in vulnerable or recovering populations, or when and where other environmental stressors are severe such as during and the aftermath of a marine heatwave. Any noise criteria that use a sound level above that which is detectable among background ambient noise could involve a compromise as to the extent of the effects of the anthropogenic noise that is considered acceptable. Full consideration of the costs and benefits of such compromises are further complicated by the inability to know what the extent of the effects for a given sound level are. Requiring this information prior to regulating noise could slow down regulatory decision-making. Due to the infinite possible combinations of sound levels, species, contexts, and internal states, and the real-world limitations on the speed of advancement of scientific knowledge and the speed of policymaking and implementation, regulating noise pollution will necessitate compromises, with imperfect knowledge about the risks of noise impacts.

## Conclusions

In summary, the effects of noise on aquatic life could broadly be divided into categories according to their mechanisms: those with physical mechanisms, where impacts could be expected to scale with sound level; and those with perceptual mechanisms, where impacts are influenced by other factors and thus impacts may not always scale directly with sound level. Using noise abatement measures to reduce the area and/or amount of time that anthropogenic noise can be detected among background noise could be the simplest way to minimize all impacts as the benefits that can be achieved by limiting noise to a given sound level cannot be fully defined

rapidly enough to meet regulatory needs in a pragmatic context where time and funding have real-world limits.

In conclusion, there are regulatory challenges for anthropogenic noise. There is a clear need for regulation to prevent harm to aquatic life from human activities, but several factors make regulation complicated. There is a desire for a simple "one-size-fits-all" approach to regulation, where a single sound level can be applied as a limit above which noise is deemed unacceptable. This desire is understandable because it would be relatively simple to apply in terms of mitigation technologies and behavior changes, as well as for monitoring compliance. However, the number of variables means that this issue is more complicated. Considering area-based and time-based limits rather than level-based limits for indicator species who are vulnerable to other stressors or in sensitive contexts (e.g., Atlantic cod (*Gadus morhua*) during a marine heatwave in the breeding season) could be a way of simplifying the regulatory challenge to achieve rapid improvements in the interim while more detailed evidence is gathered.

**Abstract**

Significant amounts of historic unexploded ordnance (UXO) are still located in our seas and waterways. Operations to clear waterways of these munitions have increased significantly in the last few decades due to increasing offshore

activities, for example, the expansion offshore wind energy development. Various methodologies for Explosive Ordnance Disposal (EOD) exist, but a historically commonly used approach is to blast-in-place (BiP). This process involves detonation of a modern explosive charge next to the historic charge initiating a simultaneous high-order detonation in both. These underwater explosive events are highly energetic and have the potential to generate high acoustic and vibrational levels in both the water column and the seabed with the associated potential for both physiological and behavioral response impacts on a wide range of aquatic fauna. An alternative EOD process has been investigated where a smaller shaped charge is used to initiate a burning process, known as deflagration, in the UXO's explosive material. This low-order process has the potential to be significantly quieter and less destructive than equivalent high-order detonation events. This chapter presents results from trials carried out in a flooded quarry in the UK in 2019 comparing the acoustics of detonations and deflagration methodologies on like-for-like munitions. Results are also presented of measurements carried out in genuine historic (WWII) UXO located in the Danish Baltic in 2022. Data from both of these trials demonstrated an around 15–20 dB reduction in the water column acoustic levels and seabed vibration levels comparing low-order with high-order methodologies. Additional factors surrounding the long- and short-term toxicity from in situ and cleared UXO processes and the potential for damage to the seabed are also discussed.

## Introduction

Historic WWI and WWII Unexploded Ordnance (UXO) still exist located in our waterways with an estimated 300,000–500,000 pieces in UK waters alone (DEFRA 2022). These munitions have individual explosive charge sizes ranging from a few tens of grams to greater than 500 kg of TNT equivalence explosive charge mass. These have been largely left undisturbed in situ in the postwar periods. In recent years, however, there has been a significant increase in the number of controlled Explosive Ordnance Disposal (EOD) operations required by a range of offshore activities, for example, offshore wind energy developments and ground fishing to make their areas of operation safe.

A commonly used method of UXO clearance (EOD) involves a *Blow-* or *Blast-in-Place (BiP)* operation carried out by colocation of a modern explosive *"donor"* charge. This is typically around 5–10 kg of TNT equivalence and is used to initiate a simultaneous "high-order" detonation in both the primary donor charge and the secondary often-larger historic charge of the UXO. This process has the potential for generation of very large underwater explosive events with associated high acoustic and vibrational energy levels in both the water column and the seabed. This has led to a growing concern of potential negative impacts on aquatic fauna and their environments related to these detonations. Potential impacts include those generated by high levels of acoustic noise and seabed vibration (Yelverton et al. 1973; Ketten et al. 1993; NOAA 2016; Dahl et al. 2020; Todd et al. 1996; Finneran et al. 2000;

Danil and St. Leger 2011; Sundermeyer et al. 2012; von Benda-Beckmann et al. 2015; Parsons et al. 2000; Salomons et al. 2021; Cottrell and Dupuy 2021; Siebert et al. 2022; Robinson et al. 2022; Jenkins et al. 2022; Smith et al. 2022; Favretto-Cristini et al. 2022a, b), seabed damage (Garlan et al. 2018), chemical toxicity (Strehse et al. 2017; Appel et al. 2018; Maser and Strehse 2020; Schuster et al. 2021; den Otter et al. 2023; Maser et al. 2023), and others.

In 2019, the underwater acoustic characteristics of both traditional high-order methodologies and an alternative low-order EOD methodology known as deflagration were investigated in trials in a flooded quarry in the UK (Robinson et al. 2020). The low-order deflagration process investigated used a small shaped explosive charge to penetrate the outer, typically metallic, shell on a munition and then to initiate a "low-order" burning process of the historic explosive material. In this chapter, data from acoustic measurements of both "high-order" and "low-order" methodologies used on like-for-like surrogate munition shells are presented. These data show a significant reduction in the acoustic levels associated with the low-order methodology of around 20 dB for a 10 kg historic charge disposal. Following on from the quarry experiments, provisional data are presented for open water trials that took place in the Little Belt, Denmark, in January 2022 of both high- and low-order methodologies used on actual historic (WWII) UXOs of charge sizes in the range 200–430 kg. As with the quarry test, significantly lower acoustic noise outputs were observed using a deflagration process on these UXOs compared to the high-order detonation clearances. Potential noise impacts and relative noise levels of both high- and low-order methodologies are discussed as well as other factors such as seabed damage and chemical toxicity in the context of current EOD operations and potential impacts on underwater environments.

## Controlled Quarry Trials of Low- and High-Order EOD Methodologies (2019)

### Methodology

In 2019, a series of acoustic tests were conducted of both high-order (detonation) and low-order (deflagration) EOD methodologies using surrogate shells filled with modern plastic explosives of charge size 5 kg and 10 kg. These were conducted at Limehillock quarry in Aberdeenshire in Scotland. This is a freshwater flooded quarry around 200 m long and 20 m deep operated by Thornton Tomasetti Defence Ltd., UK. Figure 1 shows the experimental layout. Both high-order and low-order test rigs were placed at a depth of approximately 8 m from the surface in around 20 m water. A series of T11 low sensitivity recording systems (Neptune Sonar, UK, nominal charge sensitivity: 0.07 pC/kPa; maximum pressure: 275 MPa) and 138A26 transducers (PCB, nominal voltage sensitivity: 0.29 mV/kPa; maximum pressure: 172 MPa) were used to capture the pressure waveforms at horizontal ranges 8–20 m from the source. Additional measurements were made at the far

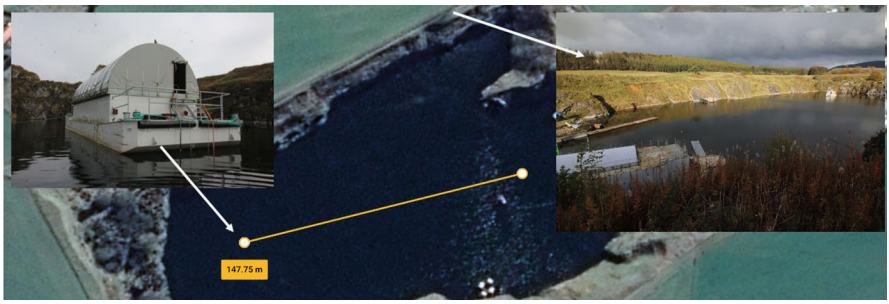

**Fig. 1** Limehillock quarry field site in Aberdeenshire in Scotland (Robinson et al. 2020). (Courtesy of Thornton Tomasetti Defence Ltd)

**Fig. 2** VULCAN deflagration charge placed on a 5–10 kg surrogate shell before deployment (Robinson et al. 2020). (Courtesy of Thornton Tomasetti Defence Ltd)

end of the quarry using a series of hydrophone arrays deployed from a floating barge at a range of 147 m (Robinson et al. 2020).

High-order detonation clearances were achieved by direct placement of a detonator through a threaded endcap into the main charge explosive in surrogate shells filled with either 5 kg or 10 kg of P4 plastic explosive. Low-order clearances were achieved using a deflagration methodology based on a 25 g shaped charge technology known as a VULCAN™ developed by Alfords Technologies, UK (VULCAN 2023), into identical surrogate shells at both 5 kg and 10 kg TNT charge size. The explosive filler was a plastic explosive (PE4) which consisted of 88% RDX plastic explosive (Grade 1 A), 11% plasticizer, and 1% pentaerythritol dioleate. Figure 2 shows a VULCAN deflagration charge positioned on the 10 mm thick steel endcap of a surrogate shell casing before deployment (Robinson et al. 2020).

In total, seven tests were conducted on surrogate shells including 1 × 5 kg (high-order), 2 × 10 kg (high-order), 2 × 5 kg (low-order), and 2 × 10 kg (low-order). In

addition, acoustic analysis was carried on several unconstrained charge masses including 15 g, 25 g, 48 g, 250 g, and 18.7 kg with 17 charges tests in total. Trials were also carried out on the deflagration VULCAN charge (25 g) directly onto a steel plate. All systems were deployed at similar depths and measured using identical methodologies outlined above (Robinson et al. 2020).

## Quarry Trial Results (2019)

All the high-order detonation trials demonstrated apparent disintegration of all the charge mass, the shell, and the detonator. For the total charge sizes 5 kg and 10 kg, significant surface plumes were observed as shown in the example in Fig. 3 for a 5 kg shell high-order event. By comparison, the low-order deflagration events showed no significant surface plume; however, bubbles were observed at the surface within a few seconds of the initialization indicating the deflagration "burning" process happening at a much slower speed than the high-order detonations. Inspection of the remaining shells where deflagration was carried out showed a significant reduction in the original PE4 material from the deflagration process, as shown in two examples in Fig. 4. This reduction in explosive material without an associated detonation was between 47 and 58% in both the two (5 kg & 10 kg) tests considered here.

Figure 5 shows the peak sound pressure level ($L_{p,pk}$) measured from the initial highest amplitude for each of the test charges at ranges of around 15–20 m. Note these arrivals were considered free-field before significant multipath arrivals from the surrounding quarry walls, bottom, and water surface. The data, shown in Fig. 5, shows a strong relationship between charge size and peak sound pressure amplitude, with significant peak pressure amplitudes of around 4 MPa (a $L_{p,pk}$ level of 252 dB re

**Fig. 3** Surface plume from a high-order 5 kg filled surrogate shell detonation. (Courtesy of Thornton Tomasetti Defence Ltd)

**Fig. 4** Examples of two post deflagration (after the endcap has been removed from surrogate shell) events showing the degree of burnout of the original P4 explosive (Robinson et al. 2020). (Courtesy of Thornton Tomasetti Defence Ltd)

1 μPa) being reached for a 10 kg charge size at 20 m and greater than 255 dB re 1 μPa for the 18.7 kg charge size. This measured data relationship (black dashed line) aligns well with midwater detonation models such as those developed and described in various forms by investigators such as (Cole 1948; Arons 1954, and Weston 1960). Here the peak pressure in the initial positive-going shock wave as a function of scaled range is as follows:

$$L_{p,pk} = 52.4.10^{6} \left( \frac{R}{W^{1/3}} \right)^{-1.13}$$

where $L_{p,pk}$ is the peak pressure in Pa, $R$ is the measurement range in meters, and $W$ is the charge weight in kg of equivalent TNT (Robinson et al. 2020, 2022). By comparison, the low-order deflagration trials showed peak sound pressure ($L_{p,pk}$) levels around 20 dB lower at around 232 dB re 1 μPa for clearance of identical 5 kg and 10 kg filled surrogate shells compared to the equivalent high-order events. These levels were almost identical (green dashed line) to the levels measured for initialization of a 25 g deflagration charge on its own (without an associated surrogate shell), suggesting that most of the acoustic output of the deflagration clearance was

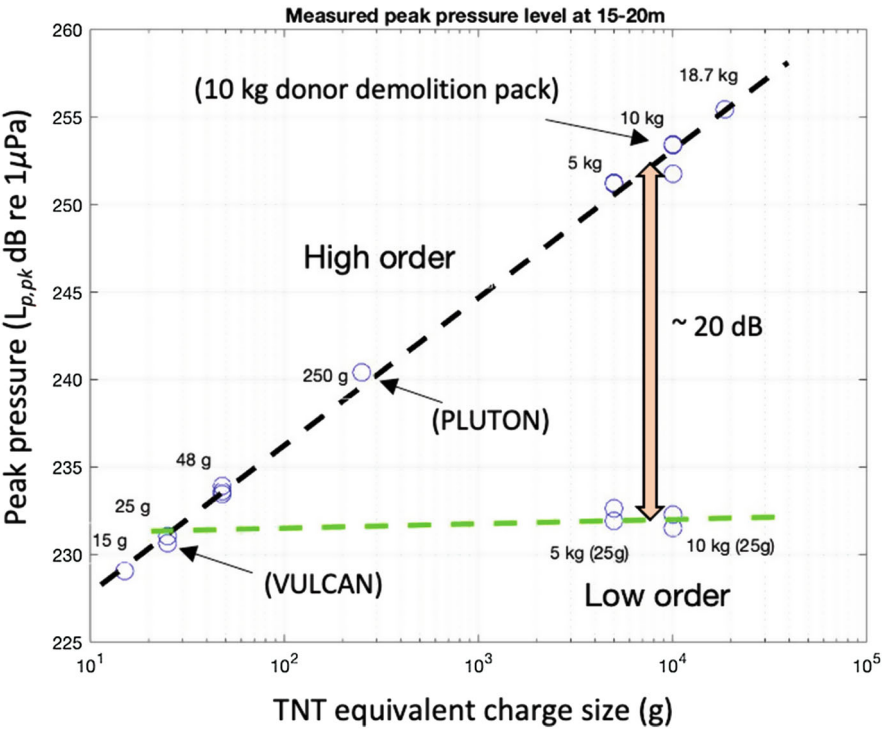

**Fig. 5** Peak pressure ($L_{p,pk}$) measured at ranges 15–20 m for each of the various charge sizes. Note that the low-order charges indicated show either the 5 kg or 10 kg of the original shell size that was deflagrated by the VULCAN charge in this case of 25 g. Also indicated here is the data for the equivalent charge size for the PLUTON deflagration technology and the typical 10 kg donor charge equivalent discussed in section "Comparison of Low- and High-Order EOD Methodologies on In Situ Historic UXO (2022)"

primarily due to the deflagration charge solely. Good replication of acoustic levels was observed for similar charge sizes across all the trials carried out suggesting a high degree of predictability in determining potential acoustic levels using models such as those outlined above in the case of the use of "modern" explosive material and midwater detonations.

## Comparison of Low- and High-Order EOD Methodologies on In Situ Historic UXO (2022)

### Methodology

In January, 2022 acoustic measurements were made of four high-order EOD and four low-order EOD clearances of historic WWII mines (UXO) in the Little Belt area of the Danish Baltic. The EOD operations were carried out by the Royal Danish Navy

on six WWII British marine mines (MK4, MK6) of original UXO-equivalent TNT charge sizes ranging from 340 kg to 430 kg in water depths from 18 to 22 m. Water column acoustic measurements of all these events were made on a range of bottom-deployed autonomous recorder systems at ranges from a few kilometers to greater than 20 km. Figure 6 shows the bathymetry of the trial site, locations of the six UXOs (with the following identifiers: Foxtrot [F], Golf [$G_1$,$G_2$], Mike [M]), November [$N_1$,$N_2$], Juliet [J], & Lima [L]), and the deployment of an array of ten bottom-mounted autonomous recording stations (R0-R9) in water depths of 12–20 m. Additionally vertical hydrophone arrays were also deployed from the *RV Aurora* operated by Aarhus University at ranges varying from 1.54 to 6.08 km as well deployment of a continuously recording GPR™ seabed vibrational system (Sercel, France) at the R0 station (GPR 2023). All recordings were made with sufficient high bandwidth to allow capture of representative time domain waveforms due to rapid rise times typical with explosive sources, and these bandwidths were also sufficient to capture higher frequency components from the acoustic signal to >150 kHz bandwidth (Lepper et al. 2024). Measurements were carried out where possible in line with protocols described in (NPL 2020).

In total, eight clearance events were carried out, listed here chronologically, F(high-order), $G_1$ (low-order), $G_2$ (high-order), M (high-order), $N_1$ (low-order), $N_2$ (high-order), J (low-order), and L (low-order). Both the Golf [G] and November

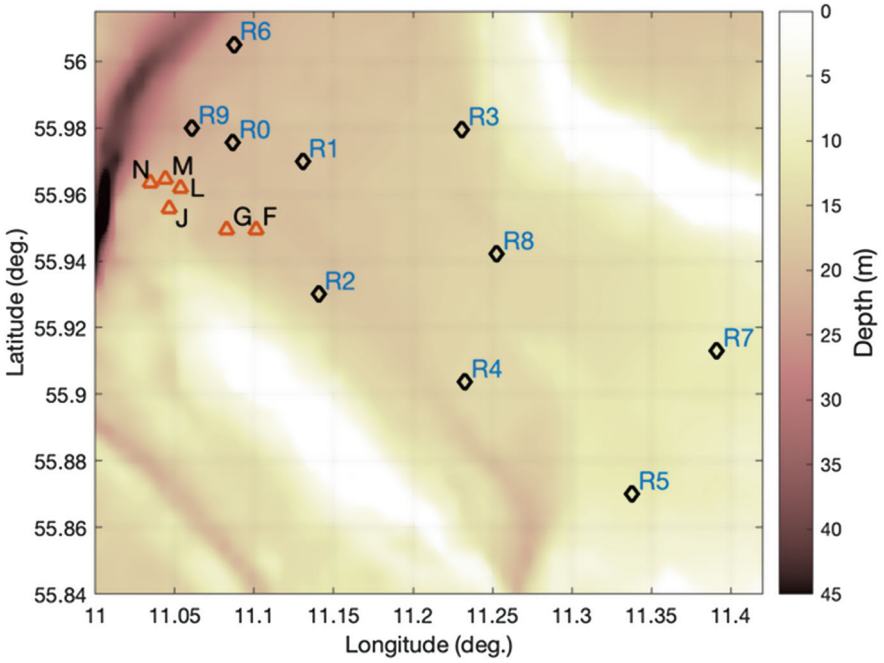

**Fig. 6** Bathymetry of trial site overlaid with UXO positions [F, $G_1$, $G_2$, M, $N_1$, $N_2$, J, & L] (red triangles) and recorder station R0-R9 (black diamonds)

[N] mines were initially cleared using a low-order deflagration methodology [$G_1$ & $N_1$] followed by high-order clearances of the remnants of the low-order clearances described as [$G_2$ & $N_2$]. Diver inspection and sonar scans were also made before and after each event as well as chemical analysis of water and sediment samples before and after each of the clearances. The mines were in initial variable condition on and in the seabed, ranging from severely corroded with the original explosive material exposed to the environment (Fig. 7 shows the mine Golf [G] before clearance), compared to the mine Lima [L] (Fig. 8 shows the mine Lima [L] before clearance) appearing relatively intact with minimal evidence of corrosion. The mines also showed a variable degree of burial ranging from 10% to 80% (Lepper et al. 2024).

The high-order clearances were carried out using a 10 kg (TNT equivalent) demolition pack placed adjacent to the historic UXO. Low-order clearances were carried out using a PLUTON™ deflagration charge from Alford Technologies with 250 g (TNT equivalent) charge size (PLUTON 2023). One of these systems was used on each of the low-order trials, deployed and operated by divers from the Royal Danish Navy. Both the high-order detonation and low-order deflagration events were

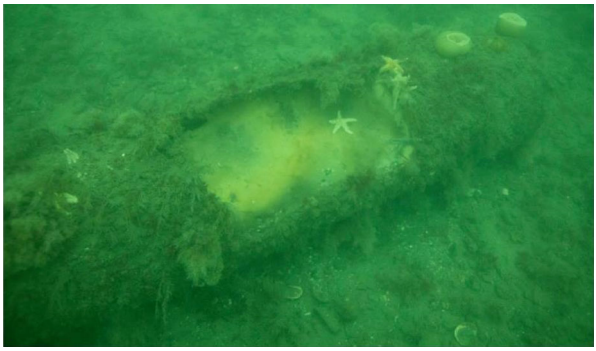

**Fig. 7** Preclearance mine Golf [G], heavily corroded with significant marine growth. Identified as a MK4 British WWII marine mine with equivalent TNT original charge mass of 340 kg (Lepper et al. 2024) (Supplementary courtesy of the Royal Danish Navy and Alfords Technology)

**Fig. 8** Preclearance mine Lima [L], partially buried but appearing relatively intact. Identified as a MK6 British WWII marine mine with equivalent TNT original charge mass of 430 kg (Lepper et al. 2024) (Supplementary courtesy of the Royal Danish Navy and Alfords Technology)

**Fig. 9** Preclerance deployment of Pluton device for low-order deflagration of mine Golf [G] (seen in Fig. 7) (Lepper et al. 2024) (Supplementary courtesy of the Royal Danish Navy and Alfords Technology)

initiated using a shock-cord to a near-by surface vessel. All acoustic systems recorded continuously during each of the trials. Figure 9 shows the deployment of a Pluton deflagration charge on mine Golf [G] before the low-order $G_1$ clearance.

## Explosive Ordnance Disposal (EOD) Results

From an Explosive Ordnance Disposal perspective, the Royal Danish Navy considered each of the eight clearance events (four high-order and four low-order) successful and they considered the munitions safe and free from further risk from uncontrolled detonation and could be approached by EOD divers for postclearance analysis (Royal Danish Navy, personal communication). The four high-order events (Foxtrot [F], Golf [$G_2$], Mike [M], & November [$N_2$]) resulted in generation of significant surface plumes, several tens of meters high, observed from several kilometers away. Post analysis of the seabed by divers and sonar scans showed no visibly detectible fragments of the UXO but often with significant cratering at the UXO site. Figure 10 shows postdetonation sonar scan of the Foxtrot high-order clearance with generation of a seabed crater around 6.4 m diameter and approximately 1–3 m deep. Similar cratering was seen for all the high-order events.

By comparison, no surface plume was observed during any of the low-order clearance events (Golf [$G_1$], November [$N_1$], Juliet [J], & Lima [L]). Postclearance inspection by divers showed in all cases evidence of a deflagration burn with reduction in the original UXO explosive material. In the case of mines N and L which appeared relatively intact in preinspection, there was evidence of the mine splitting or bursting, most likely due to overpressure from generated gasses during the deflagration process. Images of the chronological sequence from (initial condition) – (deflagration preparation) – (post deflagration) of the low-order clearance of mine Golf are shown in Figs. 7, 9, and 11, respectively. Other deflagration events showed similar results with all having some remaining explosive materials either still

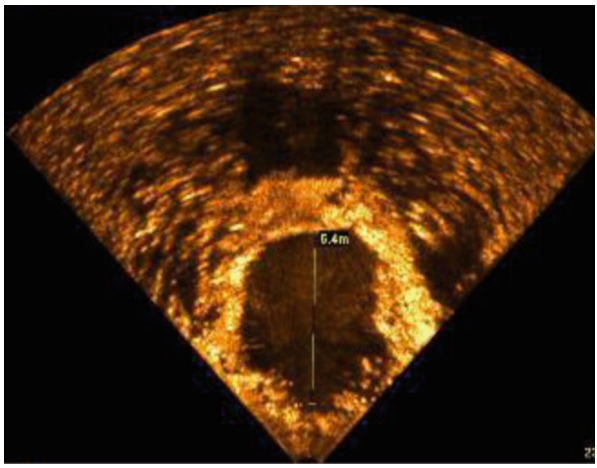

**Fig. 10** Post-high-order clearance of mine Foxtrot. No visually detectable fragments of the UXO observed with significant seabed cratering observed on all of the high-order clearnce events (Lepper et al. 2024). (Supplementary courtesy of the Royal Danish Navy and Alfords Technology)

**Fig. 11** Post-low-order clearance of mine Golf. Note the UXO has been split open and much of the original Amotol explosive charge has either been burnt via the deflagration process or shattered and ejected as the shell casing has split (Lepper et al. 2024). (Supplementary courtesy of the Royal Danish Navy and Alfords Technology)

within parts of the mine shell or nearby. In the case of all the deflagration trials, the debris from the clearance is scattered within a few meters of the original UXO site. For none of the low-order deflagration events was there any evidence of seabed damage of the form seen with the cratering observed on the high-order clearances. Analysis of the debris and acoustic outputs suggest that none of the four low-order deflagration trials carried out here underwent a deflagration-to-detonation transition (DDT).

## Acoustic Results

Analysis of all of the acoustic data from the static array and the *Aurora*-deployed sensors was made for broadband amplitude metrics $L_{p,pk}$ and sound exposure level

(SEL) at ranges from a few kilometers to around 22 km as well as linear and decidecade band spectral analysis as well as time and frequency analysis of seabed vibration data recorded with the sensor on station R0.

Figure 12 shows the acoustic time-domain waveforms measured at longer ranges (18.6–22.4 km) for each of the eight clearance events. Typical levels for peak pressure ($L_{p,pk}$) at these longer ranges for the 4 × high-order events (F, $G_2$, M, & $N_2$) were in the range 172–178 dB re 1 μPa compared to 151–154 dB re 1 μPa for the associated low-order events ($G_1$, $N_1$, L, & J). Direct comparison of both low- and then high-order events on both the Golf and November UXOs allows comparison at identical distances. In these cases, the Golf [$G_1$] low-order event had a 14 dB lower $L_{p,pk}$ than the [$G_2$] high-order event at the same distance of 19.7 km. A 17 dB lower level can be seen for $L_{p,pk}$ between the November low- and high-order events [$N_1$ & $N_2$] at identical ranges of 21.3 km. In both cases, the low-order clearances [$G_1$ & $N_1$] took place first, acting on the original, potentially much larger UXO charge mass of around 340 kg. The secondary high-order clearances [$G_2$ & $N_2$] were, however, carried out on the remnants of the preceding low-order deflagration clearances on a smaller estimated equivalent charge size of around 34 kg each + the 10 kg high-order donor charge used and therefore potentially acting on a significantly lower original + donor = total charge mass. Note the 340 kg stated here is the estimated original manufactured munition charge size of the UXO. However, several of the UXO investigated showed evidence of environmental degradation over time with, in some cases, the explosive material exposed to the marine environment for significant periods. Despite these potential differences in the size of the original explosive

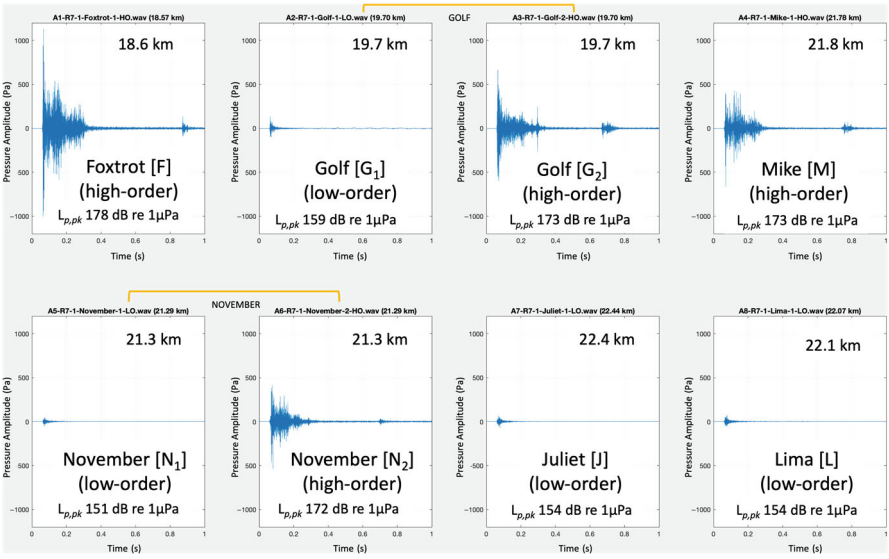

**Fig. 12** Long-range time-domain waveforms for each of the 8 × clearance events Foxtrot [F], Golf [$G_1$,$G_2$], Mike [M], November [$N_1$,$N_2$], Juliet [J], and Lima [L]

material being acted on, the low-order events still showed significantly lower overall acoustic levels. Similar differences of 14–20 dB lower levels were observed at all measured ranges for both $L_{p,pk}$ and SEL between all the high- and low-order events.

Figure 13 shows SEL versus range for all the clearance events. As with the peak pressure metric ($L_{p,pk}$), typical SEL amplitudes were between 15 and 20 dB lower for low order at all the ranges observed. Both the SEL and $L_{p,pk}$ metrics show a wider variation in absolute level for the high-order events compared with the low-order. In the case of the low-order events, the absolute measured level correlated relatively well with controlled measurements of the high-order detonation of a 250 g charge carried out in the quarry (Robinson et al. 2020); see Fig. 5. Combined with the modeled broadband transmission loss profiles for this environment, the low-order data versus range seen in Fig. 13 also aligns relatively well with the suggestion that a majority of the acoustic signal observed in these cases is from the low-order deflagration charge on its own.

By comparison, the levels associated with the high-order events were often close to, or some fraction greater, than would be predicted by a 10 kg donor charge on its own. None of the high-order events in these trials generated levels, based on the same models, that indicated detonation of the historic UXO at its original full

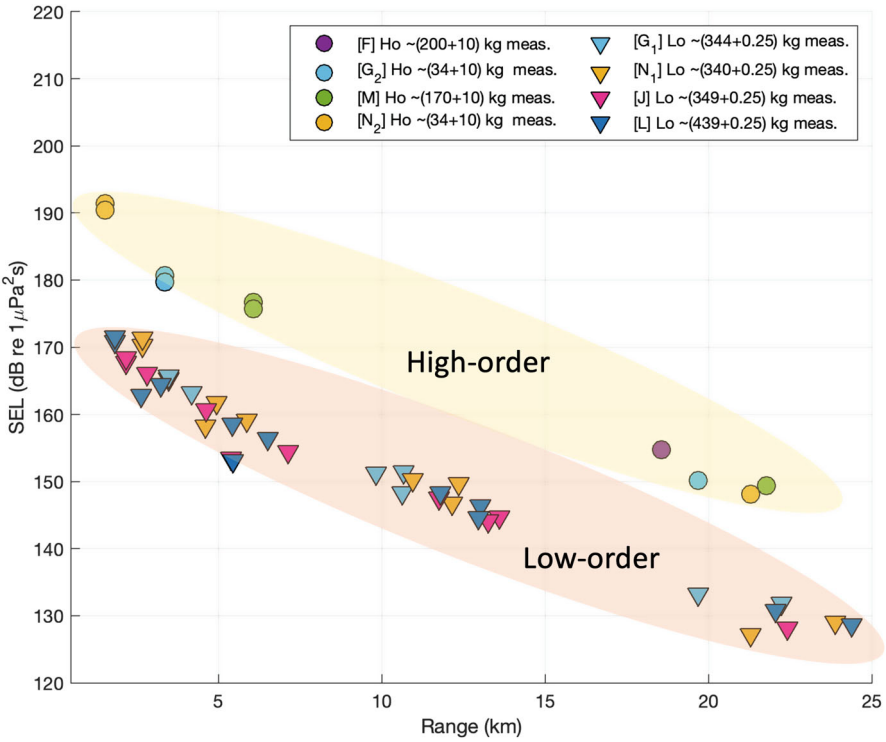

**Fig. 13** SEL level versus range for each of the eight clearance events. Legend gives the clearance methodology used and the estimated charge mass acted on for each EOD operation

potential with many having levels indicative of the donor charge plus some partial contribution from the original UXO full explosive potential. This broadly aligns with observations of 54 high-order clearances of WWII UXO made in 2022 in the North Sea, where most showed lower observed levels than might be expected from the original munition's full explosive potential. In that case, only a couple of examples out of the 54 events analyzed gave levels close to levels that models might predict based on original munition size (Robinson et al. 2022). Observation of reduction in measured versus predicted levels for high-order events have been reported by a number of investigators particularly in shallow water environments (Gaspin et al. 1979; Chapman 1985, 1988; Hannay and Chapman 1999; Soloway and Dahl 2014; Robinson et al. 2020; Salomons et al. 2021; Robinson et al. 2022; Favretto-Cristini et al. 2022a, b), and a number of or combination of potential reasons have been suggested by a number of these studies including degradation over time of the explosive materials, energy lost into the seabed compared to midwater detonation, cavitation shielding by the bubble generation and surface interaction, surface blowout, etc.

Even with these slightly lower than predicted levels, the actual measured values shown in Figs. 12 and 13 show the potential in both SEL and Peak ($L_{p,pk}$) metrics for generation of stimuli that could cause both physiological (for example, permanent threshold shift (PTS) and/or temporary threshold shift (TTS)) as well as behavioral responses at significant ranges from source in a wide range of marine species (Southall et al. 2019; Popper et al. 2014; NOAA 2016).

Provisional analysis of the seabed vibration also indicated significant levels detectable at ranges of up to several kilometers from the clearance events likely due to sediment or seabed interface borne wave propagation. Comparison of relative levels of signals from the seabed-mounted vibration recorder in both the vertical and horizontal planes showed similar relative level reduction in amplitude between the high- and low-order methodologies (Lepper et al. 2024). These propagating signals may be of significant importance in the assessment of potential impacts on a wide range of aquatic fauna particularly sensitive of vibration and particle velocity, particularly with the likely generation of complex pressure and shear wave propagation in the water column, the seabed, and the water-seabed interface from these events (Jenkins et al. 2022).

## Conclusion

Controlled measurement trials conducted in a quarry on like-for-like known munitions showed around a 20 dB reduction in noise levels for a 10 kg charge disposal using deflagration versus traditional high-order methods. The measurements from open water trials in Denmark on historic UXO of original sizes of up to 460 kg TNT equivalent showed similar 15–20 dB lower radiated noise levels at the measured ranges between the high- and low-order methodologies. None of the low-order deflagration clearances observed in these trials appear to have undergone a

deflagration-to-detonation transition (DDT); however, the potential for this is an acknowledged risk throughout the EOD industry. The overall reliability of the low-order deflagration methodology is currently based on a relatively low number of observed operations of underwater deflagration events and therefore remains an important unanswered question warranting further investigation.

In both these trials, the signal output from the deflagration methodology appears dominated by the initiating deflagration charge making it much easier to predict and model. Note that the deflagration charge technology used in these trials is essentially a much-smaller (25–250 g compared to ~10 kg for the high-order donor charge equivalent) high-order detonation and therefore intrinsically quieter. However, the historic UXO high-order clearance levels observed in the trial ranged from close to just the donor charge (around 10 kg) up to a fraction of the full historic charge in addition to the 10 kg donor charge. The potential net reductions between high- and low-order methodologies could therefore be significantly higher for larger charge sizes if the original UXO explosive material was to detonate at its full potential. This potential uncertainty in how powerfully and how much of the historic UXO detonates in high-order events combined with environmental effects, particularly in shallow water, makes assessment of potential levels more difficult with a higher degree of uncertainty for the high-order compared to low-order events.

The deflagration trials carried out did show evidence of a reduction in the original explosive material through the deflagration process but with some residual explosive material remaining either contained within the original UXO shell or dispersed over a relatively small area compared with high-order detonations that have shown significant seabed damage but with little (visually observable) evidence of the original UXO's materials remaining. Chemical analysis has, however, shown increased levels (compared to high-order events) of some explosive material by-products in the immediate vicinity of the UXO site in the case of low-order events (Maser et al. 2023; Lepper et al. 2024) which warrant further investigation.

A low-order deflagration methodology approach to EOD was demonstrated in a real-world environment on historic UXO, and the associated reduction in radiated acoustic levels and seabed damage serves as a significant improvement in the reduction of potential impact on marine life; however, it should be acknowledged that even at these lower levels the absolute levels are still relatively high and/or comparable to other typical marine noise sources (Ainslie et al. 2012). This can be seen in the water column measured data but also potentially in the seabed and water/seabed interface where impact levels are still relatively unknown. These signals in both the water column and seabed may still serve as a source of noise impact over significant ranges (Lepper et al. 2024). Reduction of levels still further may require a combination of mitigation strategies to be carefully considered and warrants further investigation.

**Acknowledgments** This project was funded by the UK's Department for Business, Energy and Industrial Strategy's Offshore Strategic Environmental Assessment program under contract OESEA-21-127. The authors would like to sincerely thank Lars Møller-Pedersen and his team from the Royal Danish Navy, Captain Torben Vang and crew members Lars Renvand, Jesper

Voetmann, Frank Landkildehus, and Michael Bach of the RV Aurora, and Clive Gale for the EOD assessment detail. The authors would like to acknowledge the contributions of the staff of Thornton Tomasetti during the controlled experiment (particularly Nick Misselbrook and Shaun Butcher), and of Alford Technologies for the design of the surrogate munitions and conducting the explosives operations, particularly Andy Carss.

**Note** Parts of this chapter have been reproduced from the following sources: (Robinson et al. 2020) for the quarry trial and (Lepper et al. 2024) for the trials in Denmark by the same authors.

**Abstract**

A joint transnational monitoring program for ambient noise in the North Sea has been developed by the Jomopans project (Joint Monitoring Program for Ambient Noise in the North Sea). Validated soundscape maps were produced that quantified the ambient sound in the North Sea. From these maps, the underwater noise can be assessed and they are valuable information to develop measures to improve the quality of the environment, required by the European Marine Strategy Framework Directive (MSFD). Jomopans developed soundscape maps for the North Sea based on acoustic modeling of the sound produced by ships and wind. The spatial and temporal exceedance of ship noise over wind noise is assessed through so-called Dominance maps. In total 15 measurement stations around the North Sea were employed and gathered long-term sound data. These data were used to validate the soundscape maps.

Following that approach, it was found that shipping noise dominates the underwater soundscape of the North Sea. In the southern part and along the major shipping routes, the shipping noise exceeds the broadband natural sound by more than 20 dB for more than 50% of the time.

## Introduction

Management of the marine environment must be based on the best available information. This information for most pollutants is obtained by a network of monitoring stations. Pollution by continuous noise consists of various sources with large spatial differences. A network of measurement stations alone cannot deliver reliable

information to be used for policy and management. Especially for the North Sea, which is almost 600,000 $km^2$, soundscape maps are required for implementing policy measures. Up until now reliable quantitative information on continuous underwater noise is largely lacking.

The Marine Strategy Framework Directive (MSFD, European Commission 2008) is the major legal framework for improvement of the marine environment in the European Union (EU). In the MSFD for the first time underwater noise was addressed as an environmental pollutant and subsequent obligations followed from this for the member states of the EU. In 2017, the regulations from the MSFD were more specified in the so-called Commission Decision (European Commission 2017). Another policy driver affecting underwater noise and its sources is the Directive on Marine Spatial Planning (MSP, European Commission 2014). This directive aims to regulate human activities at sea and the spatial planning of these activities.

Stimulated by the MSFD the regional sea convention OSPAR elaborated on the monitoring and assessment of underwater noise. For continuous noise, this resulted in a monitoring strategy (Snoek et al. 2015) and an assessment framework (Van Oostveen et al. 2020). Also, the Jomopans project (Joint Monitoring Program for Ambient Noise in the North Sea, 2018–2022) was executed to set up an operational monitoring framework. Eleven institutes from seven countries bordering the North Sea worked close together in Jomopans.

The Jomopans project contributed largely to the methodology for assessment continuous noise proposed by the MSFD working group for underwater noise (Sigray et al. 2021). Further development of the methodology by this working group is ongoing.

## Jomopans Approach to Monitoring

To develop a framework for the monitoring of ambient sound, Jomopans built upon the method proposed by the European Commission MSFD Technical Group on Underwater Noise (Dekeling et al. 2014) and the latest knowledge from relevant regional projects (e.g., the EU LIFE+ project Baltic Sea Information on the Acoustic Soundscape (BIAS), see Nikolopoulos et al. 2017). Jomopans developed a combination of numerical modeling and field measurements of ambient sound. A combination of models (creating sound maps) and measurements is regarded the best way to describe levels and their temporal and spatial variations.

The use of numerical models is cost-effective and can be operated in a controlled environment. Maps of the ambient noise levels for the North Sea region were calculated based on information associated with major human activity in the North Sea, namely shipping that contributes the most to continuous underwater noise. Modeling is a powerful tool for better insight in causes and distribution of underwater noise.

Numerical modeling always uses a schematization of reality and is dependent on various input parameters, which also have uncertainties.

Measurements for long-term monitoring of ambient sound in a large area like the North Sea is very challenging. In total 14 measurement stations were deployed around the North Sea (see Fig. 1). These stations were operated by the Jomopans

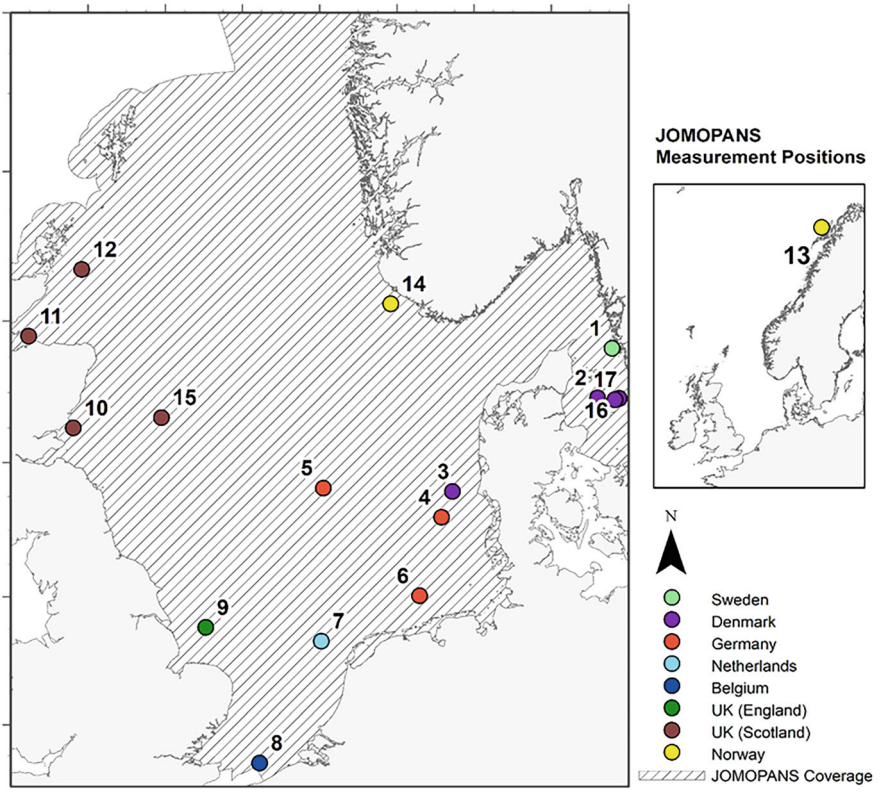

**Fig. 1** Positions of the 18 measurement stations indicated by pie charts depicting the share of ship classes on total traffic per station; contour map in the background exhibits over what percentage of the year 2019 the predicted anthropogenic noise dominates the natural soundscape by 20 dB or more (broadband 10–20 kHz), soundmap produced by TNO as part of the JOMOPANS project

partners and consisted of a range of different instruments. Special effort was made to perform a cross-calibration of the instruments and derive consistent working methods across the various parties.

Measurements are accurate and they provide a direct quantification of the local sound levels from all sources of interest at particular locations. On the other hand, measurements are influenced by sea conditions. In the North Sea, flow noise is a particular problem for measurements. Although measurements deliver a huge amount of data and information, it is not enough to make soundscape maps. Jomopans chose to use these measurements primarily for the validation of the (modeled) soundscape maps.

Assessment of underwater noise should be based on three aspects of the noise: (1) noise level, (2) temporal extent, and (3) spatial extent (TG Noise 2021). The choice of the noise level for assessment is based on the environmental effect that is considered. Jomopans specifically addressed the masking effect, which limits the communication range of various marine species. Therefore, the excess level

(difference between the total sound pressure level [SPL] and the SPL of background sound) was chosen as a metric. Various soundscape maps of both the background SPL (especially caused by wind) and the total SPL (caused by shipping) were modeled. The background SPL was calculated from a model for wind-induced sound (Ainslie 2010). Shipping noise was modeled using data from the AIS (automatic identification system) ship tracking system and the source-level model based on measurements from the ECHO Program (Enhancing Cetacean Habitat and Observation) of the Port of Vancouver (MacGillivray and De Jong 2021), in combination with an efficient sound propagation model (TNO Aquarius 3 is a range-dependent hybrid analytical mode sum + flux integral model). The modeling enabled the generation of a variety of maps. Maps for the months of the year, different ship types, and frequency bands were calculated.

The temporal aspects were addressed from all these soundscape maps by using the percentage of time over which the excess level was above 20 dB. The map giving this information is called the Dominance map. Increased knowledge on the effects of continuous noise on marine animals is needed to determine the level, which is now chosen as 20 dB. These studies were outside the scope of the Jomopans project.

## Results

The quantities that were mapped were (see also Merchant et al. 2018):

- Sound pressure level of background sound (dB re 1 μPa)
- Total sound pressure level (dB re 1 μPa)
- Excess level (dB)
- Dominance

Each of these maps is calculated for six different frequency bands:

- "Broadband," covering the 10 Hz–20 kHz decidecade octave bands
- "Decade 1," covering the 20 Hz–160 Hz decidecade octave bands
- "Decade 2," covering the 200 Hz–1.6 kHz decidecade octave bands
- "Decade 3," covering the 2 kHz–16 kHz decidecade octave bands
- 63 Hz decidecade octave band
- 125 Hz decidecade octave band

The maps covered averages over each month of 2019 and 2020 as well as yearly averages. In total, 12 ship types (fishing ships, cruise/ferry ships, bulkers, container ships, tankers, dredgers, tugs, naval ships, recreational ships, government/research ships, passenger ships, and vehicle carriers) were modeled in separate maps, based on the classification in the AIS data provided.

Here only the major soundscape maps are presented.

In Fig. 2, the median sound pressure level (125 Hz decidecade octave band) of the background sound in 2019 is shown. The background level is almost uniform for the

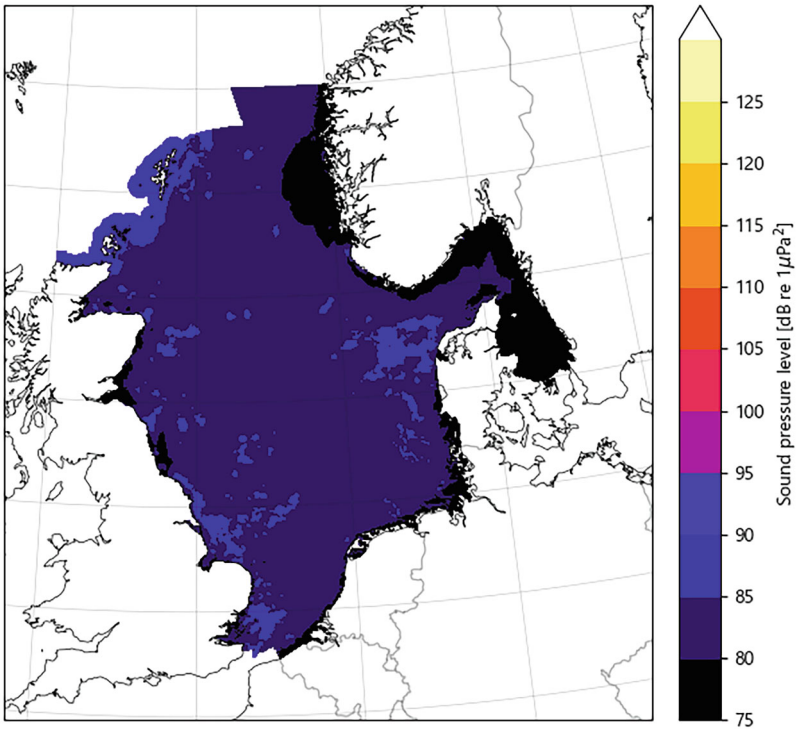

**Fig. 2** Median background sound level 125 Hz band (wind)

entire North Sea. This means that for the North Sea assessing the excess level will give similar results as assessing the SPL.

In Fig. 3, the median SPL (125 Hz decidecade octave band) of the total sound in 2019 is shown. The total SPL is dominated by the intense shipping in large parts of the North Sea. This shipping (and the SPL) shows only small seasonal variations.

Figure 4 shows the excess level (125 Hz decidecade octave band) in 2019. These levels show that for most parts of the North Sea the sound field is dominated by shipping noise. Minor seasonal variations of the excess level are caused by the variations in the background level.

Figure 5 is the Dominance (the percentage of time over which the excess level was above 20 dB) in 2019. This shows that the high excess level in some areas persists most of the time.

The independent validation of the models, using 15 Jomopans field stations, is illustrated in Fig. 6 (see also Putland et al. 2022). Monthly percentiles of the measured and modeled data were compared within decidecade frequency bands from 10–2000 Hz, in decade frequency bands, and as broadband sound levels. The general pattern of uncertainty showed that the model predicted sound levels, which were lower than the measurements at low frequencies (<1 kHz), while the model more closely agreed with the measurements at higher frequencies (>1 kHz). The

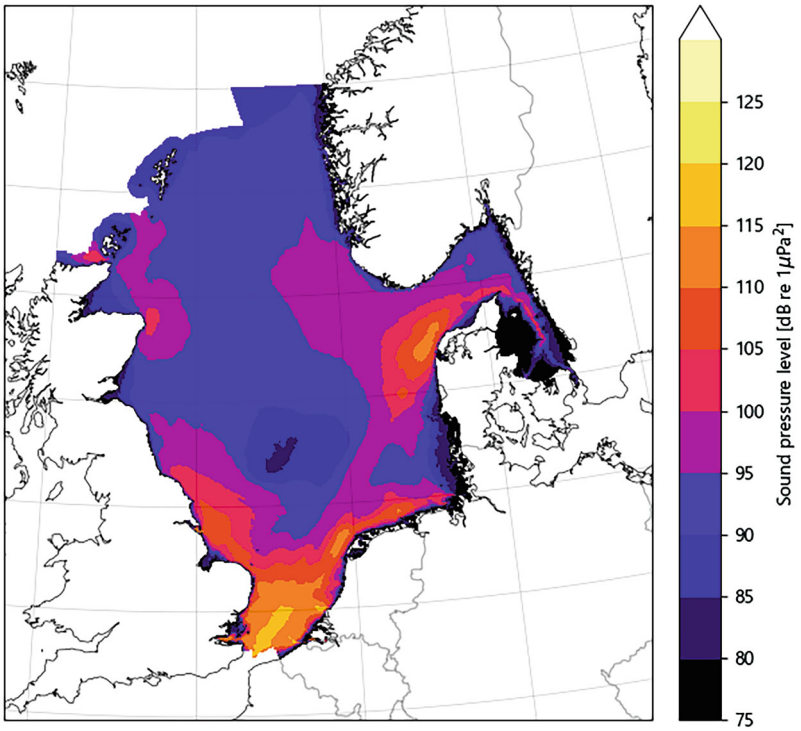

**Fig. 3** Median sound pressure level by shipping, 125 Hz band

model uncertainty is likely due to incomplete input data, because not all ships are captured by AIS and other sound sources other than ships may have contributed to the measured SPL at low frequencies (Fig. 6).

## Discussion

This chapter presents a framework for a joint monitoring program for ambient noise in the North Sea. This framework is a major building block for the assessment framework for continuous noise, which is adopted by the European Commission (Sigray et al. 2021).

Jomopans developed validated soundscape maps for the North Sea based on acoustic modeling of the sound produced by ships and wind. The modeled maps show that the soundscape in the North Sea is dominated by shipping noise. There are large differences across the North Sea. In the southern part toward the English Channel and along the shipping routes to Hamburg and the Baltic Sea, the noise exceeds the natural background noise by more than 20 dB for more than 50% of the time. The central part of the North Sea shows relatively low noise levels.

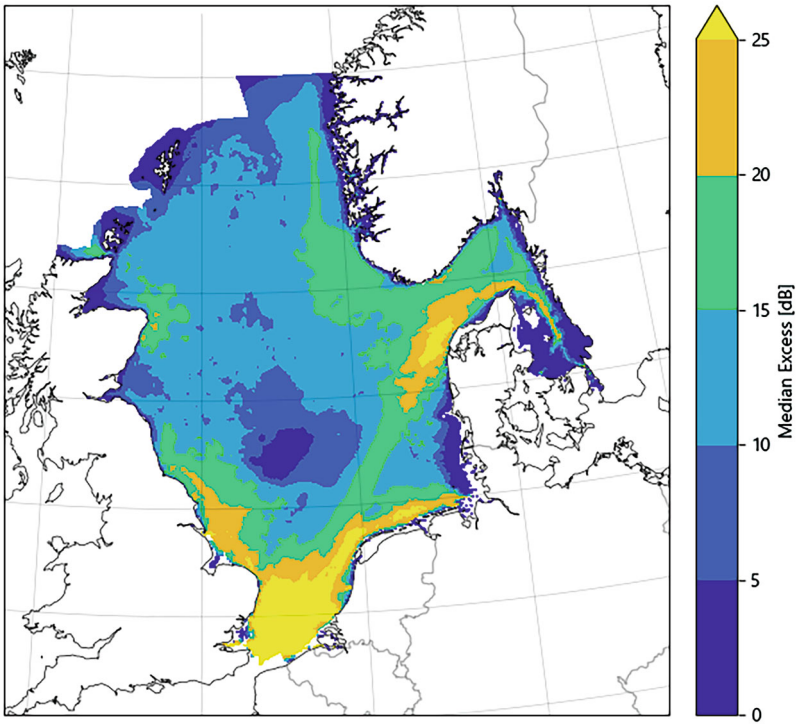

**Fig. 4** Median excess level, 125 Hz band

The Jomopans validation showed that both modeling and measurements have limitations and complement each other. The validation of the maps confirms that for large parts of the North Sea the soundscape is dominated by shipping. The modeling did not include other source types beyond shipping, which especially influenced the maps in low-noise areas. The measurements in the North Sea were in some cases hindered by flow noise. In addition, differences occurred from having different operators and instruments. A cross-calibration proved to give an insight into these differences.

Numerical modeling of soundscape maps provides marine managers with detailed information on the spatial distribution of the sound as well as the relative strength of various sources. Validation of the soundscape maps by field measurements is essential.

In future work, all major sources need to be accounted for. For many sources, a proper description of the source levels is still lacking. The measurements contain much information, which could not be evaluated within the limitations of the Jomopans project. Basan et al. (2023) give an insight of this additional information.

Improving of field measurements under North Sea conditions remains a challenge for the years to come.

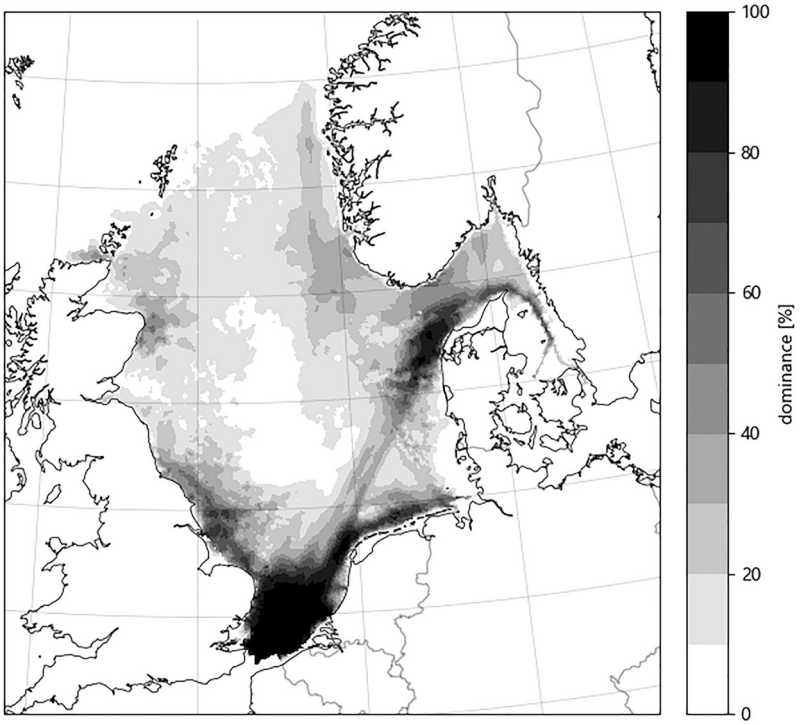

**Fig. 5** Dominance maps for a cutoff level of 20 dB of the excess level

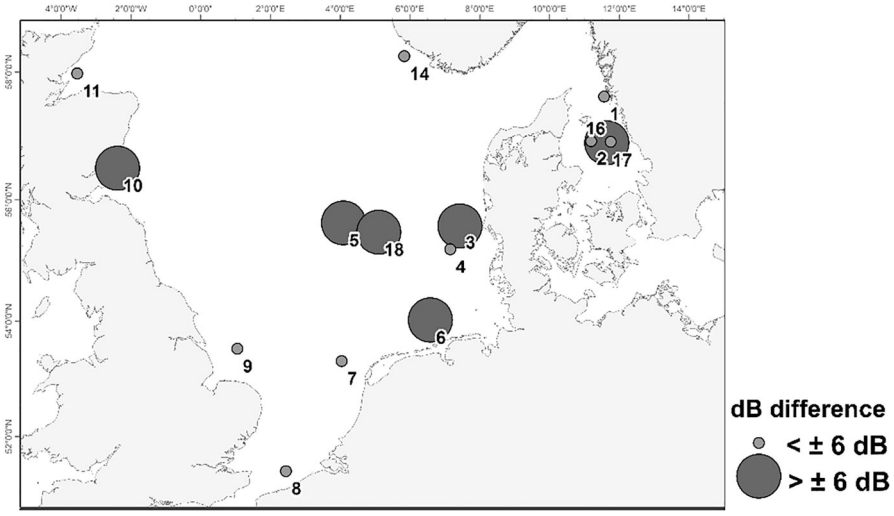

**Fig. 6** dB difference for broadband frequency (20–20,000 Hz) comparing P50 yearly measurement and model data. Possible reasons for uncertainty at individual stations: 3; proximity to an oil rig, 5; generator at platform, 6: offshore wind farm noise, 10; non-AIS fishing vessels, 17; sediment uncertainty in the Kattegat, 18; seismic survey present and proximity to oil rig

## Conclusions

Jomopans was a very successful project that quantified the continuous noise in the North Sea. These results contributed to the development of an assessment framework for continuous noise in the European Union. It was shown that transnational co-operation is the key to success.

**Acknowledgments** This project (Joint Monitoring Program for Ambient Noise in the North Sea, Jomopans) was partly funded by the North Sea Region of the European Regional Development Fund (InterReg) of the European Union. Also, thanks to all the partner institutes of the Jomopans consortium and their associated funding agencies that made this project possible.

**Abstract**

Active sonar training and testing is necessary to ensure well-trained, combat-ready maritime forces; however, in-water transmission of sonar has the potential to cause harm to marine mammals. Timely information on marine mammal presence in, or near, sonar training areas can be used to minimize the risk of harming these animals. Defence Research and Development Canada (DRDC) has investigated a variety of acoustic technologies to facilitate real-time marine mammal monitoring. A combination of fixed and autonomous systems was considered. Fixed automated monitoring capabilities included a moored surface buoy with a volumetric hydrophone and a network of acoustic volumetric and vertical line arrays. Mobile passive acoustic monitoring (PAM) systems included an underwater glider with a single hydrophone and an uncrewed surface vehicle with a towed line array. Each system is capable of onboard real-time detection and species-level classification, which generates an alert to be telemetered to a shore-based station. Alerts may be used to alter when or where active sonar training and

## Introduction

The Canadian Armed Forces (CAF) active sonar operations are critical to the defense of Canada; active sonar is often the only practical way to detect modern submerged targets. Realistic active sonar exercises must be conducted to ensure well-trained, combat-ready maritime forces and ensure operators are proficient with the required skills; however, active sonar can negatively impact marine mammals. Noise-related impacts range along a spectrum from echolocation masking and behavioral disturbance to permanent and temporary hearing damage to death or population-level consequences depending on the frequency of the signal, source level, duration of exposure, habituation, and contextual factors (Frantzis 1998; Southall et al. 2016).

During sonar operations, the CAF implements layered mitigations to reduce harm to marine mammals. The most effective measure to reduce the potential of harm is to confirm that there are no marine mammals in the area around the source where the sound levels remain above the threshold that is likely to cause hearing damage. Visual and passive acoustic monitoring for marine mammal presence during a period before the sonar exercise and throughout the sonar exercise is conducted to ensure there are no marine mammals in this area; however, these methods currently rely on operators onboard the ship or aircraft who must conduct the monitoring in addition to their primary duties. A further disadvantage of relying completely on exercise-based monitoring is that when a marine mammal is sighted, a decision must be made either to wait until the animal leaves the exercise area or to reposition the exercise to a new location and re-start the monitoring period. This reduces the time available to conduct the event and detracts from the primary objective by introducing procedures which are not intended to be used in real-world operations.

The focus of Defence Research and Development Canada's (DRDC) marine mammal mitigation project is to refocus these risk mitigation measures from operator-centric to planning-centric. In part, this is being accomplished by employing acoustic monitoring technologies in typical sonar training areas to gain better insight and understanding to how marine mammals use these areas, such that sonar exercises are planned in the right places at the right times (i.e., when/where marine mammals are less likely to be impacted). With improved information on typical marine mammal habitat usage, exercise planners and sonar operators can make decisions on exercise location and timing based on best available information.

Furthermore, timely information on marine mammal presence in sonar training areas during exercises can be used to minimize the risk of harming these animals while maximizing training opportunities, requiring real-time in situ automated detection and classification of marine mammal calls with detection alerts passed to decision-makers.

DRDC investigated four specific passive acoustic monitoring (PAM) technologies to facilitate real-time marine mammal monitoring, which included a combination of fixed and mobile systems. The ability to efficiently deliver detection results to decision-makers was a critical capability that was assessed. Advantages and disadvantages of each type of PAM system were weighed to provide recommendations on the effectiveness of each system and to assess the type of system that is best suited for a particular monitoring requirement. Additional capabilities, such as archival/long-duration recording (to obtain information on spatiotemporal habitat usage) and directional recording (to assist in localization), were also considered in the system evaluation.

## Monitoring Technologies Assessed

### Fixed Systems

Fixed monitoring systems have several advantages, including that they are:

- Relatively quiet, with mooring designs refined over decades to reduce mooring and flow noise around the sensors.
- Often easily deployed and recovered from ocean-bottom moorings.
- Cost-effective and persistent, because they can be left in place independent of a human operator in extreme or remote locations for relatively long periods of time (Sousa-Lima et al. 2013), on the order of weeks to months.

The main disadvantage of fixed systems is that they can only provide monitoring coverage within a relatively small distance surrounding the system, typically referred to as the detection range. The detection range is often seasonally variable and dependent on such factors as the sound speed profile and the local ambient noise field.

#### SmartBuoy

As part of an increasing effort for DND to establish a baseline for marine mammal presence in active sonar training and testing areas (Thomson and Binder 2021), DRDC is in the process of evaluating a JASCO-developed acoustic system for longer-term real-time and archival marine mammal monitoring. The SmartBuoy is a moored buoy with a large surface expression (see Fig. 1) and four-element volumetric array at 60 m depth. A 15 m length of electromechanical stretch hose from EOM Offshore LLC (EOM Offshore LLC 2023) isolates the subsurface array from movement of the surface buoy to reduce mooring noise in the recordings.

**Fig. 1** Example of a fixed real-time monitoring system. DRDC's SmartBuoy is anchored to the seafloor with a large buoy surface expression that allows detection alerts to be transmitted to a shore station in near real time

Onboard detectors/classifiers for nine whale species provide a real-time detection capability. A satellite communications (SATCOM) package transmits detection alerts and species classification estimates from the JASCO OceanObserver acoustics package. The large surface expression allows for the installation of solar panels which can provide continuous and stable power to achieve up to 1 year endurance with no duty-cycling of the acoustic recordings (sample rate of 30 kHz).

Deployment locations for evaluating these systems were carefully selected with locations prioritized for sites where active sonar testing is likely to occur and marine mammal monitoring has rarely been conducted. These systems will be used to generate real-time alerts to provide situational awareness of marine mammal presence before/during a sonar activity; additionally, these systems provide a baseline of marine mammal habitat usage in the absence of sonar to compare to periods of sonar activity to assess if there is any resulting modification in habitat usage. The first SmartBuoy was deployed in a Royal Canadian Navy (RCN) active sonar training area in the Pacific Ocean in September 2021. A second SmartBuoy was deployed in

an offshore RCN active sonar training area in the Atlantic Ocean in December 2022; unfortunately, the Atlantic SmartBuoy was lost at sea approximately a week after deployment due to the passage of a large storm system with offshore winds. Both deployment locations are in approximately 1500 m water depth.

Archival data was recovered from the first deployment in October 2022; acoustic data quality assurance and preliminary analysis is ongoing. Initial results show concurrent recordings of whale vocalizations and active sonar signals; these recordings combined with baseline ambient noise and marine mammal recordings will be used to assess the impacts of active sonar training activities in the RCN's Pacific active sonar training area. Multi-year data sets collected at fixed locations will allow continuous monitoring of potential impacts of active sonar on marine mammals that reside or transit through these areas. Additionally, these multi-year data sets will be used to develop and refine marine mammal habitat models for these sonar training areas. These habitat models will be used when planning sonar training events to select locations and times of year when marine mammals are least likely to be present in the area, thus reducing the risk of harm.

### Distributed Underwater Sensor Network (DUSN)

The Distributed Underwater Sensor Network (DUSN) is a DRDC-developed system, designed primarily for underwater acoustic surveillance, and thus is optimized for underwater vehicle detection. This network of sensors is made up of individual DUSN nodes that each contain a seven-element planar array and optional nine-element vertical line array (VLA) sampled at 30 kHz; an example node without the VLA is shown in Fig. 2, with the hydrophones of the planar array visible in their white protective casing on the top of the DUSN node. Each DUSN node can run real-time automated detectors onboard the node and perform bearing estimates for each detection. Multiple DUSN nodes can be used for cooperative localization and tracking by sharing detection and bearing estimate information via underwater acoustic modems. Detection and localization results can be transmitted back to a shore station via a cabled connection or surface gateway buoy.

An example of bearing estimate results for data recorded by the DUSN directional array is shown in Fig. 3. This data was recorded during a trial that took place in Bedford Basin, NS, in October 2021. Bedford Basin is a busy harbor with high levels of pleasure craft and commercial shipping activity. During this trial, North Atlantic right whale upcall recordings were retransmitted from a fixed location to assess the utility of the DUSNs for marine mammal monitoring. There are two distinct signal sources present in Fig. 3, the transmitted North Atlantic right whale upcalls from the north-easterly direction (blue) and the continuous tonals generated by a ship from the south-easterly direction (pink).

The example bearing results in Fig. 3 demonstrate how directional data may assist detection of marine mammal calls in noisy data. A display like this one may be used for real-time PAM to help visually separate signals arriving from different directions, making it easier to identify low signal-to-noise ratio (SNR) whale calls. Additionally, detection may be done on beam data; that is, one can step through bearing angles and run a detector on sound arriving solely from a limited range of bearings, thereby

**Fig. 2** Example of a fixed real-time monitoring system under development by DRDC. The image shows one DUSN node with a volumetric hydrophone array (hydrophones in white protective casing on the top part of the DUSN)

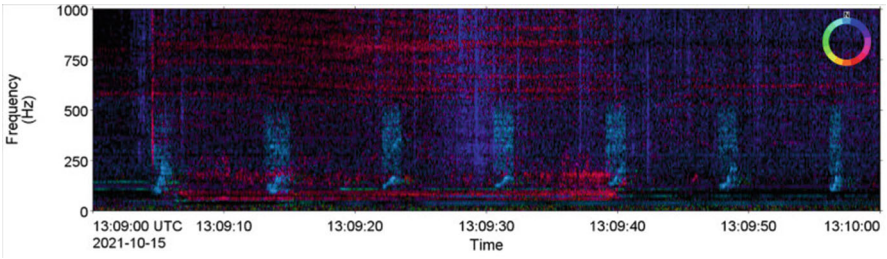

**Fig. 3** Example bearing estimate results from a trial in a busy harbor, with color representing the estimated direction from which the signal was received. The color wheel in the top right corner indicates what each color represents, with blue colors representing sounds coming from the north

rejecting noise or other signals arriving from different bearings. Using the beam data to make detections is a very useful method for improving the detection of low SNR signals, as it reduces directional noise originating from other bearings.

Though originally designed for underwater acoustic surveillance, DUSN is a capable multipurpose system that has proven to be effective for real-time marine mammal monitoring for deployments lasting up to a month. DUSNs have been tested for Southern Resident killer whale and North Atlantic right whale monitoring. Initial results show that the array design is best suited to providing bearing estimates for baleen whales; however, odontocete whistles and the low-frequency portion of some odontocete clicks can be detected within the current capabilities of this system.

Given the DUSN's strengths (real-time detection and localization) and deployment duration limitations (see Table 1), the DUSN system is well-suited for real-time monitoring during noise-generating activities, particularly in constrained waterways. For example, DUSN could be used during active sonar experiments in a bay or narrow straits. In this scenario, a "trip wire" of DUSN nodes may be set up a few kilometers away from the experimental site. If any whales are detected crossing the "trip wire" and moving toward the experimental site, the sonar experimentation would be paused until the whales leave the area where acoustic exposure is likely to cause hearing damage.

## Mobile Systems

Autonomous mobile system technology has advanced rapidly over the past two decades. Mobile systems are now capable of collecting high-quality acoustic data at relatively low cost and use onboard detection and classification algorithms to provide important data on marine mammal presence in real time (Baumgartner and Mussoline 2011; Kowarski et al. 2020). The main advantages of this type of system are a result of their mobility; they are:

- Often very easy to deploy from near-shore locations and can be programmed to transit to an offshore location to conduct their monitoring task.
- Capable of following a pre-programmed track after arriving on station. This track can be updated via satellite communications.
- Able to cover a fairly large area over the course of several days, making these systems effective tools to provide wide-area monitoring coverage.

**Table 1** Comparison of technologies. The * denotes that a capability is not currently implemented, but could be in future versions. The † highlights that ongoing work is actively being conducted to increase deployment duration

| Technology | Fixed vs. mobile | Rapidly deployable | Deployment duration | Sample rate | Directional recording | PAMLab detectors |
|---|---|---|---|---|---|---|
| **SmartBuoy** | Fixed | No | 1 year | 32 kHz | Yes | Yes |
| **DUSN** | Fixed | Yes | 1 month† | 30 kHz | Yes | No* |
| **Glider** | Mobile | Yes | 2 weeks† | 16/512 kHz | No* | Yes |
| **USV** | Mobile | Yes | 4–16 days† | 32/512 kHz | Yes | Yes |

- Capable of transmitting their position, detection/classification, and other relevant summary statistics via SATCOM because they spend at least some portion of their time at the surface.

The primary disadvantage of mobile systems is their relatively short deployment duration relative to fixed systems. The motion of the platform also results in ambient noise in the acoustic recordings which may mask low SNR whale calls. Human operators also need to monitor the mobile systems to ensure that they are staying on track and to update the track if necessary. Local currents can affect mobile system navigation and must be taken into account when planning a mission, as strong currents have the ability to "blow" mobile platforms off track.

### Glider

A Teledyne Webb Research Slocum G1 glider with integrated acoustics package (see Fig. 4) was tested during the international antisubmarine (ASW) exercise CUTLASS FURY 21 (CF21). CF21 took place in the offshore waters south of Nova Scotia in September 2021, as shown in Fig. 5. The intent of the demonstration was to monitor for the presence of marine mammals in the week preceding CF21, during CF21, and for a few days after the exercise had concluded. Acoustic recordings and real-time detection/classifications were conducted with the JASCO OceanObserver (Kowarski et al. 2020) using a Geospectrum M36 hydrophone mounted on the top of the glider in protective housing. Acoustic data were sampled simultaneously at 16 and 512 kHz sampling rate from the same hydrophone.

Initial glider detection/classification is done onboard the glider using the contour detector described in Kowarski et al. (2020). Candidate detections were transmitted via satellite communications and were verified by analysts during CF21. An example candidate detection snapshot is provided in Fig. 6, showing confirmed delphinid whistles (unidentified species) and possible fin whale calls. Candidate detections are transformed from a typical spectrogram to these contours (Kowarski et al. 2020) to save transmission bandwidth, relative to sending a full spectrogram. They contain

**Fig. 4** Example of a mobile uncrewed underwater vehicle (UUV) real-time monitoring system. This Teledyne Webb Research Slocum G1 glider has a hydrophone payload (in black protective casing on the top of the glider) and integrated JASCO OceanObserver acoustics package for real-time recording, signal detection, and marine mammal species-level classification

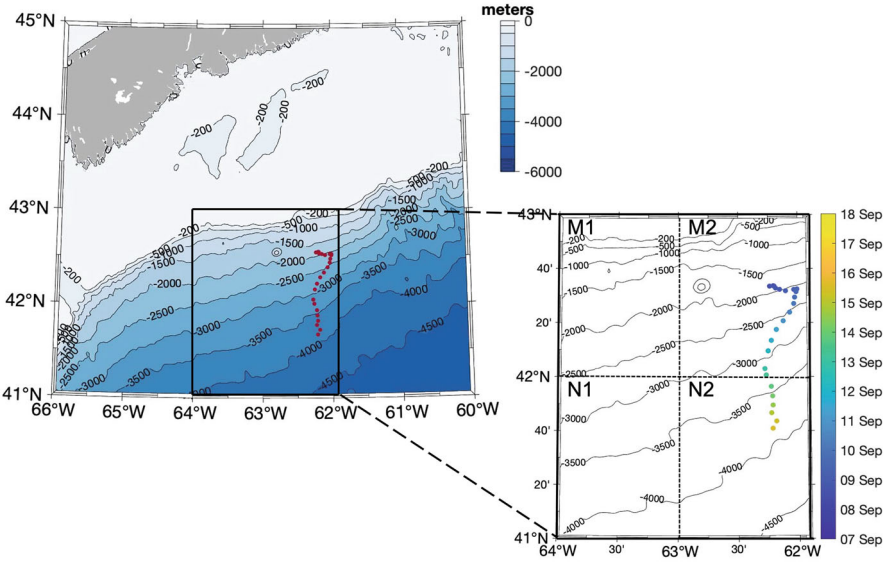

**Fig. 5** The surfacing locations of a glider used for real-time monitoring of marine mammal presence during an ASW training exercise (CUTLASS FURY 21). The zoomed-in map (bottom panel) is divided into squares representing the designated RCN operating areas

sufficient information for a trained analyst to discriminate true detections from false detections and confirm marine mammal species, to varying levels of certainty. Daily detection summary reports of the analyst-confirmed detections were passed to participating ships' commanding officers to provide situational awareness on the presence of marine mammals close to the exercise area.

Post-trial manual analysis of the glider's acoustic data verified recordings of dolphins, pilot whales, fin whales, Cuvier's beaked whales, sperm whales, kogia or porpoise species (high-frequency clicks), and beaked whales (either True's or Gervais'). Annotations made during the post-trial analysis will be used to refine the automated real-time detectors for future deployments.

## Uncrewed Surface Vehicle (USV)

DRDC assessed an Open Ocean Robotics (OOR) uncrewed surface vehicle (USV) with towed array and onboard acoustic processing (JASCO OceanObserver) during a demonstration conducted at the Canadian Forces Maritime Experimental and Test Ranges (CFMETR) in Nanoose Bay, BC, during March 2021. The Data Xplorer USV (Fig. 7) is 3.35 m long, is remotely controlled, and contains batteries and photovoltaics to provide propulsion. It was designed for offshore use, with a self-righting capability that allows it to function in high sea states; on the other hand, its high degree of controllability and shallow draft allow it to effectively operate in shallow and congested coastal waters. The USV is equipped with a configurable payload of oceanographic, environmental, and communications sensors. Standard sensors include a 360° camera, automatic identification system (AIS) receiver, weather station, and

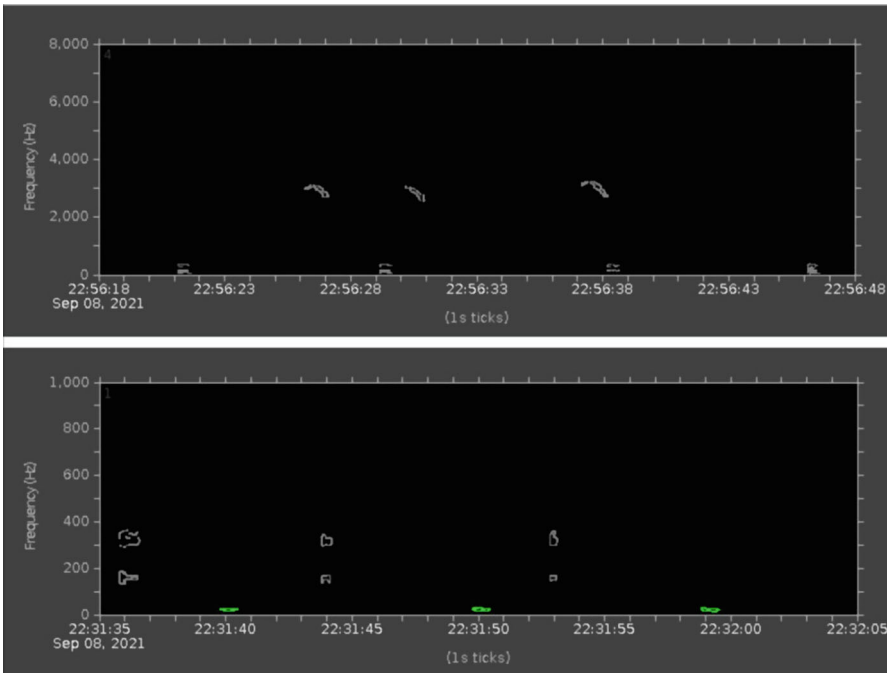

**Fig. 6** Candidate OceanObserver detections, represented as contours around automatically identified features in a spectrogram. Top panel shows confirmed delphinid whistles (unidentified species), and the bottom panel shows possible fin whale calls (highlighted in green)

**Fig. 7** Example of a mobile uncrewed surface vehicle (USV) real-time monitoring system. This USV is capable of towing a thin line array of digital hydrophones and has an integrated JASCO OceanObserver for real-time recording, bearing estimation, signal detection, and marine mammal species-level classification

triducer (for measuring depth, water temperature, and speed over water). Optionally, the USV can tow an acoustic line array. Currently, there are two options for eight-element arrays that were designed for use with the Data Xplorer. Each array has non-linear element spacing to increase the useable frequency range for broadband

beamforming. One array was designed for Southern Resident killer whale monitoring (1.875 m aperture), and the other was designed for North Atlantic right whale monitoring (15 m aperture), with bearing accuracies less than 5° for high SNR (i.e., SNR > 5 dB) signals arriving from angles within ±60° from broadside; bearing accuracy degrades for angles close to the endfire and for low SNR signals.

During the CFMETR evaluation, the USV was supported by a two-person vehicle deployment and recovery team located in situ and a remote team of acoustic analysts in Halifax, NS, while the vehicle was remotely piloted from an operations center in Victoria, BC. The USV towed an eight-element towed digital acoustic array (1.875 m aperture, with 40 m tow cable) designed for Southern Resident killer whale monitoring with detection, classification, and bearing estimate processing done onboard the USV using JASCO's OceanObserver PAM system. The OceanObserver acoustics package was fully integrated with the USV's power and communications modules. Detection/classification, bearing estimates, and ambient noise summaries can be transmitted via a low-bandwidth telemetry system, with the potential to transmit more elaborate data products if higher-bandwidth telemetry options (e.g., cellular network) are available. Similar to the process described for the glider, candidate detections are transmitted as contour plots (example in Fig. 6) that are verified by expert analysts at JASCO before being passed to decision-makers.

Testing of the USV system was done by transmitting simulated killer whale calls from a projector suspended from a drifting support vessel. During the evaluation, the USV maintained a speed of 1.25 kt (2.3 km/h), with hydrophone array at 18–20 m tow depth. Detections were automatically reported and could be viewed in (near) real time. Following the 2-day experiment, a live demonstration was conducted with the USV patrolling the waters in Nanoose Bay for marine mammals. During the live demonstration period, humpback whale call detections were reported and validated in real time.

Solar- and battery-powered USVs have limited endurance and speed, especially when towing acoustic arrays at times of the year when days are short and solar power is less effective. In addition, it is desirable to lower the vehicle speed to reduce the system self-noise (from the vehicle, towline, and array) and to make the system as power efficient as possible. At-sea trials showed that 1.5 knots (2.8 km/h) is the optimal USV speed when towing the acoustic array to achieve low flow/self-noise and maintain the array at an appropriate depth for monitoring. Given the data collected during the sea trials, estimates of deployment duration for the current USV range from 4 to 16 days in mid-latitudes, depending on seasonal solar irradiance, local sea state, wind, and currents. Efforts are ongoing to increase the deployment duration of the USV while towing an acoustic array.

## Comparison of Monitoring Technologies

Table 1 presents a comparison of the capabilities of each technology assessed. Each system with JASCO's PAMLab detectors is capable of onboard real-time detection and species-level classification (Kowarski et al. 2020), which generate alerts telemetered to ship- or shore-based command centers. The intent of these alerts is to provide

situational awareness on marine mammal presence and may be used to alter when or where active sonar training and testing occurs. DUSNs have embedded real-time detectors that have not yet been tested with marine mammal calls; however, PAMLab has been successfully used in post-trial processing of DUSN recordings for automated detection.

In general, fixed systems are best suited to longer-term monitoring scenarios at a single location. The SmartBuoy is a large system that is not rapidly deployable; however, this disadvantage is offset by its long deployment duration, providing baseline information on how marine mammals use an area over all seasons, and can be used to assess behavioral impacts of active sonar training. The DUSN systems on the other hand are small, rapidly deployable systems. They do not provide the same baseline data as the SmartBuoy; however, they could be effectively employed to provide a marine mammal monitoring "trip wire" in a bay or other area constrained by the local land mass.

The mobility of the glider and USV systems provides an advantage for larger area monitoring, though their deployment durations are shorter than for fixed systems. These remotely piloted systems are easy to deploy and control from ship- or shore-based stations and provide real-time detection/classification alerts and bearing estimates (in the case of the USV with towed array). Multiple mobile systems can be used to cover a larger area. These types of systems are best suited to conducting real-time monitoring before and during a sonar exercise to provide situational awareness on marine mammal presence to sonar operators and exercise decision-makers.

In practice, no single system is capable of meeting all the marine mammal monitoring needs of the CAF. These systems should be used in combination; for example, the SmartBuoy may be deployed in a typical sonar operating area to collect data on typical marine mammal presence. Sonar exercise planners could use this information to decide on the best time of year to conduct a sonar exercise (i.e., when marine mammals are least likely to be present). Two weeks prior to conducting the sonar exercise, a glider, USV, or combination of gliders and USVs could be deployed to the planned exercise area to monitor for marine mammals, sending back real-time detection alerts. If a high density of animals (or a sensitive and/or at-risk species) is noted in the area, a decision can be rendered to move the exercise to an alternate area. Continued monitoring with the mobile systems would take place throughout the exercise to alert exercise participants when marine mammals approach the exercise area.

## Conclusions

A review of monitoring technologies assessed by DRDC was presented. DRDC's SmartBuoy is good for area monitoring on a long timescale; it can provide baseline data on habitat usage and real-time detection capability for exercises in a localized area. In general, the DUSN network was found to be good for area monitoring on a relatively short timescale. The DUSN systems are the only technology assessed that does not have JASCO's PAMLab detectors integrated; instead, the nodes currently

only have band-limited energy detectors. Further, DUSNs are best suited to lower-frequency band detection (mysticetes) and are not capable of detecting many odontocete clicks. In contrast, the glider and USV are both good for area clearance before and during exercises. The USV has the potential for longer endurance and greater control in strong currents, but the glider is better suited to detecting highly directional beaked whale clicks since the glider has deep-diving capability.

DRDC continues to work with partners to improve acoustic monitoring technologies. Future improvements include removing the requirement for human validation of all automated detections from the JASCO OceanObserver, increasing the endurance of both the glider and USV, integrating PAMLab detectors with DUSN, and performing detections on beamformed data to improve SNR.

**Abstract**

Monitoring trends of marine mammal populations are notoriously challenging, as density and abundance estimates are frequently characterized by high levels of uncertainty. Statistical power is described as correctly detecting a trend when one is present and is influenced by the uncertainty surrounding the input parameters. The "AVADECAF" tool evaluates the power of a fixed Passive Acoustic Monitoring (PAM) array to detect changes in animal density, via simulation. The simulations can be based on existing surveys or can be used to design monitoring programs. The tool allows for density estimation via distance sampling where ranging of acoustic detections is possible, or Spatial Capture Recapture (SCR), when an animal's sounds can be detected on more than one of the acoustic sensors. The tool provides an opportunity to evaluate how the power to detect population declines might be improved by comparing alternate survey designs. Improving statistical power increases the probability of detecting a change in the population and can reduce the required duration of a monitoring program. The AVADECAF tool was applied to simulated Blainville's beaked whale clicks detected by hydrophones at the US Navy's Atlantic Undersea Test and Evaluation Center (AUTEC), and the potential future applications of this tool are discussed.

**Keywords**

Animal population density estimation · Passive acoustic monitoring · Power analysis · Distance sampling · Spatial capture recapture

## Introduction

Monitoring marine mammal populations is well established to be challenging. Animals can occupy remote regions, exist at low densities over large areas, spend much of their time subsurface, and even at the surface can be difficult to observe. They are often monitored using visual surveys; however, this is a costly process, and such surveys are weather dependent (i.e., requiring periods of good visibility and calm conditions) and restricted to daylight conditions. Due to these challenges, standard visual surveys often result in considerable uncertainty in abundance estimates (Taylor et al. 2007).

Many marine mammals produce sounds underwater as part of navigation, foraging, and communication with conspecifics, making Passive Acoustic Monitoring (PAM) a viable method for monitoring them. Monitoring equipment can be deployed at or near the seabed, making data collection less susceptible to weather conditions, and can be deployed for extended periods prior to retrieval. Therefore, this approach is widely used around the world for long-term monitoring of marine mammals.

The analysis of PAM data has been used for estimating the spatial distribution of cetacean species, species identification, research into behavior and communication, and mitigation of anthropogenic activity (Pirotta et al. 2014; Wisniewska et al. 2016; Curtis et al. 2020; Sarnocińska et al. 2020). In addition, there are now a range of methods by which cetacean density may be estimated using fixed passive acoustic devices including plot sampling, distance sampling (DS), and Spatial Capture Recapture (SCR) (Marques et al. 2009, 2012; Moretti et al. 2010; Barlow et al. 2021; Oedekoven et al. 2022).

Statistical power is the probability of correctly rejecting the null hypothesis, but could also be described as correctly detecting a trend when one is present (Thomas and Juanes 1996). While somewhat arbitrary, a value of 0.8 is considered to be an indication of a statistical test with reasonable power to detect a trend (Authier et al. 2020). In terms of population monitoring, statistical power can be described as the probability of correctly detecting a true change in animal abundance or density. Statistical power is affected by a combination of sample size, effect size and parameter variability, or sampling variance (Thomas and Juanes 1996). Effect size relates to biological significance, and in the context of population monitoring is the quantitative population trend over time, that is, a 50% decline in density over 10 years of monitoring. Considering the potential effect and sample size prior to data collection can help define the survey design and methods required to accurately assess trend and estimate the minimum detectable effect. Conducting a power analysis prior to committing to a monitoring program can help ensure that the survey design is sufficiently robust to detect a specific change in the population. Therefore, to successfully monitor long-term population trends (i.e., to determine if populations are stable, increasing, or decreasing), consideration needs to be given to both statistical power and biological significance, that is, the minimum effect size that is considered to be biologically important. This is crucial for the effective management and conservation of marine species.

Given the challenges of long-term monitoring of cetacean populations, it is unsurprising that between 1995 and 2018, only 20% of the marine mammal stock assessments published from NOAA (National Oceanic and Atmospheric Administration) fisheries were associated with population trend analyses, and even well-studied stocks required annual estimates over at least 10 years to obtain sufficient power to detect current trends (White et al. 2022). Similarly, Taylor et al. (2007) assessed power to detect trends in a range of marine mammal species and reached comparable conclusions. For example, they predicted that from the reviewed stocks, 72% of precipitous declines in large whales would not be detected given current monitoring efforts. Likewise, Moretti (2019) determined that it would require approximately 25–30 years of photo-ID data collection to detect an annual decline of 5% for Blainville's beaked whales (*Mesoplodon densirostris*) on the US Navy range "Atlantic Undersea Test and Evaluation Center" (AUTEC). The photo-ID monitoring program for Cuvier's beaked whale (*Ziphius cavirostris*) on the Southern California Acoustic Range (SOAR) is considered to be a high-intensity survey effort, however these efforts would not allow for detection of a 50% decline over the 11 years of survey effort (Curtis et al. 2020).

As the statistical power to detect a decline in marine mammals is often low, it is logical to consider how it might be increased. The original purpose of the AVADECAF project was to evaluate the utility of fixed PAM arrays for estimating cetacean density over the lifespan of "typical" oil and gas fields. Booth et al. (2017) explored the importance of detection and classification methods, hydrophone array design, and evaluated the sensitivity of the statistical power to the input parameters required to estimate annual density from PAM data. The tool was built with the capacity to estimate power given surveys from two different survey methods, distance sampling and SCR. In this overview, the methods behind the AVADECAF tool are discussed and exemplified through a simulation of distance sampling using PAM of Blainville's beaked whales at AUTEC in the Bahamas (see Booth et al. 2017 for more details of SCR approaches, sensitivity analysis for DS simulations, and the associated available R code and helpfiles). Earlier literature provides thorough explanations of distance sampling and SCR (Buckland et al. 2001, 2015; Marques et al. 2013). This chapter represents a broad overview of these methods, provides initial insight into density estimation from fixed PAM, and discusses the potential of the AVADECAF tool for guiding effective management and conservation activities.

## Methods

### Overview

The AVADECAF tool allows users to estimate statistical power to detect a trend in density using PAM – either using DS or SCR. DS with PAM data uses acoustic detections of animal cues, combined with a distance-based detection function derived from distances between the hydrophone and the cue producing animal to estimate animal density within a study area. In contrast, SCR does not rely on distance information, but requires that a proportion of the cues produced by the animals are detected by more than one hydrophone and that cues can be matched across hydrophones (Oedekoven et al. 2022). For SCR, having auxiliary information for each detected sound, namely received sound level, bearing angles or time of arrival can greatly increase performance (Borchers et al. 2015).

In either case, the tool simulates passive acoustic arrays in a hypothetical study area and detections made by the individual hydrophones. Within the tool, the DS package simulates a passive acoustic array that is suitable for applying distance sampling methods, that is, allows for localization of the detections and hence obtaining distances between the sensors and the localized detections (to generate detection functions). Within the AVADECAF tool, for DS methods it is assumed that the passive acoustic devices represent clusters of hydrophones that are capable of localization (described as p-nodes). The utility of these respective methods relates to the characteristics of the vocalizations of the species of interest.

When designing any survey (using either DS or SCR) the spacing between the PAM sensors needs to be large enough that, with a given budget, sensors can be distributed throughout the study area. For SCR, however, the spacing also needs to

be small enough that a proportion of calls can be detected by two or more detectors (e.g., Oedekoven et al. 2022). Furthermore, SCR requires that individual detections can be matched between detectors. Hence, knowledge about the approximate detection range and characteristics of the calls is necessary. DS methods require that at least for a representative proportion of the detections, distances to the detections can be obtained using the acoustic recorders from which a detection function can be estimated reliably.

Despite being a relatively recent addition to the statistical toolbox, SCR is also considered to be a "standard" abundance and density estimation approach given its genesis from mark-recapture and distance sampling methods (Borchers 2012; Borchers et al. 2015). SCR has also become a frequently used tool for estimating vocalization density or abundance (Stevenson et al. 2015). In contrast to distance sampling, SCR does not require distances to the detections for estimating the detection function or call density. It does require, however, that call detections are matched between different detectors. This "recapturing" of detected calls enables the detection probability of the sounds around the sensors to be estimated. In contrast to standard mark-recapture methods, for which abundance is strictly undefined, SCR allows the estimation of both density and abundance for a given area. Further, because the heterogeneity in detection probability is modelled as a function of the location, SCR methods deal directly with the unmodelled heterogeneity that poses a challenge to conventional CR (e.g., Link 2004). SCR has been successfully applied to both visual (Pirotta et al. 2015) and passive acoustic data (Marques et al. 2012) to estimate the abundance and density of marine mammals.

To determine the appropriate method for density estimation from PAM, it is important to identify the target species for the survey, whereby auxiliary information is required regarding the species of interest. The call frequencies, cue production rates, species behavior, and vocal detection ranges are all relevant considerations when selecting an appropriate method for density estimation using passive acoustic monitoring. This information will influence the array design, hydrophone elements, and sampling frequency. A sensitivity analysis using the original AVADECAF tool has been carried out (Booth et al. 2017) to determine the importance of each of these key input variables, including both the survey design and species-specific parameters.

This paper focuses on Distance Sampling and includes a brief overview of parameter sensitivity, however the original report (Booth et al. 2017) contains a comprehensive discussion of SCR methods and further results and outputs.

## Implementation of Models in the AVADECAF Tool

The simulation workflow within the AVADECAF tool includes the creation of a study region, the generation of a survey design (the number of localizing hydrophones and non-localizing hydrophones), and the simulation of the species of interest derived from population-specific parameters (Fig. 1). The species information is incorporated to generate one animal density surface throughout the study area and a buffer surrounding it per simulation. The parameters defining the survey

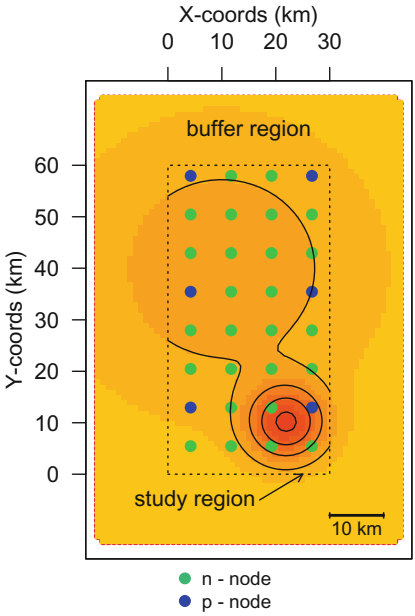

**Fig. 1** A visual representation of how the AVADECAF tool simulates the survey region, hydrophone array, and animal density. The black outline denotes the study area, the red/yellow surface represents a non-uniform animal density surface, green circles indicate a single hydrophone, and blue circles represent a cluster of localizing hydrophones

design are used to generate an array of point transects distributed throughout the study area using a systematic design with a random starting point. Combining the density surface and the parameters describing the vocalization production rate of the animals, vocalizations are generated throughout the study area.

In DS, these vocalizations are then detected by each of the sensors according to a user-defined detection function. This can be either a hazard-rate or half normal detection function, with its parameters describing the decay in detection probability with increasing distance from the detector, and a probability of detection at distance zero. In the distance sampling package, distances from the sensors to the detections are provided; the proportion of these detections depends on the number of localizing sensors that are deployed, and the number of detections that are available (see Booth et al. 2017 for presentation of SCR methods).

The subsequent step requires estimation of animal density using the "observed" data, which is described in more detail below. These steps are undertaken for each survey year and season specified by the user, resulting in a time series of animal densities and associated density estimates. Lastly, a generalized linear model is fit to the estimated animal densities, to determine the power to detect a change. The AVADECAF simulation produces estimates of the power to detect a specified decline at a user-defined prespecified level (of significance, e.g., alpha = 0.1, 0.05 or 0.01). A simulation includes 1000 iterations (or otherwise specified), and the percentage of iterations with p-values below the chosen level of significance estimates the power to detect the specified trend (e.g., a 1% annual decline over 50 years of monitoring).

## Density Estimation Equation (Distance Sampling)

An overall equation for estimating animal density from PAM using distance sampling is as follows

$$D_{animals} = \frac{n_c(1-f)}{k\pi w^2 pTca_{perc}}$$

where a total number of cues are observed ($n_c$) and detected on $k$ hydrophones over a recording time $T$. A proportion ($f$) of the detected cues may be false positives, meaning that the proportion of correctly detected cues is given by 1-$f$. As it is difficult to identify individual animals using acoustic cues, the above estimator includes a "cue production rate" $c$, representing the average number of cues produced per animal per unit time. Estimating animal density requires information on the effective survey area by the $k$ sensors, where $\pi w^2$ represents the area monitored surrounding each sensor. This value is then multiplied by $p$, the average probability of detecting a cue within this region. The directionality of animal cues, combined with the depth and orientation of an individual, can influence the probability of detection by an acoustic sensor, as such a bias parameter ($a_{perc}$) is included to account for the proportion of missed detections. Usually in visual surveys, $g(0) \neq 1$ (i.e., incomplete detection at distance 0 from the sensor, survey platform or trackline) is caused by availability bias. However, in the case of PAM, there are instances where the animal is vocalizing, that is, is technically available to be detected but for the reasons described, the animal is not detected at the sensor. Here, this might be considered a perception bias issue, causing g(0) issues. As such the $a_{perc}$ parameter in this tool represents the proportion of cues that are missed directly over the sensor (i.e., at distance 0). The perception bias here may arise due to the directionality of an animal's beam profile.

To demonstrate the application of density estimation via DS, a case study for Blainville's beaked whales is presented below. Given vocalizations are medium-high in frequency, very directional, and they are often not detected on multiple bottom mounted hydrophones, the general use of SCR is precluded. In this context, SCR might be more suited to omnidirectional sources. SCR approaches are not discussed further here (see Booth et al. 2017 and associated documents for more details).

## Case Study: Blainville's Beaked Whale

As a deep-diving, visually elusive species group that uses echolocation, beaked whale populations highlight the utility of acoustic monitoring for marine mammals. Conservation concern stems from stranding events of beaked whales that have been reported globally (D'Amico et al. 2009; Filadelfo et al. 2009) and have been associated with exposure to naval sonar use (Bernaldo de Quirós et al. 2019; Simonis et al. 2020). However, there are multiple beaked whale populations that are consistently exposed to sonar on navy training ranges, where local abundance is believed to be stable, and strandings have occurred apparently unrelated to sonar exercises

(Curtis et al. 2020; Filadelfo et al. 2009). The uncertainty surrounding the effects of sonar on marine mammals has led to long-term monitoring efforts on US Navy ranges to determine the potential short- and long-term impacts at an individual and population level (Falcone et al. 2009, 2017; Schorr et al. 2017; Jacobson et al. 2022).

The AVADECAF example provided considers distance sampling and is based on input parameters from the Blainville's beaked whale population at AUTEC (Table 1). However, not all the required metrics were available for this specific group of animals, and therefore some of the data were sourced from other Blainville's beaked whale populations. Hence, this simulation provides an illustrative example of the utility of AVADECAF, rather than a true estimation of the power to detect a decline in density from Blainville's beaked whales at AUTEC.

Developing a range of scenarios allows for a better understanding of the potential power to detect a decline. Here, this pertains to increasing the number of monitoring years and simulating a variety of survey designs. In data-rich situations, it may be possible to increase the number of density estimates made per year, improving the power to detect a decline and reducing the number of monitoring years that are required to detect a population level change. In this scenario, doubling the number of estimates per year resulted in a reduction of approximately 7 monitoring years when the population was experiencing 1% annual decline (Fig. 2), on the assumption that these estimates are independent. While this example demonstrates the change in statistical power when the number of density estimates is increased to two per year, providing there is sufficient information regarding detections, and seasonal changes in animal presence and cues, the number of density estimates per year could be increased further, with expected increases in power. However, caution is advised in the implementation of this approach, as density estimates must be independent. Consequently, there will be a practical limit in how many estimates can be derived within a single year.

In addition to varying the number of estimates per year, the model allows for specification of the number of localizing hydrophones within the array. These p-nodes are more expensive to implement (as they require multiple hydrophones per node) but, given multiple p-nodes are implemented throughout the study area, they allow for multiple detection functions to be derived, which can address

**Table 1** The parameters for the simulations shown in Figs. 2 and 3, representing only a subset of the inputs required for the AVADECAF tool

| Parameters | Value | Reference |
|---|---|---|
| Array dimensions | 1500km$^2$ | Matsumoto et al. (2013) |
| Hydrophones | 82 | Marques et al. (2009) |
| Initial population density estimate | 25.3/1000 km$^2$ | Marques et al. (2009) |
| Cue rate (clicks per second) (cv) | 0.407 (0.098) | Marques et al. (2009) |
| False positive rate (cv) | 0.549 (0.0199) | Marques et al. (2009) |
| Perception bias (cv) | 0.07 (0.1) | As used in simulations from Booth et al. (2017) |
| Density estimates per year | 1–2 | Not applicable |
| Annual decline | 1–3% | Not applicable |
| Number of localizing hydrophones (P-nodes) | 3–8 | Not applicable |

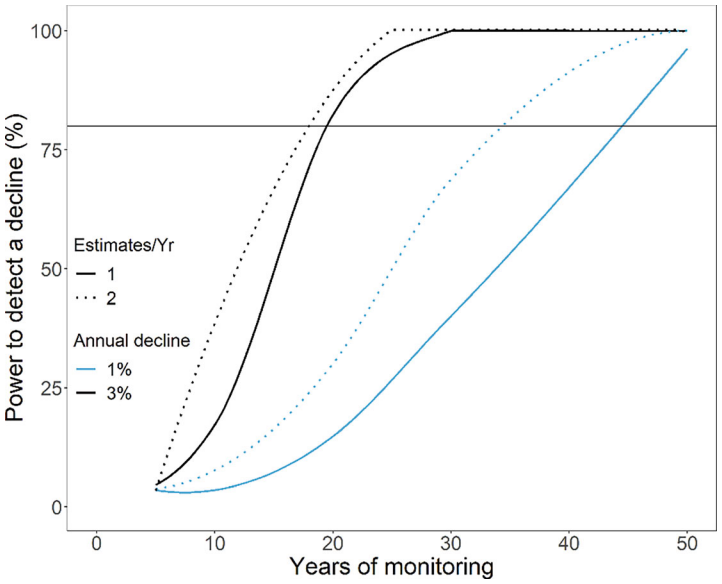

**Fig. 2** The power to detect a decline in Blainville's beaked whale based on input values derived from AUTEC. Simulations based on 1 or 2 density estimates per year, and 1% or 3% annual declines. This simulation was based on an average of 5 localizing hydrophones within the array and alpha $< 0.05$

heterogeneity in the detection probability across the study area. Increasing the number of localizing hydrophones on the array allowed for the threshold for high power (0.8) to be reached 5 years earlier, when the population declined 1% per year (Fig. 3). The reduction in the required number of monitoring years to detect a given trend will differ depending on the input parameters, but also depending on the heterogeneity of the environment. The required monitoring time will be species- and region-specific, and the proportion of localizing hydrophones and the number of estimates per year are illustrative. The impact on power for several other parameters could also be evaluated within the simulations, for example, the influence of cue rate, false positive rates, and how environmental heterogeneity may impact power by increasing the variability of the detection probability. For an example of these explorations, see Booth et al. (2017). Monitoring scenarios that are extended over a longer time series allow us to estimate the minimum number of survey years required to detect a specific decline, and the level of decline that is possible to detect, given the survey effort (noting the caveats and assumptions highlighted above).

## Discussion

In this chapter, the relevance of the AVADECAF tool is discussed in relation to estimating density using PAM. It is critical to have a PAM array and supporting auxiliary information with high precision and ideally unbiased estimates (though

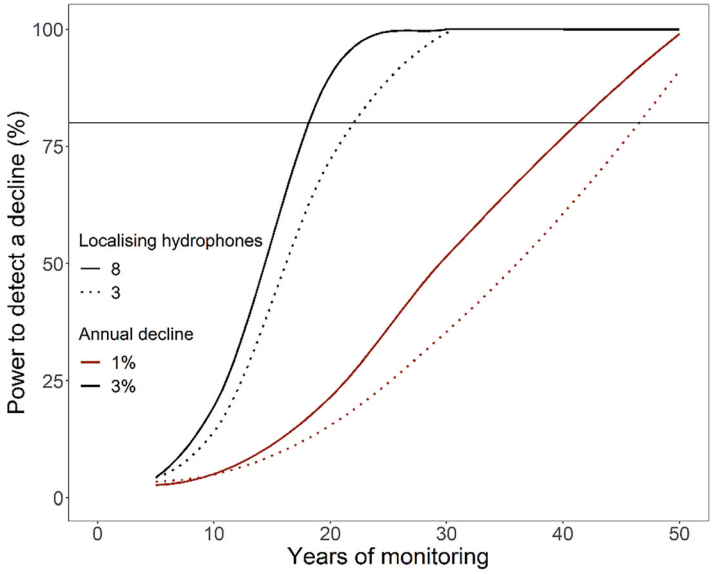

**Fig. 3** The power to detect a decline in Blainville's beaked whale based on input values derived from AUTEC, including a comparison of statistical power between arrays with different numbers of localizing hydrophones. This scenario was based on one density estimate per year, while varying the number of localizing hydrophones and the intensity of the annual decline, alpha $< 0.05$

these are practically hard to achieve). The various sources of error or bias and their impact on density estimates are described more fully in Booth et al. (2017). Key methodological elements (e.g., cue rates, detection and classification capabilities, survey design) are discussed below; these components influence density estimates, but also represent practical considerations that can help improve the utility of PAM for density estimation.

## Cue Production Rate

Booth et al. (2017) outlined the importance of cue production rate for PAM density estimation, where improved precision (and, as with all parameters, having an unbiased estimate of) the cue production rate drastically improved the power to detect a decline. It's important to note that cue production rate is not only species-specific but may vary with region/population, behavioral state, season, age, and sex, and as a result of ambient noise levels (Warren et al. 2017; Thode et al. 2020; Blackwell et al. 2021). As such, integrating cue production rate data that is region-specific and temporally aligned with the acoustic datasets is imperative to ensure an accurate representation of local density over time (e.g., Marques et al. 2013) and is equally important to evaluate the power to detect a decline.

## False Positives

The false positive rate (and variance around it) is another important input for density estimation, representative of detections that have been wrongly associated with the species of interest.

False positive rate is both species-specific and linked to the detection and classification system that is being used to process the acoustic cues; it is also spatially and temporally sensitive as other local sound sources can result in false positive detections. To identify infrequently detected species, the detector/classifier may be programmed to be sensitive (i.e., to not miss many detections), however this will likely lead to more false positives. Where the application is to use PAM for density estimation, there is some tolerance around higher false positive rates (Booth et al. 2017), providing the variance around the estimate is low (i.e., the false positive rate is precise – and unbiased) (Marques et al. 2009).

Booth et al. (2017) determined that when the false positive rate detections were imprecise (i.e., the variance around the estimate of the false positive rate was high), the power to detect a decline was considerably reduced. False positive rate is typically measured by manually checking a sample of the acoustic recording (on the assumption that an automated detector/classifier is used initially). The more often such validation is carried out, the higher the precision on the estimate of false positive rate will be. As such this is under the control of the analyst, so it is feasible to reduce the variance on the estimate.

Another practical challenge is that species with similar call frequencies and patterns co-exist in space and time – which can make detection and classification challenging. For example minke whale boing classifiers in Hawaiian waters have been found to be sensitive to humpback whale song (Ou et al. 2012), while humpback whales and bowhead whales also overlap in at least part of their vocal range (De Vreese et al. 2018). However, as long as the precision is understood and kept low, a poor false positive rate in isolation contributes very little to the final variance (sensu Marques et al. 2009).

## Survey Design

Designing a survey requires careful consideration of logistics and budget available as this directly relates to the ability to detect and estimate ranges to animals (to generate detection functions), a key component of density estimation via distance sampling. In practical terms there will be error around the estimates of the range of animals from the sensor (see Booth et al. 2017 for further details). In AVADECAF, the user is able to specify if the range of animals from the sensor (i.e., the localization of the animal) occurs accurately (which is simplistic) or with error. Error in range estimation increases with distance between hydrophones – therefore considering the species of interest and an appropriate spacing for hydrophones will help improve the estimation of components needed for PAM density estimation. As the frequency and

source level of vocalizations influence propagation distance, the space between hydrophones on the array should be species-specific. Greater distances between hydrophones increase the magnitude of the acoustic time delay of multiple detections of the same sound, which reduces the time delay error. This suggests that greater aperture size (the distance between hydrophones) would be optimal for a localizing hydrophone array. However, smaller distances between an animal and a hydrophone will increase the probability of detection. This is especially true for highly directional vocalizations. Therefore, selecting the array dimensions requires consideration of the species of interest, and an evaluation of these trade-offs.

The number of localizing hydrophones depends on the study area and corresponding array dimensions, but also on the underlying density of animals (unknown), environmental conditions, and local bathymetry. In a larger survey area, there may be more variation in habitat conditions, which will influence the detection function for acoustic cues. In this case, it would be preferable to increase the number of localizing hydrophones, to support the estimation of site-specific detection functions, or at the very least detection functions dependent on site-specific covariates, for example, depth. Increasing the number of localizing hydrophones allows us to account for heterogeneity in the environment, which may improve the precision of the detection function model. However, estimating cetacean density using passive acoustic monitoring can be a costly process if the equipment is not already deployed. Booth et al. (2017) evaluated the potential costs of the acoustic technology required for an array unit capable of localization, estimating ~$20-30 k per unit, extending this array to cover a large survey area would magnify these costs, with the distance between units (and therefore the number of units required) depending on the species of interest and their respective vocalization characteristics. Conversely, initial investment in passive acoustic technology can support long-term monitoring efforts, with acoustic devices being redeployed over several years.

## Applications

The AVADECAF simulation tool presented here provides an opportunity to explore the statistical power of a monitoring program for PAM density estimation before deployment of equipment. For existing hydrophone arrays, it provides a means to assess the utility and scope of monitoring. To our knowledge this tool has been infrequently applied since its development, possibly due to lack of awareness and difficulty accessing the software. However, there is a need for PAM survey designs associated with the fast-growing offshore wind sector where significant uncertainty around occurrence and response of marine mammals to construction noise remains. Baseline density and long-term monitoring at offshore wind farms could be explored using the AVADECAF tool, to determine the potential power of an array to detect cetacean density changes considered to be the result of windfarm development. Booth et al. (2017) stressed the importance of precisely estimating cue production rates (following Marques et al. 2009). Ongoing efforts are improving our knowledge of the factors driving cue rates and their variability for a variety of marine mammals.

As such it is expected that within the next few years these outputs will be highly relevant to the AVADECAF tool by facilitating additional cue production rate parameters, allowing for more realistic simulations.

The potential applications of the AVADECAF tool are numerous, including opportunities to evaluate existing passive acoustic monitoring programs. Distance sampling-based density estimation from fixed PAM has been minimally explored for marine mammals, however these methods have been applied to North Pacific right whales, fin whales, and bowhead whales (Marques et al. 2011; Harris et al. 2013; Oedekoven et al. 2022). Navy training ranges represent regions where cetacean density estimation using PAM is possible using their cabled bottom-mounted hydrophones. In other locations, developing an array for the purpose of cetacean density estimation is also possible, however Booth et al. (2017) suggest that deploying a small-scale acoustic array as a trial would facilitate a better understanding of the required dimensions for detection and localization for a range of species. The results of a carefully designed trial could directly contribute to the planning of acoustic arrays for the purpose of density estimation in the future.

The US Navy has already invested heavily in PAM to evaluate the impacts of sonar on marine mammals at both the individual and the population level. As the current literature demonstrates low power to detect declines from marine mammal visual surveys, statistical power of PAM surveys should also be evaluated to better understand the underlying trends that may be missed. Evaluating statistical power should be a component of designing a monitoring program, facilitating the detection of less dramatic declines, and allowing for earlier management of struggling populations. While a single data source monitoring method may not provide sufficient power to detect a moderate decline, initial power analysis offers a baseline value of statistical power that can be improved upon. Efforts to integrate multiple data streams have successfully demonstrated their capacity to reduce uncertainty in population estimates and improve the power to detect population level changes. Jacobson et al. (2020) determined that by combining multiple data sources, they were able to calculate biologically plausible estimates of population trends for Cook Inlet beluga whales, where this had previously not been possible. Boyd and Punt (2021) simulated data representative of a large whale population and demonstrated that only an integrated population model (IPM) with the maximum combination of data sources (including environmental and demographic data) was capable of differentiating between a stable or heavily declining population. The AVADECAF software can provide an evaluation of statistical power for fixed passive acoustic monitoring, however if power remains low despite a range of monitoring scenarios, the next step could be to consider integrating data sources to improve monitoring power.

## Conclusion

The AVADECAF software tool is freely available online and provides an opportunity to investigate the statistical power of an acoustic monitoring program, where density estimation of sound producing species like cetaceans is the desired outcome.

The software is customizable to tailor the simulation to a region of interest and simulate a population trend for a specific species. The original development of the tool included a parameter sensitivity analysis that demonstrated the importance of precision around input parameters including cue production rate and false positive rate. This tool is most applicable to species that are well-researched and supported with detailed information on vocalizations, notably this information should be population-specific where possible. Given the frequent use of fixed PAM to monitor cetaceans there is scope to apply simulation power analysis tools like AVADECAF to a range of future research projects and species groups to help improve the utility of this field.

**Abstract**

Energy companies have been exploring for (and extracting) oil and gas (O&G) from offshore hydrocarbon fields since the late 1890s. Yet, relatively little research has been conducted into how marine megafauna interact with, and are subsequently impacted by anthropogenic structures in the marine environment. Utilizing passive acoustic monitoring equipment (C-PODs), this study investigated harbor porpoise (*Phocoena phocoena*) occurrence in the vicinity of a new O&G platform, recording click data between 2015 and 2020, at control and impact sites, pre-platform

installation, during construction, and once the platform was *in situ*. Within five months, porpoise detections per day had returned to pre-platform levels. Drilling-noise measurements of a nearby drilling installation produced a Sound Pressure Level of 120 dB re 1 μPa at 2–1400 Hz. Porpoise forage regularly near offshore O&G installations and are exposed to various noise sources while travelling through the water column, and may hear high-frequency noise from drilling activities up to 70 m from the stem. Findings have important consequences for decommissioning, which does not presently consider impacts of anthropogenic infrastructure on marine megafauna in anything other than a noise-mitigation milieu.

## Introduction

While many Oil and Gas (O&G) reserves in the North Sea dwindle, some remain productive, and the current Ukrainian-Russian war has seen a resurgence in new creation of shallow-water O&G infrastructure. Consequently, offshore platforms are likely to persist for decades to come (Leporini et al. 2019), so further insight into how they may impact marine fauna in the long term is vital.

Some well-located and older offshore platforms (and their 500-m shipping exclusion zones) form a series of interrelated manmade reefs (McLean et al. 2022), attracting and providing sites of reproduction for fish and invertebrate species (Fujii et al. 2014, 2020; Todd et al. 2018, 2020b, 2021).

As part of routine integrity checks, platforms are assessed regularly for marine growth, but are considered rarely in the context of generated underwater noise and impacts on marine mammals. This is especially important, since cetaceans utilize different frequency ranges for communication, feeding, and other behaviors (Southall et al. 2007; André et al. 2010; Erbe et al. 2018; NMFS 2018; Southall et al. 2019). While mitigation measures are carried out during offshore O&G Exploration and Production (E&P) activities, long-term underwater noise studies are missing from the literature. Noise-measurement campaigns are brief, controlled by operator schedules, often in poor measurement conditions, and data are bound mostly by Non-Disclosure Agreements (NDA). Moreover, while underwater noise monitoring datasets are often included in Comparative Assessments (CA) (Bagstad et al. 2013) and Net Environmental Benefit Analysis (NEBA) procedures (Nicolette et al. 2023) for decommissioning activities, they do not consider marine mammals in anything other than a mitigative context, during, for example, the Plugging and Abandonment (P&A) process (*e.g.* protections from explosions). Consequently, peer-reviewed literature investigating associations between marine megafauna and O&G structures

is limited to a handful of papers (Todd et al. 2009, 2016, 2020a, 2022; Triossi et al. 2013; Delefosse et al. 2017; Clausen et al. 2021).

Research quantifying effects of installing a new O&G structure on harbor porpoise presence and activity is presented here while impacts on potential prey species are published elsewhere (Todd et al. 2020b, 2021). In this study, between 2015 and 2020, passive acoustic click-detectors (C-PODs) were deployed to record harbor porpoise presence around the platform legs and at control sites further afield, pre-platform installation, during construction, and once the platform was *in situ*. Recordings of underwater noise from a nearby operational jack-up-drilling rig were also carried out to elucidate what noise porpoise are exposed to when searching for prey around offshore installations.

## Methods

### Location

C-POD data were collected from the A18 gas-production platform, which is positioned in The Netherlands sector of the Dogger Bank special Area of Conservation (DBSAC) (Fig. 1a). Near-field drilling noise was monitored from the exploration jack-up rig,

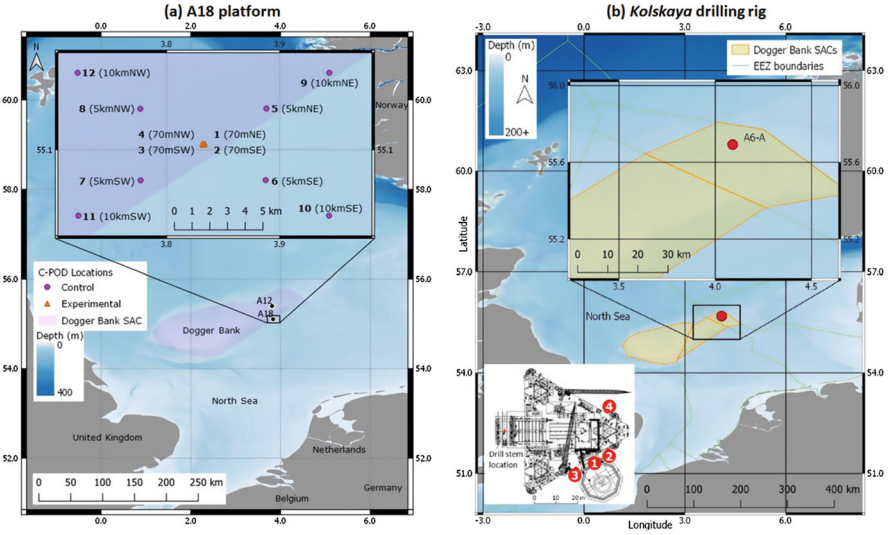

**Fig. 1** (**a**) Position of the A18 platform and control and experimental C-POD deployments in The Netherlands region of the Dogger Bank Special Area of Conservation (DBSAC). ## BACI Measurements and Analysis

Full details of Before After Control Impact (BACI) study design are available in Todd et al. (2022). Twelve acoustic loggers (Version 1 C-PODs, Chelonia Ltd., UK) were deployed in the vicinity of the A18 gas-production platform before, during, and after its construction. Four were deployed in experimental locations 70 m northeast (NE), northwest (NW), southeast (SE), and southwest (SW) of the predicted wellhead location. Eight controls were deployed in the same formation, with four at 5 km and four at 10 km distance away from the wellhead. Default settings were used for all C-POD deployments, and they were deployed using acoustic-release moorings.

Several factors were considered when choosing C-POD deployment locations. Experimental C-PODs were positioned to ensure no interference with routine platform operations, but also to maximize chances of detecting porpoise present around the structure. Beamwidth of porpoise echolocation is narrow and, therefore, porpoises are detected primarily on-axis (Koblitz et al. 2012); therefore, deploying four C-PODs 70 m from the proposed wellhead and sound source increased likelihood of detecting all porpoise sonar around the platform, as per research by Tougaard et al. (2006). While no standard practice exists in the literature for this type of study, control locations were established based on comparable BACI research around wind farms (*e.g.* Diederichs et al. 2008). Control locations were synonymous with experimental locations in regards to topography, water depth, bottom type, fauna, and flora, which was established by consulting surveys of the site and pipeline (Fugro 2013, 2015). C-PODs were also close enough to the A18 to minimize potential overlap with nearby O&G fields. The possibility of simultaneous detections was also eliminated given that C-PODs detect porpoises when they are within 300 m (e.g. see Tougaard et al. 2006; Kyhn et al. 2012; Nuuttila et al. 2018).

In accordance with Dähne et al. (2013), CPOD.exe (Chelonia Ltd.; version 2.044) was used to process C-POD data. The KERNO classifier was run to extract Moderate (Mod) and High (Hi) confidence detections and detection Positive Hours per Day (DPH $d^{-1}$) were derived.

To determine short (<12 months) and long (>12 months) -term impacts of A18 platform construction and operation on porpoise detections, ecological causal assessment was carried out according to Norris et al. (2012) (Norton and Suter 2014; Webb et al. 2016). Additional analysis was also performed on select data sets collected between 2015 and 2020 to determine whether any observed biological effects occurred prior to construction of the A18 (Cormier et al. 2010; Norton and Suter 2014).

Using the '*CausalImpact*' package in R (Brodersen et al. 2015), casual inference was investigated, as per explanations included in Todd et al. (2022). As described by Abadie and Gardeazabal (2003), a synthetic control was determined using detections recorded at control sites to predict the number of detections that would have occurred at experimental locations if no platform had been installed. The synthetic control was

established using a Bayesian-structural-time-series model (BSTS) with DPH $d^{-1}$ from the impact site before A18 construction as the response variable and DPH $d^{-1}$ from control sites over the same timeframe as explanatory variables. Posterior distribution was calculated using Markov Chain Monte Carlo; 10,000 simulations were performed with a burn-in period of 10%. To investigate impact of individual A18 industrial operations, the difference between derived values for the synthetic control and values recorded at experimental locations were examined for each day. To avoid autocorrelation between experimental moorings, a single experimental location was utilized for calculations. It was predicted that any variation between detections at the experimental location and the synthetic control were because of A18. Refer to Todd et al. (2022) for additional description of equations.

Using the '*randtests*' package in R (Mateus and Caeiro 2014), a Cox–Stuart test was carried out to examine whether DPH $d^{-1}$, recorded at the experimental site changed over time. See Todd et al. (2022) for the R code and further information on model choice and validation. A Kruskal-Wallis test was conducted to compare detections at experimental and control sites.

## Drilling-noise Measurements & Analysis

Noise from the jack-up-drilling rig, *Noble Kolskaya,* was recorded using methods outlined by de Jong et al. (2011) and NPL (2014) in Beaufort Sea state $\leq$3; procedures conformed to current ANSI/ASA (2009) and ISO (2016) standards. Near-field measurements were taken from four locations on the platform (as shown in Fig. 1b) and far-field measurements were recorded by researchers onboard the vessel *Northern Seeker*, in an attempt to calculate source levels.

Two hydrophones (Sonar Research and Development; SRD) were deployed simultaneously to obtain noise measurements: a 25 mm HS70 and a 12.5 mm HS150; primary resonance frequencies were 70 kHz and 150 kHz, respectively, and low frequency sensitivity for both was −205 to −211 dB re 1 V/μPa for noise below 10 kHz. Data were transferred to a PC hard disk using a Roland UA30 digital interface (16-bit resolution 48 kHz sampling rate) for low-frequency noise (<24 kHz) and a National Instruments PCMCIA interface (12-bit resolution 320–400 kHz sampling rate) for high-frequency noise (10 Hz – 200 kHz). Further noise recordings of the audio bandwidth (24 kHz) were taken using digital magnetic tape and a Sony TDS-D7 digital DAT recorder (16-bit resolution). Signal-to-noise ratio was enhanced using conditioning preamplifiers, and a 1 Hz high-pass filter was utilized for Alternating Current (AC) coupling of recordings in the audio-bandwidth; high bandwidth recordings were made with a band-passed preamplifier set from 2 to 150 kHz.

Custom-written scripts created in MATLAB v. 2.0 were used for time and frequency domain analysis. Broadband and tonal components associated with rig operations were analyzed and compared with generalized ambient noise spectra published by Wenz (1962). Using methods similar to Alessio (2016), and allowing for hydrophone systems' transfer functions, data were converted to receive Sound Pressure Level, SPL (dB re 1 μPa), or Power Spectral Density, PSD (μPa/√Hz), using

a 0.091 Hz bandwidth for analysis of low-frequency noise (1–110 Hz) and a wider 2.93 Hz bandwidth for analysis of higher frequency noise (90 Hz–24 kHz). For spectral analysis, high resolution, Fast Fourier Transforms (FFTs) were performed (Welch 1967). In order to assess tonal-component-time stability and reduce indistinct noise variance, Welch (1967) averaging techniques were applied to 43.7–87.4 s time windows; ⅓ octave band analysis was carried out for noise in the 25 Hz – 13 kHz frequency band. Data show standard noise characteristics of rig operations over time. Sound-speed profiles obtained from Conductivity Temperature Depth, CTD (Seabird Scientific, Washington, USA), measurement data were used to calculate Transmission Loss (TL) at several frequencies using Bellhop ray tracing (Jensen et al. 2011).

### A18 Platform & Kolskaya Drilling Rig Operations

No O&G activity occurred during the baseline period in summer/autumn 2015, which lasted 61 days. The construction phase lasted five days and took place between October 9th and 13th, 2015; various operations were then on-going until November 2nd, 2015, at which point a jack-up rig joined the production platform for 109 days to drill new wells; the rig left on February 18th, 2016. Following this period, the platform was unmanned.

A detailed record of *Kolskaya* drilling operations was cross-referenced with noise measurements recorded during various rig activities; recordings spanned several frequency bands. Operations were categorized as follows: rig installation with tugs present, tank discharge, preloading, drill preparation, drilling 30″ hole, drilling 24″ hole, coming and going of helicopters, and support vessels. Operations data were sourced from platform and rig logbooks.

## Results

C-PODs were deployed for 997 days between August 2015 and January 2020 at 12 monitoring stations. Of the 132 deployments, 129 C-PODs were recovered and three were lost; recovery rate was 97.7%. A timeline of C-POD deployments is shown in Fig. 2.

Noise measurements were taken directly from the rig's barge around the legs of the *Kolskaya* and from the support vessel *Northern Seeker* in 2004. Results reported here are additional to those previously reported in Todd et al. (2020c).

### Effects of A18 on Porpoise Detections

Differences between expected and observed platform operation-related porpoise detections were significant at all impact locations and the probability of achieving this result by chance was negligible ($p < 0.001$). There was, however, variation over

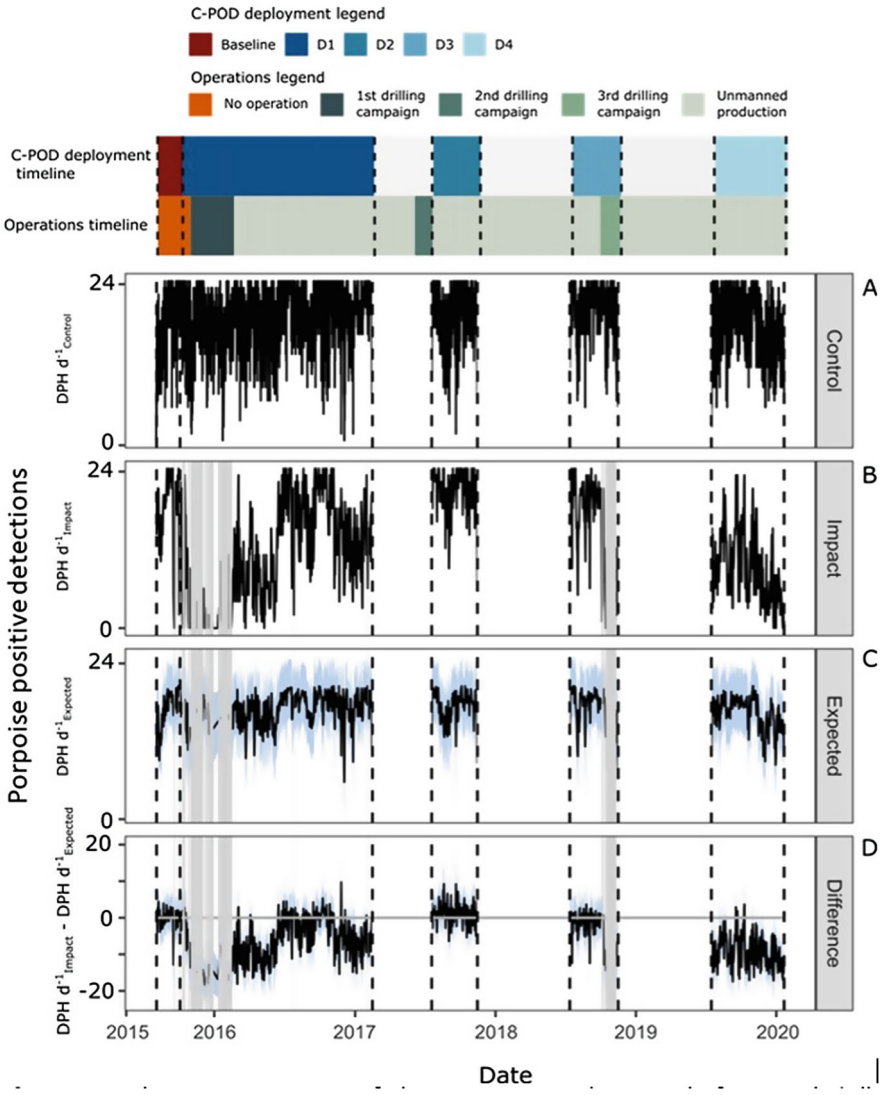

**Fig. 2** Short-term impacts of the A18 gas production platform and drilling rig on porpoise detections. (**a**) Detection positive hours per day (DPH $d^{-1}$) at 5 and 10 km control locations (DPH $d^{-1}_{Control}$), (**b**) DPH $d^{-1}$ 70 m NE of the platform (DPH $d^{-1}_{Impact}$), (**c**) Expected DPH $d^{-1}$ if the platform had not been installed (DPH $d^{-1}_{Expected}$), (**d**) Difference between expected and observed DPH $d^{-1}$ at the 70 m impact location (DPH $d^{-1}_{Impact}$ - DPH $d^{-1}_{Expected}$). No difference is shown by the grey line. A breakdown of C-POD deployments is shown (vertical dashed lines), including the baseline period when no platform was present, the construction period when the A18 was installed, and the three drilling campaigns that took place once the platform was in situ (D1–D4); platform installation is included in the first drilling campaign. Gray bars show where >10% of data were omitted, for example, because of excess noise resulting in C-POD shut-down. 95% credibility interval is shown by the blue ribbon in plots C and D. (Source: Todd et al. (2022))

time; any differences found between expected and observed DPH $d^{-1}$ pre-platform installation (baseline) were not significant (Fig. 2).

As predicted, there were significantly fewer porpoise detections following A18 installation and the first drilling campaign in all locations except controls (Fig. 2); however, between 2nd November 2015 and 18th February 2016, significantly more porpoises were detected at control location 5, 5 km away from the A18, than during the baseline period (Kruskal-Wallis test, $P < 0.001$).

During summer and winter in 2019, DPH $d^{-1}$ were lower than anticipated in all locations (Fig. 2).

For all sites, DPH $d^{-1}$ were explored to determine if short-term changes in porpoise presence following A18 installation persisted or whether presence returned to baseline levels with time. No significant change in porpoise detections was found ($p = 0.2985$), indicating that porpoises were neither attracted to nor displaced by the platform.

## Drilling Noise – Near-Field Measurements

Noise levels recorded during different operational phases on the *Kolskaya* rig are reported by Todd et al. (2020c). Results shown here expand on those noise profiles by investigating how the noise regime changes with depth and time during the drilling phase.

Figure 3 shows depth profiles for low (Fig. 3a) and mid-frequency (Fig. 3b) noise. Strong tonals are evident, for example, at 880 Hz, 1263 Hz, and 1373 Hz, and for sound below 1 kHz, noise level increases with depth.

Drilling noise varied over relatively short time scales. Figure 4a shows prominent 2.8 and 5.6 Hz components present in one recording but absent 30 min later, and this corresponds with a general increase in surrounding noise density level, which is also shown in Fig. 4b for frequencies up to 1.5 kHz; tonal components are evident at

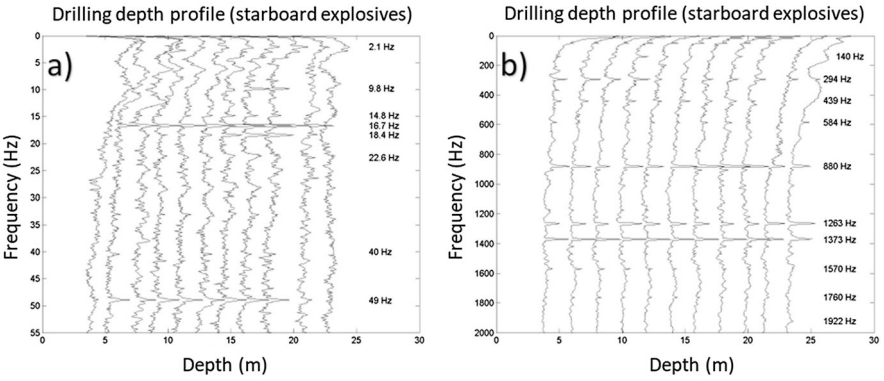

**Fig. 3** Low (**a**) and high (**b**) frequency noise depth profiles taken from the starboard explosives platform of the *Kolskaya* during drilling. (Source: Todd et al. (2007))

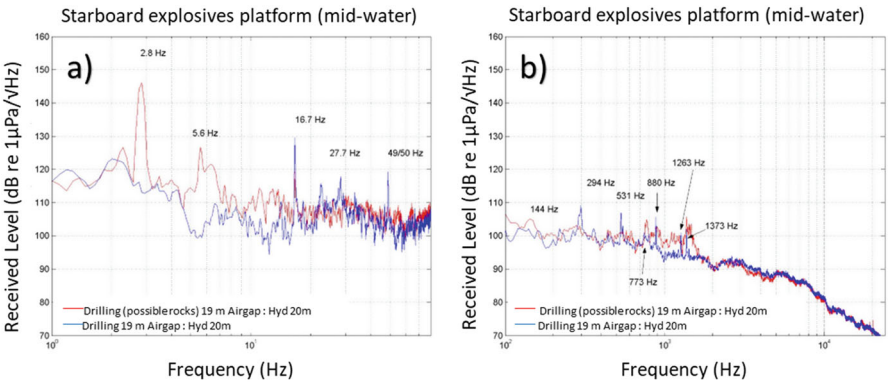

**Fig. 4** Spectral comparison of two mid-water noise recordings made from the starboard explosives platform of the *Kolskaya* drilling rig within 30 min of each other during the drilling phase for (**a**) low-frequency and (**b**) high-frequency noise. (Source: Todd et al. (2007))

294 Hz and 531 Hz. Over 1.5 kHz, noise density level remains stable. These findings are corroborated in Fig. 6 which shows a single time analysis window; Received Level is highest at 210 s and 260 s (Fig. 5).

## Drilling Noise – Far-Field Measurements

Far-field measurements taken 9260 m to the west of the platform from the support vessel, *Northern Seeker*, are shown in Fig. 6. Recording conditions were suboptimal (Beaufort Force 6) and high levels of vessel noise (for safety reasons, engines were switched off only for brief periods, of insufficient duration to obtain high-quality recordings), so attempts to calculate source level are not presented here, as figures are likely highly inaccurate.

At frequencies below 1 kHz, ship noise exceeded noise emitted by the rig while it was drilling. Ship noise was quieter above 400 Hz once main engines were turned off, but with the main engines on, ship noise was louder for frequencies up to 2 kHz.

## Discussion

This chapter investigates porpoise echolocation activity pre, during, and post construction of the A18 gas platform and presents noise measurements taken from the *Kolskaya* exploration jack-up drilling rig and its support vessel, *Northern Seeker*. Knowledge on porpoise/offshore O&G drilling rig/platform interactions is limited and, thus so far, is confined to six peer-reviewed papers (Todd et al. 2009, 2016, 2022; Delefosse et al. 2017, 2020; Clausen et al. 2021). This research, therefore, responds to the requirement for more in-depth studies in this area and builds on results reported by Todd et al. (2020c).

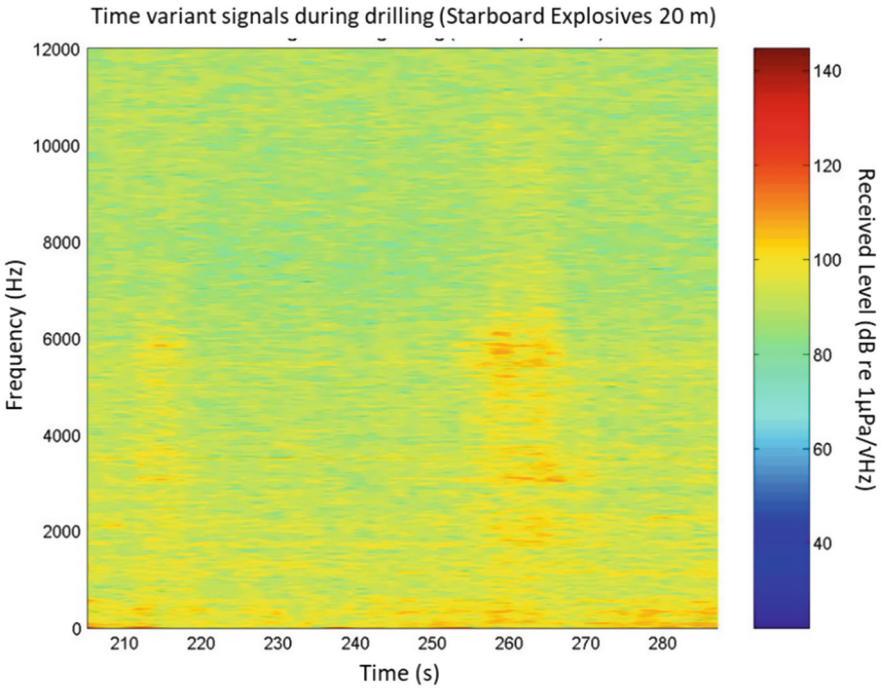

**Fig. 5** Time variant components in noise recorded from the mid-water starboard explosives platform of the *Kolskaya* exploration drilling rig during drilling activities. (Source: Todd et al. (2007))

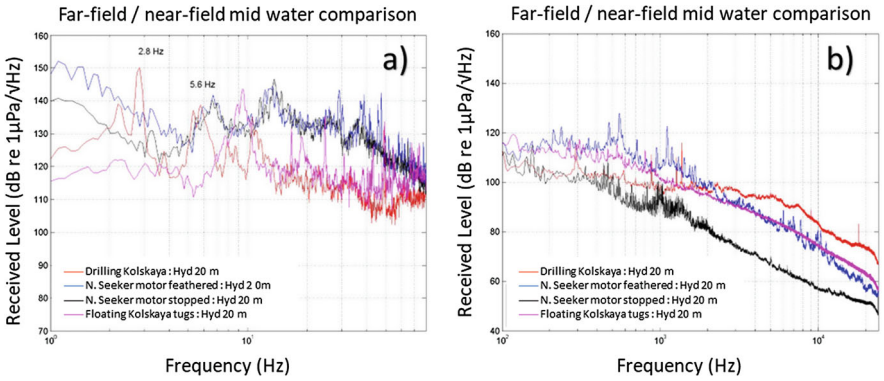

**Fig. 6** Low (**a**) and high (**b**) frequency plots of far-field noise measurements taken from support vessel, *Northern Seeker*, with motor running and switched off. For comparison, noise measurements taken during drilling and during rig positioning when three tugs were present are shown. (Source: Todd et al. (2007))

## Porpoise Presence

Significantly fewer porpoise detections were recorded during A18 platform construction and the first drilling campaign than during the baseline, with the only exception to this being Location 5, 5 km from A18, where more porpoises were detected in the four-month period between November 2015 and February 2016 than during the baseline. A reduction in porpoise presence is in line with studies investigating impact of windfarm construction (e.g., Carstensen et al. 2006; Brandt et al. 2018) and was expected given likely noise levels produced during the construction phase and in subsequent phases prior to start of unmanned production where various preparation activities are taking place. It is, however, important to acknowledge that the absence of detections during the construction phase could be a result of suboptimal recording conditions and, therefore, not a true reflection of porpoise presence. Furthermore, though the increase in porpoise detections at location 5 in 2015/2016 is interesting and potentially linked to platform presence, the result is considered cautiously. While ROV research, reported previously in Todd et al. (2020b), revealed that fish and invertebrates were attracted to the A18 platform just four days post-construction and previous research shows that porpoises are attracted to rigs and platforms generally (Todd et al. 2009, 2016, 2020a; Fernandez-Betelu et al. 2022), few comparisons can be made here with older, more established structures given that the A18 was newly installed and therefore relatively free of marine life (Todd et al. 2020b, 2021). Moreover, Research by Fernandez-Betelu et al. (2022) found that the increase in porpoise presence and foraging behavior around platforms was limited to 200 m; therefore, further research at the A18 is required to determine whether more porpoises are present around the platform than elsewhere and whether numbers have increased over baseline levels.

Considering that, once in place, platforms are operational for 30–40 years, construction/drilling effects were comparably short term, with porpoise acoustic activity returning to pre-platform baseline levels within five months. This is in agreement with porpoise observations during other studies investigating the impact of industrial noise on porpoises, such as piling during the construction phase of windfarm development (Graham et al. 2019) and seismic surveys for the O&G industry (Pirotta et al. 2014).

Over time, porpoise detections remained stable, with no significant increase or decrease, which suggests that, in the long term, porpoises were neither displaced by nor attracted to the platform. Unmanned gas-production platforms like A18 continually emit low-intensity noise, with research suggesting that the higher frequencies, more audible to harbor porpoise, are highest around the platform (Clausen et al. 2021). During unmanned operations in 2017 and 2018, differences between expected and observed DPH $d^{-1}$ were not significantly different, which could suggest that platform operations are not an ideal indicator for porpoise acoustic activity around platforms, though noise data are needed to confirm this hypothesis. Statistically significant differences were, however, found between expected and observed detection rates in the winter of 2016–2017, when there were no *in situ* operations, and during the 2019–2020 monitoring period. Without a further collection of winter data, it is impossible to ascertain what caused the observed decrease in

porpoise detections though, it is likely, given that detections were lower in all locations in 2019–2020, changes are linked to other factors. For example, season, weather, prey abundance, and fishing activity are all likely to have contributed and are the subject of further study. While the majority of data were collected during the summer months, the impact of this bias may be limited given that porpoises are present within the DBSAC throughout the year (Todd et al. 2009, 2016; Gilles et al. 2012), though they are most abundant between July and November (Gilles et al. 2011). Furthermore, Clausen et al. (2021) stated that between July and January, porpoises are most active around O&G platforms, and that is when the majority of these data were collected. Further year-round data are required to investigate this further.

## Drilling Noise

The drilling noise study within 60 m of the drill stem assessed potential noise exposure levels for porpoise near a drilling rig. Results published in Todd et al. (2020c) stated that rig noise had SPLs of 120 dB re 1 lPa in the frequency range of 2–1400 Hz and that, at a depth of 10 m, there is potential for harbor porpoises to detect drilling noise of 880 Hz within a range of 69 m and of 1263 Hz within 66 m from the source horizontally. Further analysis, reported here, demonstrates how drilling noise varies throughout the water column, with a gradual increase in broadband sound level with depth for frequencies below 1 kHz. Strong variations in noise level also occur over relatively short time periods. This is likely due to variations in substrate type with the strong 2.8 Hz tone evident in the sound files present only when boulders or similar relatively hard materials were encountered, as confirmed by drilling logs. This would also explain the general increase in sound level at the time; the 5.6 Hz component is likely a harmonic.

Hearing detection thresholds for harbor porpoise at the low frequencies produced by drilling are difficult to ascertain given that measuring hearing thresholds at those frequencies is impractical – a 1500 m deep acoustic holding tank is required to play a 1 Hz signal to a porpoise. They are most sensitive to sound between 100 and 140 kHz (Kastelein et al. 2002) and they produce dominant Narrow-Band High-Frequency (NBHF) click components within 110–150 kHz (Møhl and Andersen 1973; Verboom and Kastelein 1995; Verboom and Kastelein 1997; Au et al. 1999; Teilmann et al. 2002; Villadsgaard et al. 2007; Kastelein et al. 2017). Given that porpoise peak hearing and vocalizations are five orders of magnitude higher than dominant tonal components of drilling noise, it is unlikely that drilling will impact or mask their echolocation. There is potential for them to detect HF components of drilling noise, and it is evident that noise exposure varies on a spatial and temporal scale as they traverse through the water column. Behavioral effects, whether short or long term, are outside the scope of this study, so no inferences are made here.

To obtain more complete picture of noise emanating from a drilling rig, far-field measurements were taken from a support vessel 9260 m west of the platform. Conditions in the field were not ideal with high winds, swell, and vessel engine noise, and, at

frequencies below 1 kHz, vessel noise far exceeded noise from the rig. To measure far-field noise levels accurately, the support vessel would have had to have been located at least 500 m away from the rig, where, considering (for example, basic spherical spreading applied), noise from the rig would have reduced by 53 dB. This decreases to 26 dB using cylindrical spreading equations, but even then, noise from the vessel would exceed received levels from the rig, so accurate quantification of rig noise was not feasible under the circumstances.

With regard to conservation and impact assessments, this study questions the traditional conservation view that all effects should be temporary and that, post activity, areas need to be returned to pre-construction (pristine) conditions. As an example, common understanding of the European Union Environmental Impact Assessment (EU EIA) Directive is that projects assess and mitigate negative impacts only. While methodologies such as Net Environmental Benefit Analysis Comparative Assessment, NEBA-CA (Nicolette et al. 2023), do balance positive and negative effects of a project, OSPAR's 'clean-seabed policy' is based on the idea that, with the exception of outside of windfarms and O&G fields, the North Sea is pristine. This, however, is arguably not the case: fishing methods cause considerable damage to the seabed and have a larger impact than other industrial activities (Pauly and Zeller 2016; Kroodsma et al. 2018), and, furthermore, the fishing industry, along with decommissioning and other industries, benefit financially from the North Sea's clean seabed policy, therefore, it is essential, when developing decommissioning regulations for end-of-life offshore infrastructure, that the potential of leaving structures *in situ* is considered alongside both benefits and costs involved in implementing policies dictating everything must be removed at end of life (Fowler et al. 2018; Sommer et al. 2019). Consequently, it is vital that NEBA-CAs/EIAs and regulations all consider the science and that both ecological benefits and aversive effects are evaluated.

**Acknowledgments** Thanks to Petrogas E&P Netherlands B.V. and Wintershall AG for funding fieldwork aspects of the studies and for release from NDA to publish the findings. For clarity, no Petrogas or Wintershall personnel were involved with, or provided funding for, data analysis, or manuscript preparation, all of which were performed solely by the authors in their own time.

**Abstract**

There is interest in the ability to detect the acoustic presence of franciscana dolphins in an area with active bycatch. To meet that objective, two-dolphin click detectors (F-PODs) were placed in two artisanal fishing gillnets in Claromecó (Buenos Aires province, Argentina). Narrowband high-frequency (NBHF) clicks were found near both gillnets, compatible with the description of the franciscana sound production. These preliminary results confirm that passive acoustic is a good tool to assess franciscana presences. Moreover, understanding the echolocation behavior around gillnets can lead to the design of better mitigation tools in order to reduce the bycatch.

## Introduction

Cetaceans are found in all marine ecosystems as well as some rivers and the biggest threat to their survival is being caught in fishing nets, known as bycatch (e.g., Brownell Jr et al. 2019). One of such cetaceans is the franciscana dolphin (*Pontoporia blainvillei*), whose distribution is restricted to small marine areas in coastal waters off Argentina, Uruguay, and Brazil (Cunha et al. 2014). It is the most affected dolphin species in the Southwestern Atlantic Ocean, with between 2000 and 3000 individuals incidentally caught in gillnets every year. The population along the coasts of Buenos Aires province is estimated at 20,000 (Crespo et al. 2020), and at least 400 dolphins get entangled annually (Negri et al. 2012). For this reason, the International Union for Conservation of Nature (IUCN) and the Mastozoological Society of Argentina (SAREM) have classified franciscanas as vulnerable A3D (Denuncio et al. 2019). In Argentina, the annual levels of bycatch (3.5%–5.6%) far exceed the 2% suggested as the maximum sustainable level by the International Whaling Commission (Crespo et al. 2010). With a potential growth of less than one percent for this species, this bycatch level endangers the population's viability (Cáceres et al. 2020). Additionally, gillnets are killing functional social units that involve mother-offspring pairs along the Argentinean coast (Mendez et al. 2010).

Why franciscanas get entangled is still unknown, but several hypotheses have been raised, including failing to acoustically or visually detect the nets (Bordino et al. 2002, 2013), immature echolocation system (Tellechea and Norbis 2014; Frainer et al. 2015), or because they may be using passive listening for foraging and thus not detect the nets (Tellechea et al. 2017). Several solutions have been developed to decrease franciscana bycatch levels, including acoustic deterrent devices (i.e., pingers) (Bordino et al. 2002, 2004; Paitach et al. 2022) and alternative gear with increased acoustic reflectivity or stiffness (Bordino et al. 2013) with mixed results. The use of bottom longlines would reduce bycatch compared to gillnets but entails an extra effort for fishermen, who are not always willing to endure it (Berninsone et al. 2020).

Although Tellechea et al. (2017) suggests franciscanas forage using passive listening, there have not yet been any studies to support this hypothesis. Studies of sound emissions in franciscana, both in captivity and in the wild (not near fishing nets), show they produce narrowband high-frequency (NBHF, sensu Madsen et al. 2005) sounds with a peak frequency of 139 kHz (Melcón et al. 2012, 2016) and center frequency at 130 kHz (Paitach et al. 2021). Franciscanas have also been recorded producing burst pulses (Barcellos and Santos 2021; Tellechea et al. 2016) and whistles at lower frequencies under stress conditions (Cremer et al. 2017). Calves and juveniles also produce echolocation clicks with low-frequency content

(Melcón et al. 2016). It is therefore thought that franciscana would have the ability to detect gillnets, as suggested for other species with similar echolocation characteristics (Kastelein et al. 2000). Given the franciscanas is a small dolphin, with cryptic and erratic behavior, that lives in small-sized groups, they are difficult to observe in the wild (Bastida et al. 2000; Bastida and Rodriguez 2009; Barcellos and Santos 2021). Therefore, passive acoustic monitoring can potentially be used to investigate the acoustic behavior of franciscanas in close proximity to fishing operations where they are potentially entangled, as it is still unknown (Paitach et al. 2021, 2022).

The main goal of this work was to study the acoustic activity of franciscanas near gillnets in coastal waters of Argentina. Preliminary results of the project are presented.

## Materials and Methods

In November 2021, two artisanal gillnets in Claromecó (Buenos Aires, Argentina) (Fig. 1), 1.4 nm offshore (depth = 15 m), were fitted with automated passive acoustic monitoring instruments (F-PODs).

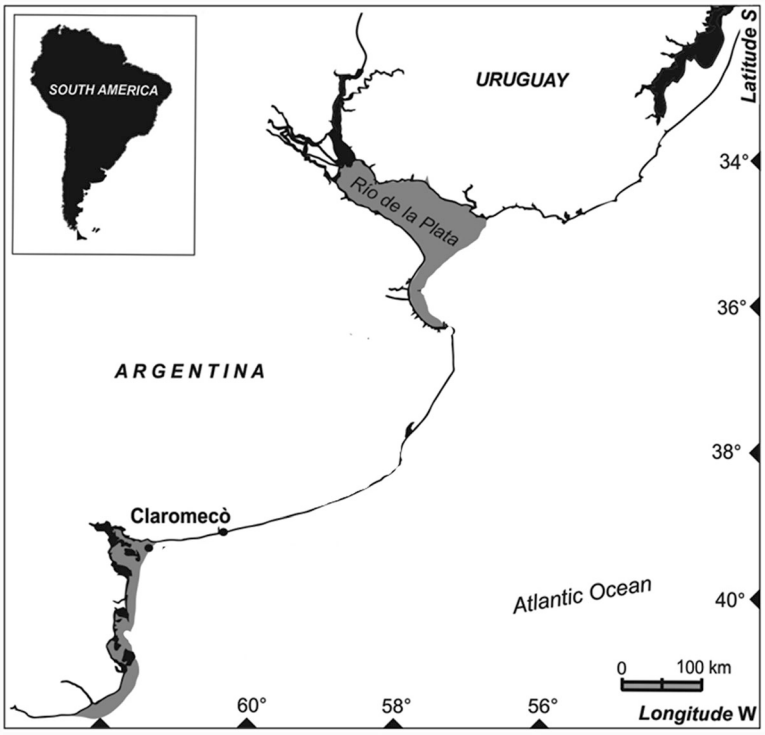

**Fig. 1** Study area. Recording site in two gillnets of Buenos Aires province (Argentina)

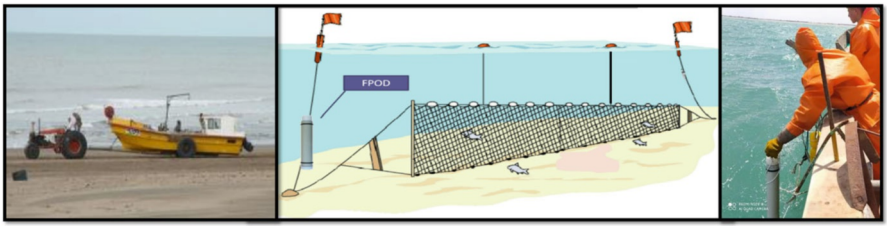

**Fig. 2** Fishermen fiberglass boats from Claromecó artisanal fleet (left), in the middle schematic of the gillnet. (Picture from http://www.miseagrant.umich.edu/nets/largegill.htm and Das et al. 2007) and location of the detector, and on the right fishermen setting up the equipment

The fishermen travel in 8 meter fiberglass boats and use 50-meter-long (Fig. 2), 1.5-meter-high, monofilament gillnets with a mesh size of 10.5 cm as fishing gear. This rigging is composed of 50 m net sections that are generally assembled in 5 or 6 sections (250–300 m). The upper part is equipped with floats or buoys and a footrope with lead weights and monofilament or multifilament nylon threads. These nets are anchored at the bottom, with the main fishery target being sciaenids (*Cynoscion guatucupa* and *Micropogonias furnieri*). Sciaenids are sonorous (Tellechea and Norbis 2012) and are the common prey species of franciscana (Rodriguez et al. 2002; Paso Viola et al. 2014; Denuncio et al. 2017; Tellechea et al. 2017).

Each net was fitted with one F-POD (Chelonia Ltd., UK) placed on the anchor. The nets were deployed by two different fishermen on the 11th and the 14th of November 2021, where the first stayed underwater for 23 hours and the second for 3 days and 21 hours.

F-PODs detect a frequency range from 16 to 220 kHz. According to the manufacturer, F-PODs have a maximum detection range for NBHF cetacean of approximately 400 meters.

However, F-PODs do not record the waveform themselves, but store metadata such as measurements of frequency, amplitude, number of cycles, and bandwidth of the detected sounds. Some full waveforms are also saved. The imported data of F-POD was analyzed with the software provided by the manufacturer (the F-POD app) and the standard KERNO click and click train classifier.

## Results and Discussion

The F-PODs recorded clicks during 20% of the deployment time of net 1 and 17% on the deployment time of net 2. Most of the logged clicks (two-thirds of all clicks), during both deployments, were classified as narrowband high-frequency clicks (NBHF) (Table 1).

For both deployments, the number of clicks and the number of detection positive minutes (DPM) for NBHF signal types were recorded more frequently after sunset (Fig. 3). This is similar to what has been reported for other dolphin (e.g., Caruso et al.

**Table 1** Summary of the F-POD detections during two deployments off the province of Buenos Aires (Argentina). *NBHF* narrowband high-frequency clicks. Other Cet, all other cetaceans – dolphins, beaked whales, pilot whales, etc. Unclassed, clicks not classified into any of the cetacean categories. *DPM* detection positive min

| Unclassed | 1731 | 0.3 | 19.2 | 462 | 11.73 |

2017; Gregorietti et al. 2021) as well as porpoise species (Carlström 2005; Todd et al. 2009; Brandt et al. 2014).

The mean peak frequency of the recorded clicks was 126.8 kHz (SD, ± 3.1; range, 114–140 kHz). These numbers are similar to what was previously reported for franciscanas recorded in Brazil (Paitach et al. 2021), whereas in southern Argentina the reported peak frequency was much higher, at 139 kHz (Melcón et al. 2012) (Table 2). It is worth noting that Melcón et al. (2012) used continuous recordings with different equipment (handheld hydrophone connected to the compute) in their study, whereas Paitach et al. (2021) placed the same PODs we used here.

The mean number of cycles (i.e., peaks in the waveform) within each click was 10.8 (SD, ±8.10; range, 3–59). This is consistent with what has been reported for other species that emit NBHF clicks. For example, the number of peaks in harbor porpoise clicks range between 8 and 15 (Møhl and Andersen 1973). This indicates that the detections were in fact of franciscanas and not of other species, as delphinids in the area emit clicks with different characteristics. While NBHF clicks are long in duration, with many cycles, and all the energy concentrated in high frequencies (Fig. 4), dolphin clicks have fewer cycles (only one or two) and are broadband and short duration (see Cosentino et al. 2022, for a comparison).

On the other hand, the detection classified as "other cetacean" may also be a franciscana, as according to Melcón et al. (2016), juveniles can produce sounds with energy in lower frequencies.

The average number of click trains detected per minute was 3.46 (SD, ±2.84; range, 1–12), with a mean of 17.43 (SD, ± 16.37; range, 5–95) clicks per train. The mean interclick interval (ICI) was 24.76 ms (SD, ±17.19; range, 1.54–110.51). This means that the click production rate within a click train varied between 9 and 647 clicks per second. Tellechea et al. (2017) reported between 25 and 58.8 clicks per second during echolocation events, reaching a maximum of 110 clicks per seconds during "burst pulses" for franciscanas. However, these franciscanas were recorded in Uruguay, in estuarine waters, which may explain the difference, although

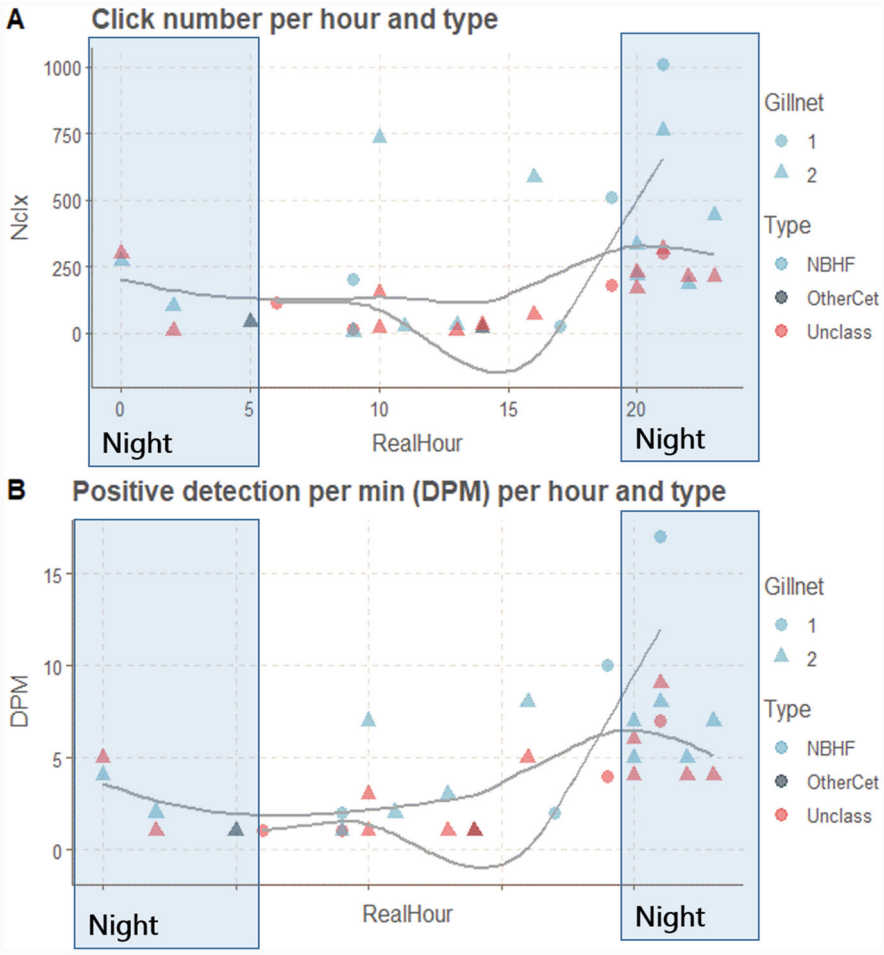

**Fig. 3** Number of click recorded (Nclix) per hour (below) and n. of minutes per hour with detection (DPM) by F-PODs in two fishing gillnets (A and B) in Claromecó (Buenos Aires, Argentina) classified as narrowband high-frequency (NBHF) click other cetacean and unclassified per hour

the equipment was limited to a sampling frequency of 192 kHz. On the other hand, Cremer et al. (2017) reported similar numbers for franciscanas recorded in estuarine waters of Brazil, ranging between 125 and 734 clicks per second. Similarly, Melcón et al. (2012) reported between 23 and 71 clicks per second for echolocation events and between 142 and 250 clicks per seconds for burst pulses.

In other echolocating species, the production rate was found to be related with the behavior of the emitting animal. For example, harbor porpoises typically emit 20–60 clicks per second when moving through the environment, while they reach hundreds of clicks per second when feeding (DeRuiter et al. 2009). Given the existing literature, it is expected that the click production rate differs depending on the behavior of the emitting animal. Further research on this topic is warranted.

## Conclusions

This is the first time that acoustic detectors have been placed in artisanal fishing nets anywhere within the distribution range of franciscanas. The results show that it is possible to monitor the acoustic activity of this species around fishing nets and confirm that they indeed are acoustically active near gillnets. Furthermore, they seem to emit clicks at high repetition rates, which could indicate foraging.

The information derived from these two fishing days can give preliminary information of occurrence, timing, and movement of franciscanas around fishing gear in the coastal marine waters in southern Buenos Aires province. If the higher echolocation rate during twilight hours is confirmed in future studies, this is key information for further protective measures for this species. For example, if franciscanas are present in the area mostly during the night, fishing activity could be restricted to sunlight hours to reduce incidental entanglement.

Therefore, the information derived from this ongoing project will provide valuable information for the design of new mitigation measures based on the differential acoustic response of dolphins to the existence of nets in the area. This first step is key to understanding what mitigation strategy could be better to implement. These results show the importance of passive acoustics as a complementary tool to improve conservation regulations of this vulnerable dolphin and prevent extinction risk.

**Acknowledgments** We would like to thank Chelonia Ltd. (UK) for providing the equipment (F-POD) free of charge, without which, this work could not have been completed. The equipment was provided to the winners of the Bycatch Mitigation Competition (2020) organized by Chelonia Ltd. and Fishtek Marine. We would also like to thank Nick Tregenza for his support to ensure the robustness of the data analysis. We want to thank the fishermen, in particular to the Sologubik family, the Mulder family (Lucas and German), and Gaston Sorensen. For support in the field, we thank Raul Ruiz. This project was funded by BOSS project IT/GR/17/01, dedicated in memory of Dr. Salvatore Mazzola.

**Abstract**

Unknown or variable detection ranges are one of the obstacles to address before being able to derive accurate animal abundance and density estimations from acoustic data alone. Many factors can influence the capability of a device to detect acoustically active animals, and assessing the ability of detectors to receive and identify acoustic cues should therefore be an essential step prior to any passive

acoustic study, especially as it may influence the reliability of results and interpretation of the data. This chapter describes a passive sonar equation-based detection probability model. This passive sonar equation-based model uses state-of-the-art propagation model BELLHOP to simulate the propagation of a specie-specific cue around a given detector. The model, handled by a standalone graphical user interface, allows users to specify environment parameters and source properties. Other environment features, bathymetry and ocean properties, are, respectively, queried from GEBCO_2021 global grid and online Copernicus models. The set of parameters is then used to estimate a detection probability map. The overall objective of the model is to provide any researcher using passive acoustic monitoring with a detection probability specific to their location and their species of interest.

Detection probability · Propagation modelling · Sonar equation · Underwater acoustics · Bio-acoustics

## Introduction

Assessing the population density and abundance of cetaceans is crucial for understanding and protecting these marine mammals. Cetaceans are an important part of ocean ecosystems, and their populations can be affected by a variety of factors such as human activities, climate change, and pollution. By understanding the distribution, abundance, and trends of cetacean populations, better conservation policies and management plans can be implemented to protect and preserve these species for future generations. However, studying cetaceans can be challenging due to their mobility, habitat use, and the limitations of traditional monitoring methods (Zimmer 2011). Therefore, it is essential to develop and use new, efficient methods for assessing cetacean populations. One such method is passive acoustic monitoring (PAM), which is particularly useful for monitoring vocal species. This method is increasingly being used by the scientific community to assess cetacean population density as it provides a noninvasive, cost-effective, and long-term monitoring approach.

The density of a species (which is equivalent to the total number of animals in a given area, the abundance) can be defined as the ratio of the number of individuals by the area they occupy. The size of the area considered plays an important role as it may considerably influence the density result. Estimating the size of the area covered by a single acoustic detector is therefore one of the obstacles to address before being able to derive accurate animal abundance and density estimations from acoustic data alone. Another important parameter required to estimate cetacean density and abundance is the rate at which animals produce sounds (Jacobson et al. 2017). There is little information in the literature about sound production rates of wild

animals as it is difficult to measure this parameter experimentally and this aspect will not be covered by this chapter. Yet, one should remain aware that sound production rates are a potential source of significant bias in density and abundance estimations as some animals may not be detected because of a low sound production rate making them silent while crossing the area monitored.

## Detection Probability Modelling: Theoretical Considerations

### Global Approach

The purpose of this study is to model the detection probability associated with a given detector and a given study (mooring location, deployment period, species of interest). To accurately model the detection probability, one should consider several parameters such as noise level (NL), detection threshold (DT), as well as animal-specific parameters source level (SL), directional loss (DL), and behavior features (position in the water column and head movements). The objective is to produce a 2D probability field around the mooring position. To do so, one can consider a set of 2D profiles corresponding to a set of bearings uniformly distributed around the detector (0° to 360°). The 2D detection probability field can then be derived by modelling a 1D detection probability function $g(r)$ for each 2D profile and by merging the results for the entire set of profiles.

Modelling the detection probability along a 2D profile requires precise information about the transmission loss (TL). This can be achieved by either in situ measurements or numerical modelling using underwater acoustic propagation models. In situ measurements are expensive and time-consuming and therefore cannot be realized for small-scale or low-budget projects. Underwater acoustic modelling, on the other hand, is a reliable and cost-effective approach to estimate the transmission loss and will therefore be used in this project.

### Signals of Interest

Cetaceans produce a large variety of sounds for a variety of purposes (Zimmer 2011) which leads to a large variety of specific detectors. Most studies tend to focus on echolocation clicks using click detectors. Currently, the most commonly used click detectors are continuous porpoise detectors (C-PODs) which are fully automatic, static, passive monitoring systems that recognize click trains of porpoises, dolphins, and other toothed whales. The detection probability model developed focuses on echolocation clicks similar to the type of click emitted by porpoises. In other words, the model can be considered to be dedicated to species emitting narrow-band and relatively high-frequency clicks. (The range of validity of the model could be widened in the future.)

## Sound Propagation Modelling

A large variety of sound propagation models (computer solutions to the wave equation) have been developed over time. As most vocalizing species (the acoustic sources of interest) produce sound at high frequencies (few kilohertz or above), the infinite-frequency approximation, ray theory, is the most suitable kind of model for the purpose of this study. The ray model considered is the model BELLHOP.

BELLHOP is a state-of-the-art beam-tracing model for predicting acoustic pressure fields in ocean environments. This acoustic ray theory-based model uses a finite number of acoustic rays emanating from a source to derive a transmission loss field. This model is particularly suitable for high frequencies and allows for range dependence in the top and bottom boundaries as well as in the sound speed profile (Porter 2011). The ray theory is based on a high-frequency approximation and therefore can only produce reasonably accurate results in the region of validity of this approximation. A first-order assumption as well as an often-quoted rule is that the acoustic wavelength should be substantially smaller than any physical scale in the problem (Jensen et al. 2011). Therefore, the wavelength should be small compared to the water depth and the bathymetric features of the area of interest.

## Reciprocity Hypothesis

The situation to model can be described as follows:

- A detector is moored at the position ($lon_{mooring}$, $lat_{mooring}$).
- A vocalizing animal is located at a random position ($lon_{animal}$, $lat_{animal}$).
- The objective is to model the probability of a single click emitted by the animal to be detected by the detector.

This situation is represented in Fig. 1 where the propagation of sound goes from the right side to the left side.

In order to estimate the detection function $g(r)$ along the profile (x-axis), one needs to compute the transmission loss at the receiver location (*blue point* on Fig. 1) for a large set of random positions of the source along the profile. Such a strategy, although theoretically feasible, is far from realistic in terms of time and computational effort. Thus, to model this situation for all range of bearings ([0°, 360°]), it is convenient to consider the reciprocal situation where the positions of the vocalizing animal and the detector are exchanged.

The wave equation from which the BELLHOP model is derived offers a very useful property which is reciprocity. This means that, in a given environment, the positions of the source and the receiver can be exchanged without modifying the received field (Jensen et al. 2011). One can show that the ray theory, which is only an approximate solution of the wave equation, preserves the reciprocity property (Jensen et al. 2011).

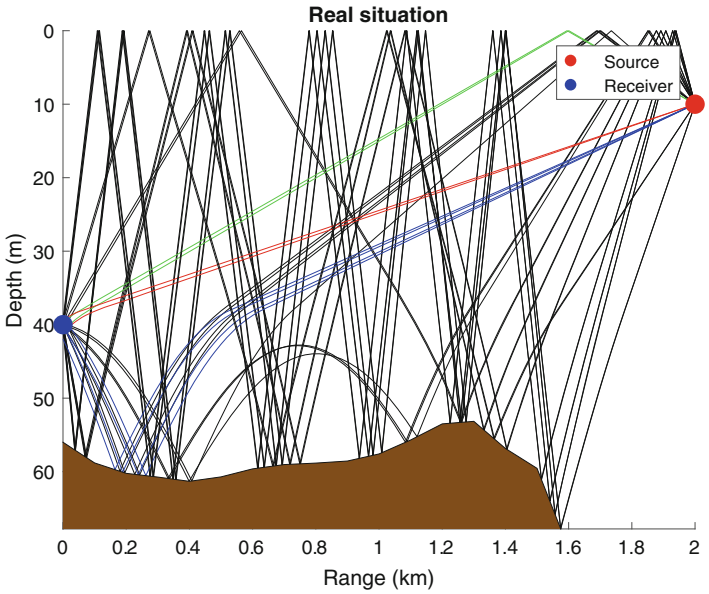

**Fig. 1** Real situation to model. *Red point*, vocalizing animal; *blue point*, detector. *Green lines*, rays hitting surface only; *blue lines*, rays hitting bottom only; *red lines*, direct path from the source to receiver

Considering the reciprocity property, the situation modelled can now be described as follows:

- A vocalizing animal is located at the mooring position ($lon_{mooring}$, $lat_{mooring}$).
- A detector is located at a random position ($lon_{animal}$, $lat_{animal}$).
- The objective is to model the probability of a single click emitted by the animal to be detected by the detector.

In this situation, the transmission loss can be evaluated at different positions of the receiver along the profile with a single simulation (single position of the source).

## Sonar Equation Approach

A usual way to estimate the performances of a PAM device is to use the sonar equation. As devices considered in the model are passive ones, the sonar equation is used in its passive form as stated in Eq. (1). Because it is customary to use decibels in underwater acoustics, all equations presented below are expressed in decibels and thus appear as additive terms. All detectors are assumed to be omni-directional, and no detector processing gain is considered here. Sound sources considered in the model are all assumed to be rotationally invariant (relative to the acoustic axis) so

that quantities relative to the apparent source level (SL) only depend on the off-axis angle which is the angle between the acoustic axis and the direction of the receiver (Zimmer 2011).

$$\mathrm{SE}(\theta, r) = \mathrm{SNR}(\theta, r) - \mathrm{DT} \tag{1}$$

In this equation signal, excess SE corresponds to the difference between the signal-to-noise ratio SNR and the minimal signal level for detection, detection threshold DT. Therefore, a detection occurs if SNR is greater than DT. In other words, a detection occurs if SE $\geq 0$. This equation can be reformulated in Eq. (2)

$$\mathrm{SE}(\theta, r) = \mathrm{ASL}(\theta) - \mathrm{TL}(r) - \mathrm{NL} - \mathrm{DT} \tag{2}$$

where $\theta$ is the off-axis angle and $r$ is the x-axis coordinate along the profile. ASL($\theta$) is the apparent source level (ASL) defined as

$$\mathrm{ASL}(\theta) = \mathrm{SL}_0 - \mathrm{DL}(\theta) \tag{3}$$

with $\mathrm{SL}_0$ the source level on the source main acoustic axis (on-axis) and DL($\theta$) the directional loss for the off-axis angle $\theta$. NL is the ambient noise level.

The 2D TL($r$, $z$) map provided by BELLHOP needs to be reduced to a 1D vector only depending on the $r$ coordinate. To do so, each column of the TL($r$, $z$) map is reduced to the Gaussian weighted mean TL over depth. In other words, considering that the animal is usually swimming at a depth $d$ (mean living depth) with a uncertainty of $\sigma_d$, for a given distance $r$ to the mooring, TL($r$) is defined by

$$\mathrm{TL}(r) = \frac{\sum_i \omega_i \mathrm{TL}(r, i)}{\sum_i \omega_i} \tag{4}$$

where the weights $(\omega_i)_i$ are normally distributed: $(\omega_i)_i \sim \mathcal{N}\left(d, \sigma_d^2\right)$.

It is important to note that in Eq. (2), $\mathrm{SL}_0$ and NL need to be defined with respect to the same reference pressure and frequency bandwidth (usually one should consider a one-third octave band).

Another useful quantity to define is the figure of merit FOM which is the transmission loss that gives a zero signal excess (Jensen et al. 2011).

$$\mathrm{FOM} = \mathrm{SL}_0 - \mathrm{NL} - \mathrm{DT} \tag{5}$$

The on-axis source level is assumed to be normally distributed around the average value $\mathrm{SL}_0$ with a standard deviation $\sigma_{\mathrm{SL}}$. Hence, one can rewrite (5)

$$\mathrm{FOM}(\xi) = \xi - \mathrm{NL} - \mathrm{DT} \tag{6}$$

where $\xi \sim \mathcal{N}\left(\mathrm{SL}_0, \sigma_{\mathrm{SL}}^2\right)$. Equation (2) may then be written as

$$\mathrm{SE}(r, \theta) = \mathrm{FOM}(\xi) - \mathrm{TL}(r) - \mathrm{DL}(\theta) \tag{7}$$

Using the previous definitions, one can finally define the detection function

$$g(r) = \int_{-\infty}^{+\infty} \omega_{\mathrm{SL}}(\xi)\ P[\mathrm{SE}(r,\theta) > 0]\ d\xi \tag{8}$$

where $\omega_{\mathrm{SL}}(\xi)$ is the probability density function of the on-axis source level and can be expressed as

$$\omega_{\mathrm{SL}}(\xi) = \frac{1}{\sigma_{\mathrm{SL}}\sqrt{2\pi}} \exp\left\{ -\frac{1}{2}\left( \frac{\xi - \mathrm{SL}_0}{\sigma_{\mathrm{SL}}} \right)^2 \right\} \tag{9}$$

The quantity $P[\mathrm{SE}(r, \theta) > 0]$ is the probability for a signal emitted by a source with an on-axis source level $\mathrm{SL}_0(\xi)$ in a direction resulting in an off-axis angle $\theta$ to be detected. This equation is equivalent to Eq. (10).

$$g(r) = \int_{-\infty}^{+\infty} \omega_{\mathrm{SL}}(\xi) P[\mathrm{FOM}(\xi) - \mathrm{TL}(r) > \mathrm{DL}(\theta)]\ d\xi \tag{10}$$

For a given pair $(\xi, r)$, the probability $P[\mathrm{FOM}(\xi)–\mathrm{TL}(r) > \mathrm{DL}(\theta)]$ can be derived by integrating the off-axis angle distribution $\omega_{\mathrm{OA}}(\theta)$ over all angles matching the condition $\mathrm{FOM}(\xi) - \mathrm{TL}(r) > \mathrm{DL}(\theta)$.

$$P[\mathrm{FOM}(\xi) - \mathrm{TL}(r) > \mathrm{DL}(\theta)] = \int\limits_{\mathrm{FOM}(\xi)-\mathrm{TL}(r)>\mathrm{DL}(\theta)} \omega_{\mathrm{OA}}(\theta)\ d\theta \tag{11}$$

For a directional loss function, $\mathrm{DL} : \theta \mapsto \mathrm{DL}(\theta)$ bijective on the interval $[0, \mathrm{DL}_{\max}]$ (11) becomes

$$P[\mathrm{FOM}(\xi) - \mathrm{TL}(r) > \mathrm{DL}(\theta)] = \int_0^{\mathrm{DL}^{-1}(\mathrm{FOM}(\xi)-\mathrm{TL}(r))} \omega_{\mathrm{OA}}(\theta)\ d\theta \tag{12}$$

where the term $\mathrm{FOM}(\xi) - \mathrm{TL}(r)$ is limited to values less than $\mathrm{DL}_{\max}$. For values greater than $\mathrm{DL}_{\max}$, the condition $\mathrm{FOM}(\xi) –\mathrm{TL}(r) > \mathrm{DL}(\theta)$ holds for all angles $\theta$, cues will be detected from all angles, and $P[\mathrm{FOM}(\xi) - \mathrm{TL}(r) > \mathrm{DL}(\theta)] = 1$. Considering (12), (10) can be written as

$$g(r) = \int_{-\infty}^{+\infty} \omega_{\mathrm{SL}}(\xi) \left( \int_0^{\mathrm{DL}^{-1}(\mathrm{FOM}(\xi)-\mathrm{TL}(r))} \omega_{\mathrm{OA}}(\theta)\ d\theta \right) d\xi \tag{13}$$

The figure of merit can be written as

$$\mathrm{FOM}(\xi) = \xi - F_0 \tag{14}$$

where $F_0 = \mathrm{NL} + \mathrm{TH}$ describes the environmental and PAM system parameters. The nominal figure of merit is then defined as

$$\mathrm{FOM}_0 = \mathrm{SL}_0 - F_0 \tag{15}$$

In order to derive (13), three cases can be differentiated:

1. $\xi < F_0 + \mathrm{TL}(r)$ no detection is possible.
2. $F_0 + \mathrm{TL}(r) < \xi < F_0 + \mathrm{TL}(r) + \mathrm{DL}_{\max}$ cues can potentially be detected.
3. $\xi > F_0 + \mathrm{TL}(r) + \mathrm{DL}_{\max}$ detection always occurs.

For case n°1,

$$P[\mathrm{FOM}(\xi) - \mathrm{TL}(r) > \mathrm{DL}(\theta)] = 0 \tag{16}$$

and (13) reduces to

$$\begin{aligned} g(r) = &\int_{F_0+\mathrm{TL}(r)}^{F_0+\mathrm{TL}(r)+\mathrm{DL}_{\max}} \omega_{\mathrm{SL}}(\xi) \left( \int_0^{\mathrm{DL}^{-1}(\xi - F_0 - \mathrm{TL}(r))} \omega_{\mathrm{OA}}(\theta)\, d\theta \right) d\xi \\ &+ \int_{F_0+\mathrm{TL}(r)+\mathrm{DL}_{\max}}^{+\infty} \omega_{\mathrm{SL}}(\xi)\, d\xi \end{aligned} \tag{17}$$

With the following notations,

$$\Phi : x \mapsto \int_x^{+\infty} \omega_{\mathrm{SL}}(\xi)\, d\xi \tag{18}$$

$$u = \xi - F_0 - \mathrm{TL}(r) \tag{19}$$

(17) can be written as

$$\begin{aligned} g(r) = &\phi(F_0 + \mathrm{TL}(r) + \mathrm{DL}_{\max}) \\ &+ \int_0^{\mathrm{DL}_{\max}} \omega_{\mathrm{SL}}(u + F_0 + \mathrm{TL}(r)) \left( \int_0^{\mathrm{DL}^{-1}(u)} \omega_{\mathrm{OA}}(\theta)\, d\theta \right) du \end{aligned} \tag{20}$$

The first term of Eq. (20) is independent of off-axis angles and integrates over all source levels for which detections occur (Zimmer 2011). Considering the source-level distribution defined by Eq. (9), one can write

$$\omega_{\mathrm{SL}}(u + F_0 + \mathrm{TL}(r)) = \frac{1}{\sqrt{2\pi}\sigma_{\mathrm{SL}}} \exp\left\{ -\frac{1}{2} \left( \frac{u + \mathrm{TL}(r) - \mathrm{FOM}_0}{\sigma_{\mathrm{SL}}} \right)^2 \right\} \tag{21}$$

With this last equation, the detection function can finally be written as

$$g(r) = \Phi(F_0 + \mathrm{TL}(r) + \mathrm{DL}_{\max}) + \frac{1}{\sigma_{\mathrm{SL}}\sqrt{2\pi}} \int_0^{\mathrm{DL}_{\max}} \exp\left\{-\frac{1}{2}\left(\frac{u + \mathrm{TL}(r) - \mathrm{FOM}_0}{\sigma_{\mathrm{SL}}}\right)^2\right\} \left(\int_0^{\mathrm{DL}^{-1}(u)} \omega_{\mathrm{OA}}(\theta)\, d\theta\right) du \tag{22}$$

where the second term of the equation handles the cases where the off-axis has an impact on the detection probability.

To derive this quantity, the off-axis attenuation DL and the off-axis distribution $\omega_{OA}$ need to be defined explicitly.

## Off-Axis Attenuation

Echolocation signals emitted by cetaceans can be classified into two categories, brief broadband signals (40–70 $\mu$s) such as clicks emitted by dolphins and longer narrow-band signals (greater than 100 $\mu$s) emitted by species such as harbor porpoises (Au et al. 1999). Usually, signals from both categories are directional which means that the source is not radiating the same amount of energy in every direction. Thus, the ASL needs to be taken into account when considering the detection probability (Macaulay et al. 2020). As stated in Eq. (3), the ASL depends on the on-axis source level and the DL pattern of the source. This last quantity is usually referred to as the off-axis attenuation.

Limiting this study to the sound beam of odontocetes, the sound projector can be modelled by a plane circular piston of radius $a$. The directivity pattern of a circular piston source of radius $a$ is given by Eq. (23) (Zimmer 2011).

$$\mathrm{D}(\theta) = \left[\frac{2\mathrm{J}_1(\mathrm{ka}\ \sin(\theta)}{\mathrm{ka}\ \sin(\theta)}\right]^2, \theta \in \left[-\frac{\pi}{2}, \frac{\pi}{2}\right] \tag{23}$$

where $J_1$ is the first-order Bessel function of the first kind. As previously mentioned, due to rotational symmetry, this expression only depends on the off-axis angle $\theta$. The DL function is then defined as

$$\mathrm{DL}(\theta) = -10 \log_{10}(D(\theta)) \tag{24}$$

As most studies concerning odontocetes' acoustic signals provide directional index (DI) values, it is convenient to express DL as a function of this property. For a circular piston model with $ka \gg 1$ (high directionality),

$$\mathrm{DI} \approx 20\ \log_{10}(\mathrm{ka}) \tag{25}$$

Hence,

$$\mathrm{DL}(\theta) = -10 \ \log\left(\left[\frac{2J_1\left(10^{\mathrm{DI}/20}\sin(\theta)\right)}{10^{\mathrm{DI}/20}\sin(\theta)}\right]^2\right) \tag{26}$$

This function is not bijective and needs to be approximated in order to be used to derive the detection function.

### Narrow-Band Approximation

To derive detection probability, the off-axis attenuation (DL) function must be reversible on the interval [0°, 90°] (as stated in Eq. (12)). The circular piston model can be transformed into a bijective function by limiting the model to the main lobe. Yet, as (Macaulay et al. 2020) puts it forward a main lobe ([−30°, 30°]) piston model with no side energy largely underestimates detection probability. Moreover, while the piston model cannot mathematically describe off-axis angles greater than 90°, click energy is radiated at those extreme off-axis angles (Macaulay et al. 2020). In order to get a full 360° ASL pattern, the back beam is set to the lowest value of the narrow-band piston model (approximately −35 dB for a directivity index of 23.5 dB).

Thus, the model considered here is a hybrid model built as described below:

1. The circular piston model presented in Eq. (23) is considered.
2. A zero finding algorithm is then used to find the knots of the $\mathrm{DL}_{\mathrm{nb}}$ function by finding the zeros of the numerator.
3. The $\mathrm{DL}_{\mathrm{nb}}$ model is then modified to fit with the injectivity requirement as follows:

$$\mathrm{DL}_{\mathrm{modified}}(\theta) = \begin{cases} \mathrm{DL}_{\mathrm{nb}}(\theta), & \theta \leq \theta_{\mathrm{mainlobe}} \\ \mathrm{DL}_{\mathrm{nb}}\left(\theta = \frac{pi}{2}\right), & \theta \geq \frac{\pi}{2} \\ \mathrm{DL}_{\mathrm{slope}}(\theta), & \theta_{\mathrm{knot2}} < \theta < \frac{\pi}{2} \\ \mathrm{DL}_{\mathrm{interp}}(\theta), & \theta_{\mathrm{mainlobe}} < \theta < \theta_{\mathrm{knot2}} \end{cases} \tag{27}$$

where $\mathrm{DL}_{\mathrm{slope}}(\theta)$ corresponds to $\mathrm{DL}_{\mathrm{nb}}\left(\theta = \frac{pi}{2}\right)$ to which has been added a light decreasing slope to make it injective on the interval $\left[\theta_{\mathrm{knot2}}, \frac{\pi}{2}\right]$. $\theta_{\mathrm{mainlobe}}$ is defined as the greatest angle verifying condition (28)

$$\begin{cases} \theta \leq \theta_{\mathrm{knot1}} \\ \mathrm{DL}_{\mathrm{nb}}(\theta) > \mathrm{DL}_{\mathrm{nb}}\left(\theta = \frac{\pi}{2}\right) \end{cases} \tag{28}$$

and $\mathrm{DL}_{\mathrm{interp}}(\theta)$ is an interpolated value using *pchip* interpolation method.

The piston model and the narrow-band piston model are illustrated below (Fig. 2). One should note that the little decrease of the detection range (white line) next to the

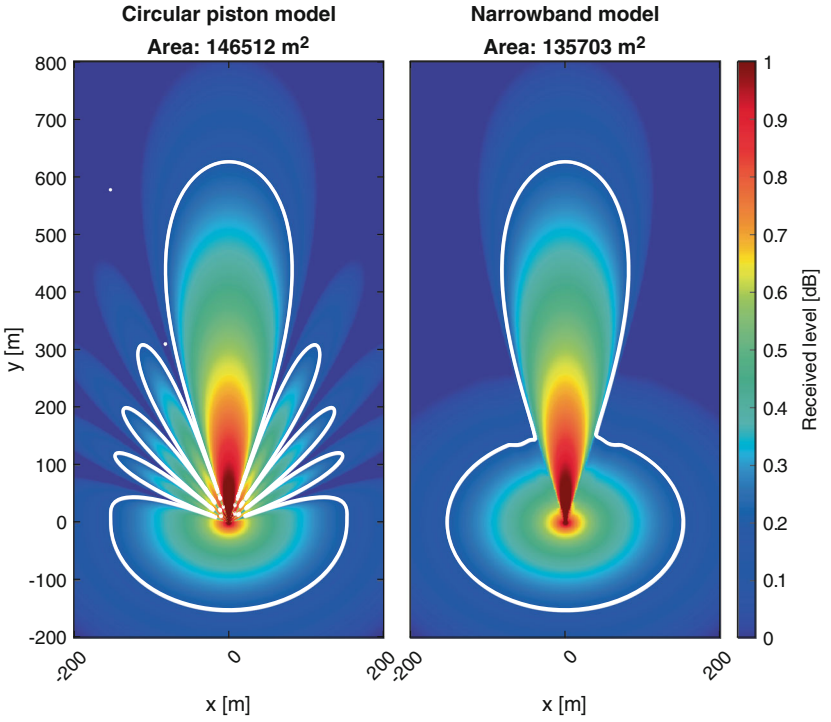

**Fig. 2** Received level computed for a source located at (0,0), facing the y-direction and emitting an echolocation click with $SL_0 = 191$ dB pp re 1 $\mu$Pa @ 1 m and DI = 23.5 dB

main lobe (narrow-band model) is due to an interpolation artifact (for visualization purpose only) and does not represent any knots in the DL pattern.

The white line indicates what the detectable area would be for a PAM study using an automated detection algorithm with a peak-to-peak threshold of 110 dB re 1 $\mu$Pa pp. Received level has been derived assuming a spherical transmission loss law $TL = 20 \log_{10}(R) + \alpha R$ where the absorption coefficient $\alpha$ is set to a casual value of 0.04 dB/m. This configuration is set to be comparable with the porpoise pattern presented in (Macaulay et al. 2020).

## Off-Axis Distribution

In order to model the detection function, one should also consider the off-axis distribution. Two different cases are considered here based on the models presented in (Zimmer 2011). The user of the model can either model the detection probability of arbitrary click considering a uniform spherical distribution or consider the detection probability of click emitted by an animal generally heading toward the detector.

### Uniform Spherical Distribution

Considering that there is no preference in off-axis angles $\theta$ between the source on-axis and the detector direction, the off-axis distribution can be modelled by a uniform spherical distribution (Zimmer 2011).

$$\omega_{\mathrm{OA_A}}(\theta) = \frac{1}{2}\sin\theta \tag{29}$$

### Near On-Axis Distribution

As clicks are more likely to be detected if the animal heads toward the detector, one can also consider a near on-axis distribution. To model this distribution, small variations of the off-axis angles around the main acoustic beam direction due to head motion are considered. To do so, head movements are assumed to be distributed around the nominal on-axis without vertical or horizontal preference. Therefore, off-axis can be modelled by a Rayleigh distribution:

$$\omega_{\mathrm{OA_H}}(\theta) = \frac{\theta}{\sigma_H^2}\exp\left\{-\frac{1}{2}\left(\frac{\theta}{\sigma_H}\right)^2\right\} \tag{30}$$

## Gathering Data

Once the mathematical aspect is implemented, one needs to gather data relative to the situation the user of the model is willing to simulate. Indeed, as shown in section "Detection Probability Modelling: Theoretical Considerations," the model requires several information about the environment to run.

### Environment Data

Sound propagation in the ocean is a very complex phenomenon which is influenced by physical and chemical properties of the medium. Even though the real world can't be accurately described with a finite number of parameters, a sufficient accuracy can be obtained by taking into account main properties influencing the sound propagation. To simulate propagation, the program uses bathymetry data, ocean properties, seabed properties, as well as ambient noise information. In this section, the different sources of information used by the app to run will be presented.

### Bathymetry

Bathymetry can have a significant impact on the propagation of the sound in the ocean. Thus, bathymetric features such as seabed slopes or seamount must be correctly described in order to accurately estimate the transmission loss.

To do so, the model offers two options:

- The users have a bathymetric file describing the area of interest. This file can be then used as an input file (csv or netcdf format required).
- Bathymetry surveys are usually expensive, and therefore, it can be convenient to use a global model. With no user file provided, the bathymetry of the area of interest is automatically retrieved from the GEBCO_2021 global grid.

## Ocean Properties

The transmission loss may be considered to be the sum of two components: the loss due to the geometrical spreading and the loss due to attenuation (Jensen et al. 2011). The geometrical spreading, which traduces the fact that the signal is weakening as it propagates outward from the source, is driven by the geometry of the propagation environment and in a weaker way by the sound speed profile (SSP). The loss due to attenuation can result from either volume attenuation in the water column or loss due to bottom or surface reflections. This second component of the transmission loss is influenced by two factors: the absorption coefficient, usually written $\alpha$ (in dB/km or dB/wavelength), which describes how fast the signal weakens while propagating and drives the volume attenuation, and the SSP which curves ray paths influencing reflections on boundaries (inducing reflection losses) and path length (driving the total volume attenuation along the path).

### Sound Speed Profile

The Mackenzie Eq. (Mackenzie 1981) is used to derive the sound speed profile as a function of temperature, salinity, and depth. Temperature and salinity are automatically queried from online models produced by Copernicus Marine Environment Monitoring Service (CMEMS) for the location of the mooring and the corresponding deployment period. Data are collected from the Global Sea Physical Analysis and Forecasting Product *global_analysis_forecast_phy_001_024*.

### Absorption Coefficient

Similar to the SSP, the absorption coefficient is derived using an empirical formula. The formula used here is the Francois and Garrison formula (Francois and Garrison 1982). As for temperature and salinity, the pH is queried from CMEMS online database with the *globalanalysis-forecast-bio-001-028-daily* model.

## Seabed Properties

As mentioned in section "Bathymetry," reflection of the sound on the seabed needs to be taken into account in order to accurately estimate TL. The type of sediment covering the area of interest can be selected among a list of five: *boulders and bedrock*, *coarse sediment*, *mixed sediment*, *muddy sand and sand*, and *mud and sandy mud*. The classification used is based on the folk 7-class classification from the European Marine Observation and Data Network (EMODnet).

The values associated with each type of sediment are described in Table 1.

**Table 1** Sediment characteristics

| Sediment type | Density ($ton.m^{-3}$) | CWC ($m.s^{-1}$) | CWA ($dB.\lambda^{-1}$) |
|---|---|---|---|
| *Boulders and bedrock* | 2.50 | 3820 | 0.75 |
| *Coarse sediment* | 2.37 | 2122 | 0.88 |
| *Mixed sediment* | 2.03 | 1855 | 0.89 |
| *Muddy sand and sand* | 1.53 | 1708 | 0.91 |
| *Mud and sandy mud* | 1.16 | 1517 | 0.37 |

## Ambient Noise Level

The last parameter to influence the detectability of the signal is the ambient noise level NL. Indeed, as stated in section "Sonar Equation Approach," a signal is assumed to be detected if and only if the SNR of the received level is greater than the DT associated with the detector.

### Root Mean Square Sound Pressure Level

Because of the growing necessity to assess the ambient noise level, a lot of studies use a continuous recorder as an extra recorder in order to monitor the NL in the area monitored by click detectors such as C-PODs. Therefore, the ambient noise level can be estimated from recordings within the app. The metric considered is the average root mean square SPL over the entire recorded period. As the noise level depends on environmental (rain, wind, biologic sources) and anthropogenic factors (traffic intensity, offshore construction), one should consider an audio file extending over a long period.

### Wenz Model

As mentioned earlier, continuous recorders are expensive devices and cannot always be used. For studies with no broadband recordings available, the ambient noise level can be integrated from Wenz curve for an octave band centered on the signal frequency.

## Preliminary Results

In order to evaluate the performance of the model, the estimated detection probability needs to be compared to empirical values for a known configuration. To do so, a first test case is considered. Please note that the configurations modelled are specific to the present study and therefore cannot guarantee the accuracy of the model outside of this scenario. The user is strongly advised to read the results with caution and should keep in mind that some computing artifacts could potentially lead to inaccurate results.

In order to evaluate the accuracy of the model, two metrics are defined:

1. Effective detection range (EDR) is defined here as the mean 50% detection range (maximum range having a detection probability greater than 0.5) over all bearings.
2. Maximum detection range (MDR) is defined here as the mean 5% detection range (maximum range having a detection probability greater than 0.05) over all bearings.

## Test Case 1

The first test case considered is based on a published study (Nuuttila et al. 2018). This study evaluates the detector performance of C-PODs using artificial and recorded harbor porpoise clicks played at a range of distances and source levels. A network of C-PODs located off New Quay headland on the west coast of Wales was used to estimate the click detection probability as a function of distance. The two types of clicks (artificial and recorded) are treated as two different test cases: test case 1a and test case 1b. Test case 1b is the most likely to fit with reality and will therefore be the only one presented in this chapter.

In the paper (Nuuttila et al. 2018), several C-PODs are used to accurately estimate the detection probability. As none of the exact positions are given, an approximate position is considered $(lon, lat) = (-4.370°, 52.225°)$. For both test cases (1a and 1b), the bathymetry is automatically queried from GEBCO_2021 global model for a 2.5 km box centered on the mooring position. As mentioned in (Nuuttila et al. 2018), the C-PODs are deployed 1.5 m above the seabed from 26/04/2012 to 04/05/2012. According to (Nuuttila et al. 2018), the area presents "a generally even, sandy bottom" substrate. Therefore, the seabed property is set to *muddy sand and sand*.

The C-POD manufacturer does not provide any information on the way the detection is affected by ambient noise, though some papers (Dähne et al. 2013; Nuuttila et al. 2018) do evaluate the detection threshold of those detectors as a SPL detection threshold. In other words, the detection threshold estimated in the literature is independent from the noise level. With such a detection threshold, 1 is still valid (SNR is replaced by RL and the casual DT by a detection threshold in terms of received level). The model can then run with $NL = 0$.

The peak-to-peak detection threshold measured by calibration by (Nuuttila et al. 2018) varies from 111 dB to 119 dB re 1 $\mu$Pa peak to peak (pp) (at 130 kHz) across the C-PODs used in the study. The average value of 114 dB re 1 $\mu$Pa pp is used here. (This value is in line with the one given by (Dähne et al. 2013), 114.5 +/− 1.2 dB re 1 µPa pp at 130 kHz.)

### Test Case 1 Settings

The common properties of test cases 1a and 1b are described in Table 2.

**Table 2** Test case 1 – common properties

| Property | Value |
|---|---|
| Frequency | 130 kHz |
| Living depth | 2 m |
| Living depth std | 0.5 m |
| Maximum detection range | 1500 m |
| Detection threshold | 114 dB pp re 1$\mu$Pa |

**Table 3** Porpoise recorded clicks' properties – test case 1b

| Property | Value |
|---|---|
| Source level | 156 dB pp re 1$\mu$Pa @ 1 m |
| Source level std | 9 dB pp re 1$\mu$Pa @ 1 m |
| Directivity index | 23.5 dB |

**Table 4** Porpoise recorded clicks' off-axis properties – test case 1b

| Property | Model | Note |
|---|---|---|
| Off-axis distribution model | Near on-axis | Head movement simulated |
| Off-axis attenuation model | Narrow-band | Directional transducer |

**Table 5** Test case 1b – results

| Metric | Simulation | Reference | Difference | Relative difference (%) |
|---|---|---|---|---|
| EDR | 167 m | 188 m | 21 m | 11.2 |
| MDR | 519 m | 566 m | 47 m | 8.3 |

## Test Case 1b: Recorded Clicks

In test case 1b, recorded clicks (with source levels between 130 and 182 dB re 1 $\mu$Pa) from captive porpoises are played through a calibrated directional transducer, a Reson TC2130. The directional transducer has a narrow beam (about 12.3°) used to replicate the directionality and beam width of a real porpoise. During playbacks, the transducer is continuously rotated from side to side horizontally in an arc of approximately 90° centered on the middle of each C-POD station imitating the sweeping movement of a porpoise head. Properties of test case 1b are presented in Tables 3 and 4.

Simulation results for test case 1b are presented in Table 5.

The model shows a satisfactory accordance with the results from (Nuuttila et al. 2018). MDR error might be due to the definition of the metric. Adjusting the probability threshold (5%) used to derive MDR may lead to a better fit with the empirical results. The probability map describing the probability of a modelled porpoise to be detected according to its position is represented below (Fig. 3).

The detection probability is nearly isotropic due to the nearly flat bottom and the smooth SSP (no acoustic channel).

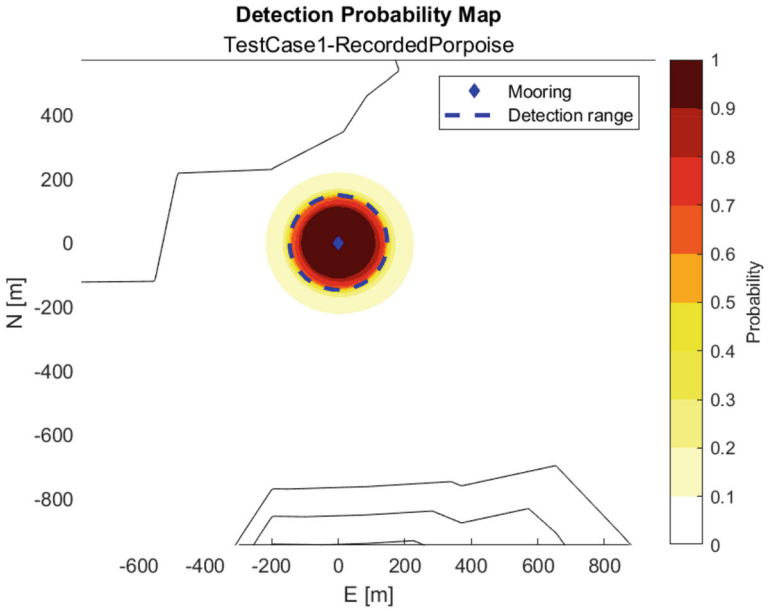

**Fig. 3** Detection probability map – test case 1

## Conclusion

The increasing number of endangered species and unsustainable population declines highlight the need for a better understanding of their distribution and habitat use. To effectively protect these animals, it is crucial to fill the knowledge gaps by acquiring relevant data. PAM, using affordable click detectors like C-PODs, has become an essential technique for studying vocalizing cetaceans. However, there are several challenges that can impede accurate density estimations. One important factor is the estimation of the effective detection area, which directly affects data processing and survey design. A model has been developed to address this issue, and it is handled by a standalone app, which provides tools for modelling the detection probability, offering full control over the different parameters.

It should be noted that the results presented here are preliminary. While the model shows relatively satisfactory results for the first test case considered, it is essential to keep in mind that the signals considered are recorded clicks and may not be representative of real click detection. Furthermore, the accuracy of the model should be tested against a range of frequencies and locations. Finding studies that estimate the detection function while providing enough information to be modelled has been a difficult task and remains the main obstacle to further testing. Ideally, the model should be tested against a dedicated measurement campaign to control all the parameters of the model.

**Abstract**

Bottlenose dolphins (*Tursiops truncatus*) produce individually distinctive signature whistles that develop early in life and are used to recognize and maintain contact with conspecifics. Health assessments in Sarasota, Florida (USA), have provided a unique opportunity to record signature whistles of wild individuals of known age, sex, and matrilineal relationships. After 37 years, the Sarasota Dolphin recording library contains 930 recording sessions of 296 individual dolphins. Here, a deep convolutional neural network classifier was trained using a curated subset of 200 different signature whistles from each of

70 individual bottlenose dolphins. A MobileNetV2 trained on spectrogram data allocated signature whistles to the correct individual with an accuracy of 95.8%. To improve generalization to novel audio datasets, a data augmentation step was implemented that incorporated time stretching, pitch shifting, and mixing database whistles with natural background noise recordings. This augmented model achieved a classification accuracy of 94.5% for high signal-to-noise ratio (SNR) signature whistles, and 92.6% under more realistic conditions with signature whistles mixed with ambient noise at −6 to 12 dB SNR. These initial results are promising and suggest that automatic signature whistle classification techniques could enable acoustic monitoring of movements and habitat use of individual bottlenose dolphins at scale.

## Introduction

Bottlenose dolphins (*Tursiops truncatus* and *Tursiops aduncus*) produce individually distinctive signature whistles (Caldwell and Caldwell 1965; Caldwell et al. 1990; Gridley et al. 2014) that are recognized by familiar conspecifics (Sayigh et al. 1999) and serve to mediate contact and cohesion among individuals (Janik and Slater 1998; Quick and Janik 2012) as well as to maintain social bonds (Chereskin et al. 2022). Signature whistles are learned early in life and generally remain stable across an animal's lifetime (Sayigh et al. 1990, 2022), facilitating maintenance of differentiated social relationships in complex, cooperative societies (King et al. 2018).

Free-ranging animals produce a range of different whistle types, but on average some 38–70% of all whistles tend to be signature whistles (Buckstaff 2004; Cook et al. 2004; Watwood et al. 2005), and these can typically be differentiated from other whistle types through their temporal bout structure (Janik et al. 2013). Combined with acoustic localization (Quick et al. 2008), this can enable identification of signature whistles from wild animals given enough time spent following individuals (King et al. 2018). However, signature whistles typically account for more than 80% of emitted whistles when animals are isolated from conspecifics (Caldwell et al. 1990; Sayigh et al. 2007), making it much easier to identify the signature whistle of each individual in such contexts.

Sarasota Bay (Florida, USA) constitutes a natural laboratory in which to study wild bottlenose dolphins. The resident community of common bottlenose dolphins (*Tursiops truncatus*) has been studied for more than 50 years as part of a long-term research program (Wells 2020). Periodic brief catch-and-release events that are part of this program have enabled development of a unique dataset of whistles recorded from specific, known individuals with suction cup hydrophones (Fig. 1). Over more than 37 years, the authors have built a recording library that consists of 930 recording sessions of 296 individual dolphins. Of these dolphins, 58% have been recorded more than once (up to 18 times), and half of these (29%) have been recorded over a

**Fig. 1** Bottlenose dolphin being recorded with a suction cup hydrophone on the melon while being temporarily held during health assessments in Sarasota Bay, Florida. (Photo taken by the Chicago Zoological Society's Sarasota Dolphin Research Program under NOAA/National Marine Fisheries Service Scientific Research Permit #15543 to Dr. R. Wells)

decade or more. This recording library is now being converted into a systematic resource, the Sarasota Dolphin Whistle Database (SDWD), containing thousands of validated signature whistles from known animals. The intent of this database is to provide a curated dataset of known dolphin signature whistles from which to train and assess performance of automated algorithms for classification of dolphin signature whistles, in particular deep learning-based algorithms that tend to require large datasets for training and validating models.

Since bottlenose dolphins use signature whistles for identifying conspecifics, they provide an ideal study species to non-invasively track individual animals and even estimate population density acoustically by eavesdropping on their communication system (Longden et al. 2020). However, to do this at scale, automated methods are needed to extract whistles and to identify and classify signature whistles. Traditionally, this has been done by visual inspection of spectrograms and comparison to established catalogues (Sayigh et al. 2022). Several machine learning approaches have been implemented to automate the process, mainly based on dynamic time-warp contour similarity (Buck and Tyack 1993), since the contour has been shown to carry identity information (Janik et al. 2006). Neural network-based algorithms such as ARTWARP (Deecke and Janik 2006) in combination with temporal sequencing information through the SIGID method (Janik et al. 2013) show promise for identifying animal call repertoires (Janik and Oswald 2022). But despite these advances, contour-based methods for identifying signature whistles still have issues – they require an intermediate contour extraction step, and there is still a performance gap between such approaches and visual classification (Kershenbaum et al. 2013; Sayigh et al. 2007).

Recently, deep learning approaches to audio classification have shown performance far beyond many traditional acoustic detection algorithms (Shiu et al. 2020), and deep learning-based detection and classification algorithms have been applied to species from rats (Coffey et al. 2019) to orcas (Bergler et al. 2019) and beyond. The benefits of deep learning-based classification of audio signals are that they can operate directly on time-frequency representations of audio signals, and that they have the capacity to learn to classify signals based on complex time-frequency patterns. Thus, given appropriate training, deep learning-based classifiers might be able to pick up on similar features that humans use for visual classification of signature whistles. Therefore, the objectives of this study are to (1) quantify classification performance of dolphin signature whistles using a deep neural net and (2) evaluate both trade-offs between the number of whistles per individual used in model training and classification performance and the extent to which data augmentation can compensate for sparsely sampled individuals. This information will help guide decisions on suitability of these methods for different conservation applications based on what baseline information is available for different study populations.

## Methods

**Data Sampling** Whistle recordings were obtained during periodic catch-and-release sessions, when small groups of selected dolphins were encircled with a

500-m long, 4-m-deep seine net in shallow water (<2 m depth). Each dolphin was brought aboard a specialized veterinary examination vessel, one at a time, where a standard suite of procedures was carried out, including being weighed, measured, examined by veterinarians, marked if necessary, photographed, and then released (Barratclough et al. 2019; Loughlin et al. 2010; Wells et al. 2004; Wells 2009). Each animal was typically aboard the veterinary boat for less than 1 hour. Acoustic recordings were made with suction-cup hydrophones attached to the melon throughout the operations, whether on the veterinary boat or being held in the water. If for any reason this was not possible, a hydrophone would be held in the water nearby. Up to four individuals were recorded simultaneously on four different audio channels. Total time from encirclement to release (and thus of recording time per catch-and-release session) was typically 2–4 hours, depending on numbers of animals and procedures performed. A variety of hydrophones were used, including both custom-made hydrophones and commercially available hydrophones manufactured by High Tech Inc. (Gulfport, MS), with frequency responses extending at least to 30,000 Hz. Recordings have been made on cassette tapes (1984–89), HiFi VHS tapes (1989–2005), and with digital recorders (since 2006). More detail about recording methods can be found in Sayigh et al. (2007, 2022).

**Data Curation and Labeling** Field recordings were analyzed in the acoustic analysis software program Raven (K. Lisa Yang Center for Conservation Bioacoustics 2022). All analog recordings were digitized (sample rate 96 kHz) to wav files prior to analyzing. Spectrograms (FFT length of 1024, 50% overlap) were viewed in a black and white color scheme using a 10 second page length and up to 32 kHz on the frequency axis, with up to four different audio channels inspected simultaneously on a monitor. Brightness was adjusted individually for each recording until the baseline background noise was just visible, ensuring that any sound above the baseline would be visible. All other settings were kept at Raven's defaults. Whistles were selected and labeled according to the individual that produced them, which was verified by comparing amplitudes of multiple simultaneously recorded hydrophones and by consulting field notes.

The signature whistle of each individual was operationally defined as the predominant whistle type produced during a recording session; typically, the signature whistle makes up >80% of whistles produced during health assessments. Signature whistle variants were defined as whistles that contained key features of the signature whistle but that deviated in some way from the typical contour; examples are embellishments and deletions to the contour (see Sayigh et al. 2022 for more detail). Non-signature whistles were defined as whistles that were visually different from the signature whistle type and were often more variable compared to signature whistles. Finally, signature whistle copies (Janik 1997, 2000) were defined as whistles that matched the signature whistle type of another animal present in the same catch-and-release session. Whistles were classified as possible signatures in rare instances where a signature whistle could not be verified; for example, if an animal produced fewer than ten whistles of the same type or approximately equal numbers of two different whistle types.

**Data Pre-processing** For this study, a subsample of 200 verified signature whistles from each of 70 different dolphins from the Sarasota Dolphin Whistle Database was used. The 200 whistles for each individual were first split into subsets consisting of 150 whistles for training the model; 25 whistles for measuring cross-validation performance for each trained model in order to tune hyperparameters; and 25 whistles that were withheld until the end to measure final model performance. Each audio file was transformed into a spectrogram using a 1024-point FFT with a Hamming window, and a step length of 512 samples for an approximate temporal resolution of 17 ms and spectral resolution of 60 Hz. Spectrograms with a duration less than 3 seconds were zero-padded on with the whistle randomly placed within the frame, and whistles with a duration greater than 3 seconds were cropped to 3 seconds. A median filter was then applied along the frequency dimension for noise reduction. Finally, to increase contrast, pixels that were lower than the 50th percentile of the spectrogram intensities were set to the 50th percentile value before scaling its intensity range to between 0 and 255 and saving as an 8-bit PNG raster image file.

**Model Training** A MobileNetV2 deep learning architecture (Sandler et al. 2018) was used for signature whistle classification (Fig. 2). MobileNetV2 is a deep convolutional neural network with 53 layers and 3.4 million trainable parameters. The model was instantiated via Tensorflow's built-in model MobileNetV2 using randomly initiated weights. The model was then trained to identify individual whistles based on spectrogram images with an input resolution of 484x251 RGB

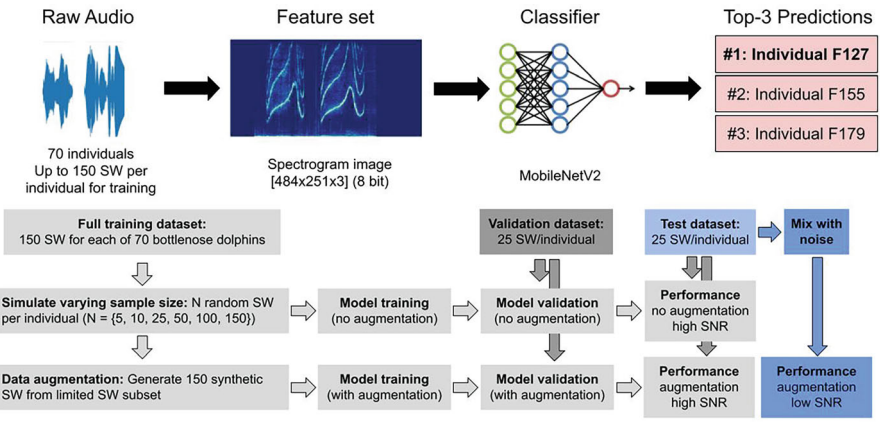

**Fig. 2** Deep learning pipeline and process for training and evaluation classification algorithms. Top: Raw audio files were converted into spectrograms and used to train a MobileNetV2 deep learning classifier that predicts ID of each signature whistle. Bottom: The classifier was trained on 70 individuals with a training dataset of varying numbers of signature whistles drawn from a total sample of 150 different signature whistles per individual. Data augmentation was used to compensate for low sample size. Final model performance was evaluated on new signature whistles (test dataset), optionally mixed with ambient noise from Sarasota

image, using an Adam optimizer and an initial learning rate of 0.0001. The code was written using Python v.3.8, and the Librosa, soundfile, SciPy, and OpenCV Python libraries were used for pre-processing and augmentation. All code is available at github.com/AllenMLI/dolphin_signature_whistles.

**Effects of Sample Size** To evaluate trade-offs between classification accuracy and size of the training dataset, a signature whistle classifier was trained based on a subset of the available training samples for each known individual. For each individual, a random subsample of 5, 10, 25, 50, or all 150 signature whistles were extracted from the full 150-whistle training dataset and used for model training. All other parameters of the training algorithm were kept constant so as to evaluate effects of sample size on final classification performance (Fig. 2).

**Data Augmentation** It was then investigated how well researchers can compensate for reduced variation in training datasets by introducing synthetic variation in individual signature whistles through data augmentation (Fig. 3). For each sample of N randomly selected signature whistles per individual (where N was 5, 10, 25, 50, or 150), each sample was modified 150/N times to achieve a constant training set size of 150 training samples per individual. For each augmented sample, the speed of audio, and hence the duration of the whistle, was changed slightly (with a randomly selected value between −10% and + 10%) using the Librosa *time_stretch* function. Afterwards, the pitch was changed slightly (with frequency multiplied by a randomly selected value between −10% and + 10%) using the Librosa *pitch_shift* function. Finally, mixture augmentation was implemented where the modified signature whistle copy was mixed with a random 3-second sample of underwater noise.

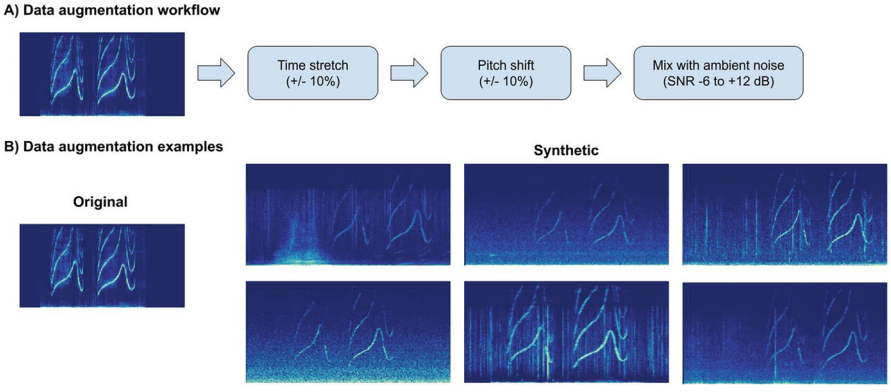

**Fig. 3** Top: Data augmentation combined time stretching (+/−10%), pitch shifting (+/−10%), and mixing known signature whistles with natural background noise (−6 dB to 12 dB SNR) to generate 150 different training examples for each animal. Bottom: Example signature whistle and six examples of synthetic versions including all types of data augmentation

To train the classifier to work across diverse noise conditions, noise samples were procured from seven long-term field sites around the US that were part of the SanctSound project (NOAA 2020), including Stellwagen Bank, MA; Gray's reef, GA; Florida Keys, FL; Santa Carolina Islands, CA; Monterey Bay, CA; Olympic Coast, WA; and Hawaiian Islands, HI. For each site, a random day every month for 12 months was downloaded, and 10 seconds of data every 30 minutes was extracted to form a random selection of noise files. Finally, a 3-second segment was extracted and mixed with the signature whistle exemplar with whistles placed with a random offset (with the entire whistle contained within the 3-second noise segment) and attenuated to result in a randomly selected SNR level between −6 dB and + 12 dB.

**Model Test Datasets** The final model performance was assessed under two separate conditions. The original test dataset of 25 signature whistles from each animal in the model was used as a clean test set to assess performance on unseen exemplars of signature whistles from animals included in the model, at reasonably high SNR given the suction cup recordings.

To assess more realistic field performance in an actual conservation application, the same test dataset files were also mixed with representative underwater noise samples. For this, underwater noise samples provided by the Sarasota Bay Listening Network (Rycyk et al. 2020) and validated to contain no dolphin whistles were used. As during the training phase, whistles were placed with a random offset within the noise file, and attenuated to an SNR of −6 to 12 dB.

## Results

A MobileNetV2 deep learning model was trained to classify different bottlenose dolphin signature whistles directly from spectrograms. Operating on data from suction cup recordings alone, where signal-to-noise ratio is high, the model achieved 98.8% cross-validation accuracy and 95.8% correct classification of whistles in the test dataset. Performance decreased with the number of different signature whistles available per individual, dropping off markedly below 25 signature whistles (Fig. 4).

Using data augmentation to create a synthetic dataset of 150 augmented whistle replicates from a limited subset of source whistles helped improve performance dramatically for low sample size. Using the full dataset of 150 SW per individual yielded a classification performance of 95.9% cross-validation accuracy, on par with the model without augmentation. However, with augmentation, classification accuracy remained above 86% even with only five different source signature whistles per individual (Fig. 4).

Classification accuracy decreased slightly when measured on signature whistles mixed with background noise data at SNR of −6 to 12 dB. Using all 150 whistles per individual, accuracy with more noisy test data was at 92.7%, and decreased for fewer whistles, reaching 82.3% correct classification with only five different signature whistles per individual (Fig. 4).

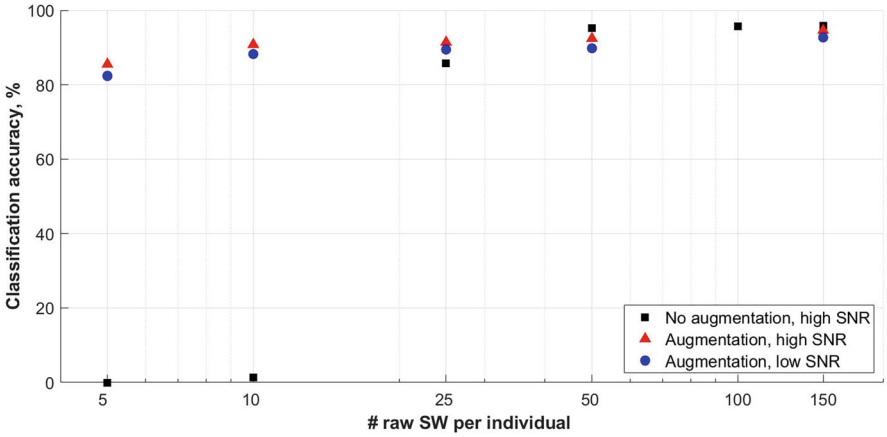

**Fig. 4** Classification accuracy (% correctly classified whistles) as a function of varying sample size for three situations: A classifier trained on limited data per individual without data augmentation (black square); a classifier trained on limited raw data but using data augmentation to generate 150 synthetic SW per individual, evaluated on either a test whistle dataset at high SNR data from the Sarasota Whistle Database (red triangles) or in a more realistic scenario with signature whistles combined with noise at SNR between −6 dB and 12 dB (blue circles)

## Discussion

The Sarasota Dolphin Whistle Database provides a unique dataset for training and assessing machine learning algorithms to automatically classify individual bottlenose dolphins by their signature whistles. Different renditions of the signature whistle of a given individual can contain a wide range of natural variation, including in the number of repeated loops per whistle, different initial and terminal loops, and deletions or additions to the whistle (Sayigh et al. 2022). Such extensive coverage of natural variation in signature whistles from so many individuals is difficult to obtain from other populations of dolphins. Our database of signature whistles from known individuals also includes some signature whistles that are quite similar to one another (especially simpler upsweeps) and while more work is needed to understand how deep learning models differentiate whistles that are similar, this is an issue that could not be resolved through a bottom-up approach of identifying different signature whistles ad-hoc from acoustic recordings.

Highly accurate classification of signature whistles could be achieved with deep learning, with classification accuracy of >92% for a dataset of signature whistles from 70 different dolphins, even under realistic, noisy conditions. For human analysts to maintain the same level of accuracy over long time periods would require extensive training and redundant work-checking, as well as considerable expenditure of time and budget. It is also noteworthy how well augmentation techniques can compensate for small sample sizes, thus giving promise for applying similar approaches in areas where fewer training data are available, or for individuals that

have been more sparsely sampled. Future work is needed both to improve classification accuracy under low-SNR conditions and also to integrate methods for anomaly detection that make it possible to identify signature whistles for which the model has not been trained.

Automated classification of signature whistles has strong potential for conservation applications given that many whistling delphinids studied to date are either known or suspected to produce signature whistles (Janik and Sayigh 2013) and since signature whistles can be used for density estimation using mark-recapture techniques (Longden et al. 2020). Our reported results are promising and suggest that automatic signature whistle classification techniques could enable acoustic monitoring of movements and habitat use of individual bottlenose dolphins acoustically at scale.

**Acknowledgements** Many people have contributed to this multi-decadal effort, both in the field and in the lab. These include, but are not limited to: Blair Irvine and Michael Scott; staff, students, volunteers, and collaborators of the Sarasota Dolphin Research Program; students at UNCW and WHOI who have helped with data extraction, including Maia Austin, Gemma Bekki, Mandy Cook, Carter Esch, Kim Fleming, Gracie Gavazzi, Nicole el Haddad, Lynne Williams Hodge, Guen Jones, Kristi Kaleel, Jessica Maher, Larissa Michel, Lucia Snyderman, Campbell Van Horn, Jessica Veo, Nikki Vollmer, and Charles White. Financial support for data collection and for developing and curating the whistle database has come from the Protect Wild Dolphins fund at Harbor Branch Institute for Oceanography, Vulcan Machine Learning Center for Impact, Allen Institute for Artificial Intelligence, Link Foundation, Earthwatch Institute, and Dolphin Quest, Inc. P.L.T. was supported by US Office of Naval Research grants N00014-18-1-2062 and N00014-20-1-2709.

for other baleen whales, several works performed in the last decade have proven the importance of song studies in the assessment of population status and conservation. Understanding the structure and use of fin whale songs within and between populations and across different oceans represents the next necessary step to improve PAM capabilities in a highly pressured environment. Many differences still exist in the methodologies and tools applied for this purpose. This chapter presents a brief overview of the main metrics and software used to define fin whale songs and to assess the influence of noise on the detection of fin whale song, and the acoustic communication system of the species is presented.

## Introduction

Marine mammals are essential to maintain the ecological equilibrium and to ensure resilience of marine ecosystems. They play a major role in the enhancement of primary productivity in their feeding areas (Roman and Mccarthy 2010). In particular, large deep divers such as sperm whales (*Physeter macrocephalus*) and baleen whales are recognized as "ecosystem engineers": they represent the largest existing marine top predators; they concentrate nitrogen near the surface by fecal plumes; they ensure the vertical transportation and mixing of nutrients from the depth to the surface; and their carcasses sequester carbon to the deep sea, providing habitat and food for many invertebrates (Roman et al. 2014). Among other baleen whale species, the fin whale (*Balaenoptera physalus*) has been studied since the 1960s by acoustically recording and monitoring the typical "20-Hz song pulses" emitted to communicate over long distances (Watkins et al. 1987). The species is protected worldwide under several national and international agreements, and it is globally considered "vulnerable" by the IUCN Red List of Threatened Species (Cooke 2018). However, some populations are more pressured than others, such as the Mediterranean sub-population, which is today listed as "endangered" (Panigada et al. 2021). To enable fin whale conservation worldwide, it will be crucial to monitor the species' distribution, to identify threats, and to provide policymakers with effective mitigation tools. Despite the vast uncertainties that still exist, acoustic monitoring represents one of the most effective methods to understand the species' behavior. It is essential to study its population ecology and conservation status, for example, to assess exchanges between neighboring populations (Castellote et al. 2012a).

In this chapter, a brief review of the studies performed between 1981 and 2022 on fin whale songs, song notes, and temporal patterns from different populations and geographic locations is reported. Methods and tools to detect and classify songs are described and discussed. Finally, the assessment of underwater noise effects on fin whale song studies is examined.

## Fin Whale Vocal Repertoire

The fin whale acoustic repertoire is mainly composed of vocalizations emitted at frequencies close to the lower limit of the human hearing frequency range, established around 16–20 Hz (Fletcher and Munson 1933; Møller and Pedersen 2004); these are referred to as "calls" and have fundamental frequencies in the range between 15 and 142 Hz (Pereira et al. 2020). These calls are produced in irregular series or in stereotyped sequences called "songs" or "bouts" (Watkins et al. 1987). Different types of calls and songs have been recorded across all oceans, showing significant differences in spectral characteristics and repetition rates. As further discussed below, these differences may be related to population-specific vocal repertoires or to the functional role of sound emissions in intraspecies communication. However, the distinction between an irregular call sequence and a song is still very uncertain.

### Calls

The best-known fin whale vocalizations are called "20-Hz pulses," calls centered around 20 Hz, used in long-range communication (Watkins et al. 1987; Edds-Walton 1997). Approximately 20-Hz calls are frequency-modulated downswept pulses, with a fundamental frequency between 17 and 25 Hz, centered around 20 Hz, and an average duration of 1 s (Morano et al. 2012). These sounds are used for intraspecies communication during the breeding period (stereotyped repetitions in songs – see section "Songs") and to keep contact and convey various information at distance (irregular repetitions) (McDonald et al. 1995; Širović et al. 2013). In some regions, a higher-frequency (HF) component also called "overtone," not harmonically related to their fundamental frequency, has been commonly found in association with the 20-Hz pulses (Castellote et al. 2012a; Simon et al. 2010; Širović et al. 2009, 2013; Oleson et al. 2014; Wood and Širović 2022). This could be representative of distinct populations' repertoires and seems to be consistent over time (Oleson et al. 2014). Calls with a frequency higher than 30 Hz have been also reported, and they may be associated with relatively short distance communication (within 20 km) (McDonald et al. 1995; Boisseau et al. 2008) and may have a function during foraging, e.g., the "40 Hz pulse" (Širović et al. 2013; Romagosa et al. 2021). Irregular rumbles were also described by Watkins (1981). These sounds have most of the energy below 30 Hz, and they were described as associated with alarming situations and hydrodynamic sounds produced by the movement of the animal during swimming or feeding.

### Songs

The term "song" is generally used in animal research to describe repeated series of sounds, structured into patterned units of variable complexity, and often nested into a

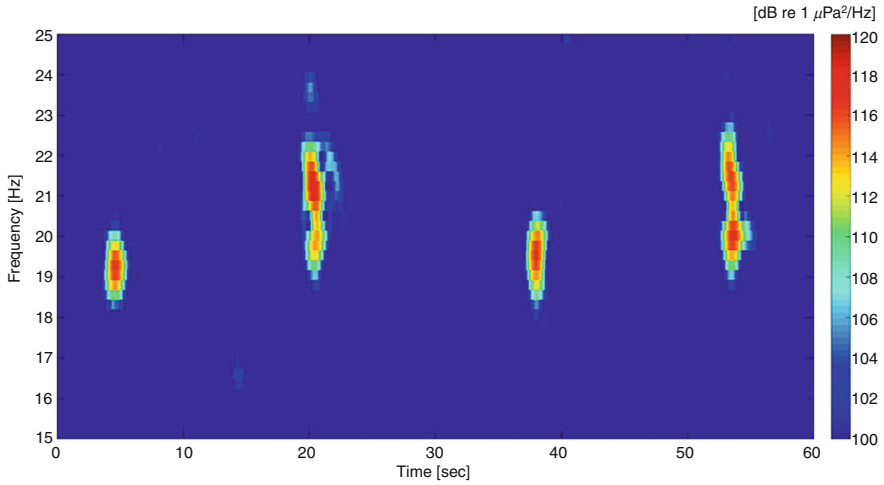

**Fig. 1** Spectrogram of a brief note sequence (BB-C-BB-C) from a song recorded in the Ionian Sea (Central Mediterranean Sea). The spectrogram was created in MATLAB© (sampling frequency, 2 kHz; 8192 FFT points, Hanning window, overlap 98%). Time resolution, 0.04 s; frequency resolution, 0.24 Hz. (Spectrogram from Sciacca et al. (2015))

hierarchical structure. Hence, there is not a common definition for the units that compose a song across different taxa. To perform accurate analysis of any song structure, and of the potential information conveyed, it is essential to characterize its constituent acoustic units (for a review, see Kershenbaum et al. 2016).

Watkins et al. (1987) attributed the definition of fin whale "songs" or "bouts" to the long sequences of stereotyped "20-Hz pulses" spaced apart by at least 2 h. Songs may last for hours, alternated by resting periods of variable length. Several studies described songs as repeated sequences mainly composed by 20-Hz pulses, hereafter called "20-Hz notes" for functional differentiation between a generic call and calls repeated in songs (Castellote et al. 2012a; Weirathmueller et al. 2017).

Most fin whale song studies focus only on the characterization of 20-Hz notes. These notes can be distinguished into a "classic" (C) note (a downswept signal from 23 to 17 Hz of about 1 s duration) and a variation of this note type called "backbeat" (BB), with a constant frequency in the range of 18–20 Hz, lasting about 0.8–1 s (Clark et al. 2002). Following the definition from McDonald and Fox (1999), two consecutive C and BB note types within a song can be defined as "doublet calls." An example of a "BB-C" doublet alternation of 20-Hz song notes produced by Mediterranean fin whales in the Ionian Sea is shown as a spectrogram in Fig. 1.

As for song produced by some other baleen whale species, fin whale songs are thought to be produced by male individuals, with a display function during courtship (Croll et al. 2002).

The acoustic characteristics of the 20-Hz notes (e.g., peak frequency, duration, and intensity), the frequency bandwidth (bw), and the timing patterns seem to vary to a limited extent within a sequence (Clark et al. 2002). Variations in the inter-note

intervals (INIs) (see section "Inter-Note Intervals (INIs)") have been more commonly observed. These changes may occur seasonally within the same population (Morano et al. 2012), but they seem to be higher between different populations, and they seem to be related to geographic location (Širović et al. 2009; Simon et al. 2010; Castellote et al. 2012a).

## Note Detection and Classification Methods

Passive acoustic monitoring (PAM) data can be used to improve knowledge and conservation of baleen whale species and of their endangered populations, for species such as the North Atlantic right whale (*Eubalaena glacialis*) (Mellinger 2004) or the endangered Mediterranean fin whale (Pintore et al. 2021). However, the analysis of large datasets derived by long-term PAM represents a growing challenge. The improvement of standardized tools for the acoustic detection of fin whale sounds represents a necessary step to acquire knowledge on the species' distribution, behavior, population structure, and abundance (Schall and Parcerisas 2022). Traditionally, the detection of fin whale vocalizations has been performed by visual inspection of waveforms, spectrograms, and power spectra analyses. These methods are long and laborious and lead to highly variable errors, depending on inter- and intra-analyst annotation capabilities (Mouy et al. 2014; Schall and Parcerisas 2022). In contrast, automatic acoustic recognition methods have many advantages, especially when enhanced with acoustic tracking techniques (Mellinger and Clark 2000). Since the early 2000s, many software tools have been developed with the aim of automatically detecting and classifying fin whale calls over long data series (e.g., Mellinger and Clark 2000; Urazghildiiev and Clark 2007; Mouy et al. 2014; Best et al. 2022). Most of these methods generally targeted the detection of 20-Hz pulses, which are the best-known signals in the fin whale song repertoire. However, the variability of acoustic habitats and background noise conditions and the rapidly growing amount of PAM data ask for increasingly efficient detection and classification methods.

### Detection Tools for 20-Hz Song

Detection software performances strongly depend on the complexity of the target signal as well as on background noise and sound propagation characteristics in the area (Mouy et al. 2014). Following the Baumgartner and Mussoline (2011) definition, fin whale call detectors can be distinguished in two main types. In the first type, the spectrogram is inspected by using a detection function (DF) represented by a template or kernel (i.e., a spectrographic picture of a certain call). In this case, detections occur when the DF exceeds a given threshold. Detectors of this type include spectrogram cross-correlation (Mellinger and Clark 2000; Mellinger 2001), neural networks (Mellinger 2004), convolutional neural networks (CNN) (Best et al. 2022), and banks of two-dimensional linear finite impulse response filters

(Urazghildiiev and Clark 2007). The second type of detectors works by setting a series of known parameters a priori, such as minimum frequency, maximum frequency, and duration of the signal to be detected. The acoustic signal is then investigated in the search of these parameters. All the signal portions that fit well into the pre-established attributes, based on the similarity to call-type models, are then classified as detections (Baumgartner and Mussoline 2011). Examples of this type of detectors are time-frequency methods based on edge detectors or instantaneous frequency tracking algorithms (Mouy et al. 2014) or detectors based on energy or power spectral density (PSD) signal-to-noise ratio (SNR) (Sciacca et al. 2016; Pintore et al. 2021; Schall and Parcerisas 2022). To account for low-frequency noise (<1 kHz) variability, in many of the existing tools, diffuse narrowband noise (e.g., ship noise) is usually minimized by subtracting a running mean or median from each frequency band of the spectrogram (Mouy et al. 2014). This technique is referred to as pre-whitening or normalizing (Baumgartner and Mussoline 2011). Still, changes in background noise and sound propagation conditions may affect detection capabilities (see section "Song Detection and Noise").

## Classification of Classic and Backbeat 20-Hz Song Notes

Classification of fin whale 20-Hz notes has been usually performed by human operators using spectral measurements. Discrimination between two note types has been mainly based on frequency bandwidth or frequency range. The main distinction performed to study fin whale song occurs between "classic note" (C) and "backbeat" (BB) (Clark et al. 2002). Apparently, the frequency limits of the two note types seem to differ, but there is not a clear cutoff between them. However, when both note types occur, the classic note is recognized as the note with a higher frequency compared to the backbeat (Helble et al. 2020). The lack of a universally accepted definition for the 20-Hz notes is probably due to the variability of the recording settings, geographic locations, and long-term trends in populations' vocal repertoire. Moreover, since the identification of different note types is generally performed by non-standardized methods based on fast Fourier transform (FFT) (e.g., spectrographic representations), time-frequency resolution capabilities are not consistent throughout literature. This causes a high inconsistency in the description of both time and frequency features of 20-Hz notes.

Only a few quantitative methods have been described for 20-Hz note classification. Rankin et al. (2018) proposed the application of a density clustering algorithm developed by Rodriguez and Laio (2014) to the classification of 20-Hz notes, using as spectral variables: centroid frequency, peak frequency, maximum frequency, bandwidth, and centroid peak difference (difference between the centroid frequency and the peak frequency). The same method was employed by Archer et al. (2020) who combined unsupervised density clustering to find note types using supervised classification. A fin whale "doublet" call detector was recently developed in MATLAB (MathWorks, Natick, MA) by Constaratas et al. (2021). Here the detection is based on the cross-correlation between a "doublet" call template and the

spectrogram of the whole signal (Constaratas et al. 2021). This approach can be useful to speed up the analysis of call sequences in highly stereotyped patterned songs. Helble et al. (2020) used a generalized power law detector to identify the start and end time of each note and to create a template of the signals. Then, the authors developed an automated classifier to categorize each detected signal as either a C or BB note, depending on the energy content of the different frequency bins. They found that it is possible to assess a threshold separating the two note types by using the "energy ratio" calculated as the ratio between signal template energy summation in the 10–23 Hz band and in the 10–50 Hz band. More recently, Best et al. (2022) fitted a two-component Gaussian mixture model to measured center frequencies (see section "Frequency Features") of Mediterranean fin whale 20-Hz notes, obtaining a threshold of 19.96 Hz to discriminate between the two types. This work showed that the center frequency may be used as a fundamental parameter to discriminate between note types. The main limitations to the establishment of a common classification framework are the definition of standardized protocols and metrics for note and song measurement and the assessment of background noise influence on established methodologies. Below is a review of the main approaches to song note classification and background noise assessment applied in literature.

## How to Define Fin Whale Songs

The differences in fin whale populations' vocal repertoire and the difficulties in obtaining reliable and common classification methods have resulted in a vast number of different approaches in exploring the features of fin whale songs. Furthermore, it is not yet known what measurable differences are between songs and irregular sequences of calls. Often the latter have been defined as sequences of calls with variable frequency features and inter-pulse interval (IPI). Irregular sequences sometimes include pulses with a peak frequency higher than the classic 20-Hz notes, ranging from 16 to 40 Hz (McDonald et al. 1995; Weirathmueller et al. 2017).

Irregular call sequences have been documented in the presence of transiting groups of whales interacting acoustically, each one emitting a different call type (McDonald et al. 1995). Soule and Wilcock (2013) recorded and tracked (in Northeast Pacific Ocean) several sequences in the 16–30 Hz frequency range, with peaks at 17, 19, and 24 Hz and with irregular IPIs. These irregular sequences contained calls with frequency components exceeding 24 Hz, defined as "24 Hz calls." These calls were recorded in association with the acoustic tracking of two near whales traveling together. The authors propose that these calls may be produced by immature males and that they could indicate social behavior other than courtship display. This work supports the hypothesis that the definition of "songs" relies on their biological function and that only long stereotyped 20-Hz note sequences (sometimes coupled with overtones) may be associated to male courtship display (Croll et al. 2002). However, given the very low number of observations, many uncertainties still exist concerning irregular call sequences. Hence, most work has focused on the analysis of regularly spaced call sequences (i.e., songs) including

"20-Hz notes" with identifiable and patterned repetitions (e.g., Weirathmueller et al. 2017; Širović et al. 2017; Constaratas et al. 2021). The most common steps in this analysis are the classification of note types in terms of frequency features and the measurement of the INIs. Recent studies (Helble et al. 2020; Best et al. 2022) considered a combination of these two approaches for the identification of recurring patterns and the study of their variation over time. An overview of the main metrics used for these purposes is reported in the next paragraphs. Call duration has been less commonly used to describe songs; hence it will not be discussed further in this chapter.

## Frequency Features

Several frequency parameters have been used to describe fin whale song notes, with only a few consistencies over the years and geographical areas. Table 1 shows a review of the frequency features of fin whale 20-Hz and higher-frequency (HF) song notes measured in research articles between 1987 and 2022. As shown in Table 1, one of the most investigated features is the peak frequency ($F_p$) corresponding to the frequency of the signal's maximum power. Taking as reference $F_p$, the frequency band attenuated by 3 decibels (dB) can be calculated, by finding the two frequencies where the spectrum level reaches 3 dB below the peak value (Crane and Lashkari 1996; Helble et al. 2020). This parameter shows how energy concentrates around the peak frequency. A small 3-dB bandwidth indicates a "tone-like" signal, and a wider value shows a more impulsive nature, respectively, meaning that the signal energy is more concentrated in a few frequency bins or more uniformly distributed over the entire band (Crane and Lashkari 1996). The center frequency ($F_c$) is the frequency value corresponding to half the distance between the initial ($F_{start}$) and the final ($F_{end}$) frequency bins. As described in section "Classification of Classic and Backbeat 20-Hz Song Notes," as an example, Best et al. (2022) show that $F_c$ may be better suited than $F_p$ for the discrimination between the two note types (C and BB). Also, the highest ($F_{max}$) and the lowest ($F_{min}$) frequency values and call frequency contours have been sometimes estimated manually by spectrogram annotation. Knowing $F_{max}$ and $F_{min}$, the overall note frequency bandwidth can be measured as the distance between these two parameters in Hz (see Table 1).

Rankin et al. (2018) proposed a method to reduce uncertainties across different analysts when measuring spectral features using spectrograms. Particularly, these authors proposed a spectrogram annotation method which allows the user to establish the percentage of signal energy to include in the selection. The same method was adopted by Archer et al. (2020) to account for differences in background noise levels among different deployment locations. All frequency features are normally measured by means of a FFT, and hence their precision depends on the frequency step selected. However, having considered this, energy-based parameters such as $F_p$, $F_c$, and 3-dB bandwidth produce more easily replicable measurements than contour-based ones.

**Table 1** Review of frequency features

A review of the main frequency features measured between 1987 and 2022 on fin whale 20-Hz notes and overtones (HF notes). $F_c$, $F_p$, $F_{start}$, $F_{end}$, $F_{max}$, and $F_{min}$, respectively, indicate the central, peak, starting, ending, maximum, and minimum frequency values expressed in Hz. Bandwidth (bw) indicates the difference in Hz between $F_{max}$ and $F_{min}$. The 3-dB bw is the width of the band at 3 dB from Fp. C and BB are classic pulse and backbeat notes. All entries are mean values, rounded to the closest integer value for comparison. Helble et al. (2020) only report median values

## Inter-Note Intervals (INIs)

The time lag between two consecutive 20-Hz notes within a song can be defined as inter-note interval (INI). Among all 20-Hz note features, the INI is the most variable feature between song repertoires and different fin whale populations (Castellote et al. 2012a; Pereira et al. 2020). Many different protocols are described in the literature to define the variation in the intervals between the two main fin whale 20-Hz note types. Besides the use of a variety of PAM systems (from deep-sea fixed observatories to bio-logging tags), different time features have been considered as a reference for the measurement of INI in fin whale song studies.

Table 2 shows a review of INI measurements described in studies between 1987 and 2022, performed as differences between various time features of consecutive 20-Hz notes: start times ($T_s$) are the most commonly used features, corresponding to the beginning of each note; central note times ($T_c$) have been sometimes used, by measuring the center of the note as it is computed and selected from the spectrogram (Castellote et al. 2012a; Rankin et al. 2018); and peak times ($T_p$) have been also considered by some authors, and these can be defined as the times of the maximum pressure level within a given frequency band (Clark et al. 2002; Best et al. 2022).

The time features of the notes are obtained by analyzing either the waveform (e.g., maxima of cross-correlation lag times between two notes), the energy envelope (e.g., the time of the maximum energy within a time window – $T_p$), or the spectrogram (Pereira et al. 2020) of a given acoustic signal. INI measurements have been performed by user annotation (directly from spectrogram image processing) or by automatic analysis (defined also as "automatic time measurement" or ATM in Table 2). Some authors adopted a combination of automatic signal detection/

**Table 2** Review of time features for INI measurement

A review of the time features used for inter-note interval measurement in different fin whale song studies worldwide. The study areas and time resolution: expressed in seconds (s) ("n.s." if not specified) are reported for each study. The alternative use of note starting time ($T_s$), central note time ($T_c$), or note peak time ($T_p$) is described, together with the use of automatic time measurement (ATM) systems, including partially automatized spectral analysis (marked with *)

selection methods and manual measurements, here defined as partially automatized spectral analysis (Table 2). In this last case, MATLAB (MathWorks©)-based custom algorithms and spectrogram editing software such as Triton (Oleson et al. 2014; Wood and Širović 2022) or XBAT (Castellote et al. 2012a) or other commercial software such as SpectroPlotter (JASCO Applied Sciences©) (Rankin et al. 2018) were used. Another fundamental difference in the measurements of INIs performed across literature is the time resolution of the spectral analysis performed, relying on selected FFT parameters (e.g., window length and overlap) and on the sampling frequency of the data. These features appear highly variable, and sometimes they are completely omitted (more commonly in earlier studies), as reviewed in Table 2.

## Pattern Identification

Following the measurement of note frequency features and INIs, the occurrence and definition of recurring patterns in spectral features and note alternation can be searched within each song. Watkins et al. (1987) described the long 20-Hz patterned series as calls with a single repeated INI value ("singlet") or sometimes as "doublets" of two alternating INIs. Thompson et al. (1992) also defined the patterned 20-Hz pulse series as pairs or doublets, alternating short and long INI duration. They also showed that doublet and singlet patterns may alternate within the same song. The understanding of these patterns for many fin whale populations' repertoires has increased over the years. "Triplet" patterns were also identified. Triplets are note sequences having at least two distinct INIs alternating, with one of them repeated two or more times (Širović et al. 2017). The definition of doublet, singlet, and triplet patterns is useful to group the songs as a function of their INIs and to understand the possible seasonal fluctuations (Širović et al. 2017) and inter-annual variations in different geographical areas and populations.

Recently, it has been shown that there is a strong relationship between note type and INI (Helble et al. 2020; Best et al. 2022). As an example, Helble et al. (2020) showed that in the "BB-C doublet" songs analyzed in their study, the BB-C interval has a shorter INI than the C-BB interval and that both doublet and singlet songs can occur with a unique note type such as BB-BB and C-C. Other authors showed that there may be more diversity in the alternation of note types than simple singlets or doublets, as observed in Mediterranean fin whale songs (Best et al. 2022). Hence, the traditional definition of singlet, doublet, and triplet songs may not be sufficient to estimate differences in song repertoires and that note type should be further considered for future studies. This is relevant when songs are used to isolate different populations, to define individuals' acoustic features (Širović et al. 2017), or to monitor long-term changes in population acoustic behavior. There is also some evidence that song patterns change over time. Seasonal variations (e.g., presence/absence of songs and INI increases) have been observed in western North Atlantic (Morano et al. 2012) and North Pacific oceans (Clark et al. 2002; Oleson et al. 2014; Weirathmueller et al. 2017). A synchronous increase in INIs was instead observed across the North Pacific during late fall and winter, and it was suggested as a feature

of the mating display (Oleson et al. 2014). Similar variations were observed by Morano et al. (2012) in the North Atlantic, and these authors suggest that seasonal INI variations may be associated with different purposes of communication. In addition, INI and frequency features have been shown to exhibit inter-annual variations worldwide, with a linear increase of INIs and a constant decrease of peak and centroid frequencies in some fin whale populations, as reviewed by Best et al. (2022). Simultaneous INI and peak frequency inter-annual shifts were found by Weirathmueller et al. (2017) and by Wood and Širović (2022). Only inter-annual INI variation was found in fin whale songs recorded in Northwestern Mediterranean Sea with no evidence of seasonality in song production and INI changes (Clark et al. 2002; Castellote et al. 2012a; Best et al. 2022), suggesting that differences across populations might arise culturally (Best et al. 2022).

## Noise Assessment in Fin Whale Song Studies

Most of the acoustic noise produced by large ships and seismic sources overlap with fin whale emission frequency band (Castellote et al. 2010; Sciacca et al. 2016). Noise may heavily alter fin whale signal detection and classification, especially when signal detection techniques based on template correlation or similar methodologies are applied (see section "Detection Tools for 20-Hz Song") (Weirathmueller et al. 2017; Best 2022). The acoustic masking induced by noise, including both natural and anthropogenic noise sources (waves, earthquakes, currents, sonars, vessels, etc.) not only alters whales' intraspecies communication, but it may also affect the detection space, thus reducing our capability to study fin whale song notes (Helble et al. 2020; Sciacca et al. 2015; Širović et al. 2015). A brief review of the studies describing background noise measurements, detection range estimation, and their variation in relation to fin whale song studies is reported in the next paragraphs.

### Measuring Noise Levels

To estimate communication masking means to define how much noise reduces the ability of a receiving animal to recognize the sounds of a conspecific (Clark et al. 2009). Similarly, PAM detection and classification capabilities depend on the possibility to receive and discern target signals from interferences, in the constant presence of random diffuse noise (Zimmer 2011).

Therefore, it is initially important to define the most suited metrics to measure background noise levels, considering target signal characteristics and study aims. Merchant et al. (2015) provided a thorough review of the main signal processing techniques, statistical methods, and metrics to measure acoustic habitats for PAM purposes. Assuming that the ability of PAM systems to accurately record sound is limited by the properties of the system itself, the authors suggest statistical analyses of sound levels to compare different acoustic habitats and time-series representations to describe discrete events and trends in sound levels. Concerning statistical sound-

level analysis, the use of root mean square (RMS), median, and percentile distribution appears particularly useful to assess the potential extent of acoustic masking (Clark et al. 2009). Furthermore, the use of spectral probability density (SPD), power spectral density (PSD), and 1/3-octave frequency band analysis is also suggested and described for spectral representation (Merchant et al. 2015). Time-series analysis is instead effective to analyze transient biological and anthropogenic sounds. The most used representation in time-series is the spectrogram, which shows how PSD sound levels vary as a function of the time. Spectrograms can be used to track trends in sound levels over specific frequency bands (Merchant et al. 2015). As an example, long-term spectral averages (LTSAs) are commonly used to compare sound levels over large time scales (Širović et al. 2013, 2015; Wood and Širović 2022). A small number of studies describe background noise measurements with the aim of evaluating noise impact on fin whale song note detection, acoustic behavior, and intraspecies communication. Castellote et al. (2012b) compared to background noise levels at four different recording locations in the Northwestern Mediterranean Sea. They investigated the occurrence of changes in the acoustic behavior of fin whales in response to shipping and airgun noise. To compare noise levels to the different sites and to correlate them with fin whale behavior, average received levels (root mean square dB re 1 μPa/5-min) were estimated, and PSD percentiles of background noise were computed for the frequency range 1–50 Hz, with a frequency resolution of 1 Hz. Other examples are shown in the next section "Song Detection and Noise," focusing mainly on the effects of noise on song detection capabilities.

## Song Detection and Noise

Acoustic detection is influenced by background noise, sound transmission path, and distance between the emitter and the receiver (Clark et al. 2009). To understand the limits of fin whale song detection studies and enable comparison across different areas, it is essential to assess the variability of detection ranges for each site and recording context and to assess transmission loss (TL) by modeling for each relevant context (Širović et al. 2015). Even discrete events, such as the passage of a ship, can cause changes in background noise levels. As a result, the choice of the metrics to compare detection range variations and fin whale songs between different sites should preferably consider both the short-term and the long-term variabilities of noise levels and of the overall soundscape dynamics. Temporal and spatial ocean sound dynamics affect sound propagation and influence the acoustic detection area of fin whale vocalizations (Miksis-Olds et al. 2015). This variability may also affect the measurement of the acoustic features of fin whale songs. Different note types with different frequency characteristics could have different propagation features. Such differences may also occur for the different frequency components of the potential noise sources occurring in the detection area. Hence, the study of song patterns should consider background noise levels and propagation conditions along with their spatial and temporal variability. To do so, several articles quantified the occurrence of whale calls by comparing the acoustic power in a frequency band

including the whole typical 20-Hz pulse signal, with different neighbor noise frequency bands above and below fin whale band (Širović et al. 2009; Simon et al. 2010). Širović et al. (2015) calculated average background noise levels (in 1 Hz bins) averaged over 5 s and as daily means at the recording locations to model detection range at different background noise conditions for each site. Finally, these authors used average background noise levels varied from −5 to +10 dB to test the variability of the detection ranges. They observed that fin whale detection range varied by 7–22%, while the detection area varied by 1–12% under different noise assumptions.

Stafford et al. (2007) modeled the maximum detection range for different baleen whales' calls in the Gulf of Alaska. They modeled transmission loss (TL) at selected frequencies, characteristic of each call type. For fin whales, the authors used a reference frequency of 25 Hz and source levels and monthly average ambient noise levels from literature (Stafford et al. 2007). Samaran and colleagues (2010) also modeled the range over which blue whale low-frequency calls (frequency modulated three-component 28 to 18 Hz calls) can be expected to propagate. These authors considered how modeled detection range changed with the monthly received levels, frequency, and source level of whale call in relation to the seasonal ambient noise levels received at the station and the seasonal propagation conditions along the transmission path from source to receiver. On the other hand, ocean dynamics may consistently change with varying operating depth and season of the year, depending on the receiver location.

Sciacca et al. (2015) also investigated the correlation between background noise levels and acoustic detection of fin whale in the Mediterranean Sea. In this study, the recording location was at high depth in Central Mediterranean Sea, where variations of the sound velocity profile (SVP) are significant only above the seasonal thermocline. The recorder was installed in an almost flat sea bottom, and due to the inter-seasonal homogeneity of the SVP, this allowed reliable estimates of the propagation of low-frequency sounds from a source close to the surface (Sciacca et al. 2015; Viola et al. 2017). Sciacca et al. (2015) measured median values and percentile distribution of noise PSD as useful indicators of the typical background noise trends. The SPL in the 1/3-octave band centered at the frequency of 20 Hz was selected for noise analysis, and the percentile distribution of integral noise amplitude (dB re 1 μPa) in this frequency interval was measured every 10 min. Fin whale calls were detected visually by trained operators through the investigation of the spectrograms. Measured values of median noise were compared to the presence and absence of fin whale calls, showing that 20-Hz calls were more often detected in lower background noise conditions. By applying a transmission loss model, the typical detection range was also estimated, and its variation was studied at the different percentiles of noise levels recorded. The estimated typical detection range was reduced by about 10 km with a 6 dB increase in the median noise levels.

In addition, acoustic behaviors, i.e., source levels and vocalizing depths of baleen whales, should be better understood (Stafford et al. 2007) to perform reliable studies on low-frequency communication sounds. In the past years, several studies have been conducted to estimate the source levels for fin whale vocalizations, which

might vary depending on their biological function (Charif et al. 2002), and different estimates are available for the 20-Hz pulses worldwide: 159–184 dB re 1 μPa at 1 m (Charif et al. 2002), 186 dB re 1 μPa at 1 m (Watkins et al. 1987), 189 ± 4 dB re 1 μPa at 1 m (Širović et al. 2007), 189 ± 5.8 dB re 1 μPa at 1 m (Weirathmueller et al. 2013), and 190.5 ± 7.4 dB re 1 μPa at 1 m (Garcia et al. 2019).

It has been shown that higher-frequency calls may exhibit completely different source levels with respect to the 20-Hz notes. As an example, fin whale 130 Hz upsweep vocalizations may show a source level about 20–25 dB lower than 20-Hz pulses (Simon et al. 2010; Garcia et al. 2019). It follows that these signals have different detection ranges, and their frequency band is also subject to different noise-level conditions. They may be undetected in spectrograms where the 20-Hz notes are visible (Garcia et al. 2019). Similarly, differences of 3–7 dB in the received levels of C and BB 20-Hz pulses have been described by Clark et al. (2002) and Weirathmueller et al. (2013). Therefore, C and BB pulses from the same emitting whale could propagate differently and be diversely subjected to background noise influence.

## Conclusions

The establishment of common metrics and methods to define the patterns of fin whale songs worldwide, accounting for both INI and note type, will favor the assessment of inter-seasonal and inter-annual variations in populations' repertoires. This chapter underlined that information concerning time-frequency resolution in the analysis performed on fin whale song notes should always be described to enable large-scale and long-term comparisons.

As shown, custom-developed algorithms are often used for song analysis and noise measurement. This points out that available commercial and open-source software tools are still not sufficiently adaptable to the wide range of recording contexts and dataset specificities. Furthermore, custom algorithms should be fully described in scientific articles, tested, and optimized (e.g., to reduce false-positive detections) for the specific dataset (Schall and Parcerisas 2022). The improvement of knowledge devoted to the conservation of fin whale populations (as enabled by PAM) would certainly benefit of the sharing of these tools and information, following FAIR principles (findability, accessibility, interoperability, and reusability) (Wilkinson et al. 2016). New automatic methods for note classification and pattern identification may be also developed by using deep-learning methods such as CNN (Best et al. 2022), which are increasingly spread.

A low number of fin whale song studies focused on background noise measurement and available detection space variations. This lack can be solved by selecting a subsample of available note sequences, based on higher SNR, to assess indexes of call abundance or note spectral features (Širović et al. 2015; Helble et al. 2020; Kowarski and Moors-Murphy 2021). Still, when measuring fin whale songs, it would be important to perform statistically relevant measurements of background noise levels. This is crucial to assess the typical detection range on significant time

scales to define whales' distance with respect to the receiver. With a view to fin whale song studies, it is also important to know the source levels of the different note types and their variability. This also enables proper definition of song notes' acoustic features and comparison between different fin whale populations.

Based on the review performed, future studies may also focus on finding a clearer definition of the differences between songs and irregular sequences, coupling PAM data with behavioral observations from visual surveys and bio-logging tags. This will improve our ability to interpret the biological significance of songs. It is commonly accepted that male baleen whales use features of their songs to promote their physical condition, as proved in other species (Clark et al. 2019). However, this hypothesis does not have exhaustive demonstrations in fin whale singing observations. Many questions about the ecological and biological significance of songs and related energetic costs are still wide open.

**Abstract**

A marine mammal baseline monitoring program was initiated offshore São Tomé and Príncipe in 2018–2019. An AutoNaut autonomous or uncrewed surface vessel (USV) was deployed by Seiche Ltd. The aim of this study was to identify occurrence and distribution of marine mammals as part of a wider baseline data

collection program, which also included the use of fixed location acoustic recorders, moored to the seabed for monitoring at specific locations. The USV provided an opportunity to collect data over an area of 6840 $km^2$ between the two islands and off the east coast of São Tomé. The minimal physical footprint of the USV equipment shipment, deployment, and autonomous or remote control provided substantial cost and safety advantages compared to conventional vessel-based towed passive acoustic monitoring (PAM) methods—which would otherwise have involved logistical resources and challenges. Assembly, launch, and recovery activities were based at a location with access to a small sandy beach. A two-person team with local support mobilized, serviced, and demobilized the USV. The mobility and unobtrusive nature of the AutoNaut platform enabled successful acquisition of PAM data over a wide area. Vocalizations of humpback whales, sperm whales, beaked whales, and delphinid species were recorded throughout the survey.

## Introduction

The Democratic Republic of São Tomé and Príncipe is a country of two islands in the South Atlantic Ocean, 200 km off the west coast of Africa. Among a growing number of visitors to the islands are humpback whales, other marine mammal, and sea turtle species. Previous studies have identified the seasonal presence of humpback whales (*Megaptera novaeangliae*) in the waters around the islands (Carvalho et al. 2011). Humpback whales are known to visit the region between July and November each year. Less information is available for the local presence of other marine mammal species that occur in the wider West Africa region. The region is inhabited by a diverse range of cetacean species (Bamy et al. 2006; de Boer 2010; Weir 2011). These include at least one other baleen whale Bryde's whale (*Balaenoptera brydei*); sperm whale (*Physeter macrocephalus*); dwarf sperm whales (*Kogia sima*), Cuvier's beaked whale (*Ziphius cavirostris*); several "blackfish" delphinids such as short-finned pilot whale (*Globicephala macroryhnchus*) and false killer whale (*Pseudorca crassidens*); several dolphins including bottlenose (*Tursiops truncatus*), Clymene (*Stenella clymene*), and pantropical spotted dolphin (*Stenella attenuata*).

Most of the available information on marine mammal occurrence in West Africa has been gathered by visual observation, either from onshore locations looking out to sea or by personnel going out to sea onboard vessels or by identification of stranded animals. Visual monitoring continues to provide important information on the

seasonal presence/absence and the distribution of species, but has its limitations and potential sources of bias—visibility and sea state conditions, group size, and the surfacing behavior of animals strongly influence the likelihood of their detection at the surface. Both dedicated and opportunistic observations can also be limited in temporal duration (often focused on the seasonal presence window) and spatial extent. In contrast, autonomous passive acoustic monitoring (PAM) technologies provide opportunities to collect marine mammal data continuously over extended periods and distances, independently of weather and sea conditions. The fundamental bias of these methods is that only animals that vocalize at sufficiently high level above background sounds in the vicinity of the hydrophone recorder, are available for passive acoustic detection. A well-chosen PAM system, however, can offer a cost-effective means of collecting long-term and/or wide areal datasets, the analysis of which can address multiple objectives. For example, these data may be applied to validate existing understanding of known species seasonal presence, to confirm the presence or absence of other species, and to understand baseline soundscape conditions and characteristics.

The wider study of marine mammal occurrence and soundscape characteristics combined the use of fixed passive acoustic recorders and an autonomous or uncrewed surface vessel (USV). Fixed recorders were placed at three nearshore locations off the east coast of São Tomé and collected data over a 12-month period. Concurrently, the USV collected data over shorter time periods but over a wider area between the islands of São Tomé and Príncipe. While the use of fixed PAM recorders has become increasingly common in recent years, USVs are a relatively new maritime platform for marine mammal monitoring. Therefore, in addition to targeted species and soundscape monitoring objectives, this study aimed to demonstrate the application of USV technology for marine mammal PAM.

The fixed PAM equipment was selected based on past experience and performance of their use, ease of manual handling, deployment, and recovery via medium sized vessels that would be available locally through tourism, hotel, and diving organizations and facilities.

Nearshore locations of the fixed PAM units were identified and selected following reviews of available information, discussions with academic researchers who had previously worked in the area and engagement with local groups and fishing communities. Aside from identifying the most likely places humpback whales would be detected, distances offshore were constrained by transit durations, with vessel availability and safe operating conditions limited to daylight hours.

An engagement and information sharing program was implemented with project personnel meeting with local organizations and fishing communities prior to and between field visits to explain the purpose of the studies and specifically what the acoustic monitoring equipment looked like. Throughout the project, continued engagement with partner personnel, local national agencies, hotel and logistics staff all helped to ensure the project was safely and successfully completed.

## AutoNaut USV and PAM System

A USV is effectively a remotely controlled mobile platform, from which hydrophones can be deployed to record underwater sound. The absence of crew onboard reduces safety exposure to personnel. The USV is controlled by a pilot located onshore, either in the same country of operation or elsewhere. The AutoNaut is a 5-m, wave-propelled USV, which towed a matched, linear pair of broadband hydrophones with 0.5 m separation, mounted on a 27-m cable and was piloted via a satellite link from the United Kingdom (Fig. 1). The PAM system was powered by 12 V batteries that were charged using solar panels mounted on the AutoNaut's deck. Acoustic and positioning data were recorded onboard the USV using the Seiche μPAM sound recorder running the PAMGuard software. The sensitivity of the ceramic hydrophone elements was −196.5 dB re: 1 V/μPa, and their preamplifier gain was 40 dB. Acoustic signals received at the hydrophones were digitized using a National Instruments NI-9222 DAQ at a sampling rate of 125 kHz per channel. The PAM system had an end-to-end frequency response of 25–62,500 Hz(−3 dB). The signals from both hydrophones were recorded continuously, as 16-bit wav-format files. Extraction and analysis of marine mammal vocalizations was carried out offline, once the USV had returned to shore and the data were downloaded.

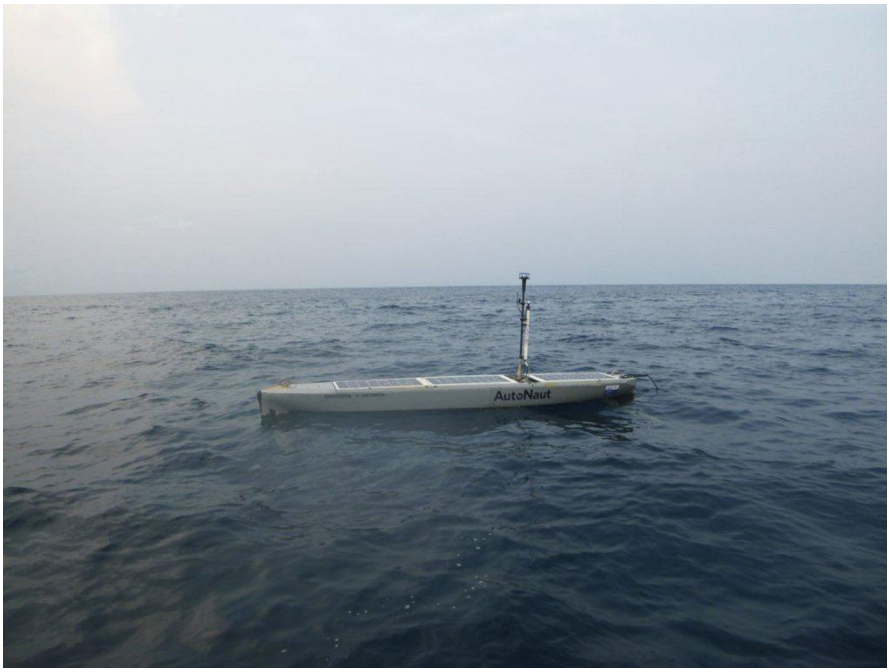

**Fig. 1** AutoNaut offshore São Tomé

## Survey Logistics and Monitoring Effort

The AutoNaut was mobilized from the grounds of a local hotel at Santana on the east coast of São Tomé. The USV and a launch and recovery trolley arrived on site in three packing containers and were assembled onsite. Vehicle movement via the trolley from a workshop area to the beach launch site was managed in close collaboration with hotel management and staff. Deployment was implemented by maneuvering the trolley into the water until the USV was able to float free. Its nearshore movements were controlled via a Wi-Fi controller, prior to hand-over to the remote pilot who thereafter navigated using an Iridium satellite connection to the vessel. In addition to positional command and control information, regular status messages were relayed via the satellite link to monitor PAM system functionality.

The marine mammal survey was planned as a series of equal-angle zigzag line transects to distribute survey effort systematically across the survey area. Transit routes were planned between the offshore survey area and the launch and recovery site at Santana, to provide additional information on marine mammals in the nearshore areas. The predetermined route was 1725 km in length, and the transect lines within the survey area were to be repeated as time allowed. The realized survey effort was 75 days duration and was carried out as a series of three deployments (Data Periods 1–3) from October 2018 to February 2019. Data was acquired for 67% of the planned mission duration. The AutoNaut traveled 1772 km while making approximately 1500 h of sound recordings. Additional sound recordings and trackline effort were excluded from the analysis data-set due to elevated background sound levels when USV propulsion was assisted by its electric motor, primarily during periods with flat seas and strong oceanic currents. Further data collection periods were excluded when the AutoNaut was approached by other vessels, events that were identified from long-term spectral average plots, headphone playback and manual inspection of spectrograms. The realized trackline and distribution of survey effort are shown in Figs. 2, 4, 6, 8, and 9. The AutoNaut attempted to follow the predetermined zigzag survey tracklines, but at times this was challenging for a number of reasons, including:

(a) Strong and unpredictable oceanic currents. AutoNaut attempted to hold position when faced with adverse currents and calm seas with little wave action with which to propel itself along the trackline. The vessel would circle or would drift off course and then use its electric motor to return to the trackline once the current speed changed direction or wave conditions improved.
(b) Interaction with other maritime users. Small boats approaching the USV and/or taking it under tow towards port.
(c) Mechanical failure that compromised the wave-propulsion system affected the ability to make way against the prevailing currents, under wave propulsion or by using the electric motor.

A summary of the sound recording effort across the three Data Periods is shown in Table 1.

**Table 1** Summary of the sound recording effort across the three Data Periods. "Deployment Days" is the number of days that the AutoNaut was deployed at sea; "Recording Days" is the number of days on which sound recordings were made. Total Survey Distance and Recording Time (the total effective survey effort) exclude periods with noise levels that would hamper marine mammal detection

## Analysis of Marine Mammal Vocalizations

### Humpback Whale Song

Humpback whales produce a wide range of tonal and impulsive vocalizations, with most energy between approximately 50–2000 Hz and higher frequency harmonics that can exceed 24 kHz (Au et al. 2006). Vocalizations include sporadic calls (Silber 1986; Dunlop et al. 2007) and song of hours duration in which unit sounds are repeated in a complex structure of phrases and themes (e.g., Payne and McVay 1971; Cholewiak et al. 2012). To search for humpback vocalizations the sound recordings were first decimated from 125 kHz to 8 kHz (IIR Butterworth, 4th order, 3500 Hz low pass), providing an analysis band of 0–4000 Hz. The PAMGuard "whistle and moan detector" (WMD; Gillespie et al. 2008, 2013) was applied to the decimated data to identify candidate humpback whale sounds within the frequency band 100–2000 Hz. A long-term spectral average (LTSA) was plotted (1024-point FFT, 100% hop, frequency resolution 7.8 Hz, time resolution 128 ms, 5-s averaging), and the output from the WMD was overlaid. The analyst inspected clusters of WMD events on short-term spectrograms and reviewed audio over headphones to verify and annotate humpback whale detections. The recordings either side of each WMD cluster were also examined, and in many cases lower amplitude detections were identified that had not triggered the automatic detector.

### Delphinid Whistles and Pulsed Calls

A similar process was used to detect and extract delphinid tonal and pulsed calls from the full bandwidth data. Whistles and pulsed call vocalizations are utilized by oceanic delphinid species as communication signals (e.g., Herman and Tavolga 1980; Herzing 1996; Lammers et al. 2003; Rankin et al. 2008). Whistles are frequency and amplitude modulated, narrowband tonal harmonic calls. Pulsed calls (or burst-pulse calls) are rapid series of broadband clicks with very short

inter-click intervals. The pulse repetition rate of pulsed calls displays as a tonal signal with harmonic or sideband structure, when viewed on spectrograms with narrow analysis bandwidth (i.e., low temporal resolution) (Watkins 1967), rendering them amenable to detection using a whistle contour detector such as the WMD (Gillespie et al. 2013). The sound recordings were first processed using an LTSA with the following parameters: FFT length 1024 points, Hann-windowed, 100% hop, frequency resolution 122 Hz, time resolution 8.2 ms, 5-s averaging. The WMD was then applied to identify candidate tonal events within the frequency band 2–35 kHz, exceeding a trigger threshold of 8 dB above background level. The large volume of delphinid vocalizations precluded manual verification of all candidate acoustic events, although inspection of the LTSA enabled the analyst to delimit periods of effective survey effort, i.e., periods unaffected by background sound from close vessel interactions or the operation of the AutoNaut's electrically powered propulsion pod. The encounter rate used for delphinids was detection positive minutes (DPM) of effective survey effort that included WMD events, with systematic adjustments applied to account for stereotyped false triggers caused by electrical system noise. The false triggers consisted of continuous narrowband tones or pulses. These events were excluded from the WMD database table as a series of SQL queries, where an event's start and end frequencies were restricted to within one of three frequency bands (4.8–6.3 kHz, 10.1–11.1 kHz, 16.5–17.5 kHz).

## Sperm Whale Vocalizations

The data were decimated to a sampling rate of 48 kHz and processed using a click detector (CD; Gillespie and Leaper 1997) to identify the regular click trains and coda click sequences of sperm whales (Whitehead 2003). The CD trigger threshold was set to 10 dB above background level in the pass-band of a "trigger filter" (2nd order IIR Butterworth 2–20 kHz band-pass), creating click data clips. Each clip included the click energy passed by a wider band "pre-filter" (4th order IIR Butterworth 500 Hz high-pass). These data were stored in binary files. The binary files were examined using PAMGuard's Offline Viewer mode. Click bearing, amplitude, and inter-click interval (ICI) were plotted against time to identify click train events. Sperm whale clicks were distinguished from broadband delphinid echolocation and other transient sounds by viewing a corresponding spectrogram (0–65.2 kHz, FFT length 4096 samples, 50% hop, Hann window function, frequency resolution 30.5 Hz, time resolution 16.4 ms). Detection events were delimited manually and annotated by vocalization type ("sperm whale click train," "coda," etc.).

## Delphinid and Beaked Whale Click Trains

A second CD was used to process the full bandwidth recordings and detect the click trains of delphinid and beaked whale species. Oceanic delphinids produce series of short (~20–50 μs), broadband clicks with most energy between 10–150 kHz

(Au 1993; Baumann-Pickering et al. 2010). In contrast, beaked whale species produce narrower band pulses, generally at a lower and less variable repetition rate than delphinids, with species-specific frequency modulation (Baumann-Pickering et al. 2013); for example, Cuvier's beaked whale emit FM upswept pulses of duration 200 μs, centre frequency of 42 kHz and −10 dB bandwidth of approximately 22 kHz (Zimmer et al. 2005). During analysis, the CD trigger threshold was set to 10 dB above background level in the pass-band of a 'trigger filter' (8th order IIR Butterworth 20 kHz high-pass), creating click data clips. Clip energy was extracted from the output of a 'pre-filter' (8th order IIR Butterworth 1 kHz high-pass). These data were stored in binary files and examined in Viewer mode. Three click-type classifiers (Gillespie and Caillat 2008) were applied to highlight clusters of clicks with the characteristics of delphinid echolocation, beaked whale pulses and catch-all 'mid-frequency clicks' respectively. The classifiers used various parameters including click length, number of zero-crossings, zero-crossing frequency sweep, energy band comparison, peak frequency and peak frequency bandwidth. Individual clicks from each cluster were examined using waveform, power spectrum and Wigner plots, time v click bearing and time v ICI displays. A spectrogram display was also helpful, and ultrasonic sounds were played back through headphones at reduced speed, lowering their pitch. Detection events were delimited manually, annotated ('delphinid click train', 'beaked whale', etc.) and written to a database. Click parameters were extracted for all beaked whale events to attempt to assign these vocalisations to particular species, using the ROCCA plug-in for Pamguard (Oswald et al. 2007; Rankin et al. 2016). ROCCA enabled the measurement of 17 parameters for clicks manually selected within the CD interface. Detection of Cuvier's and other beaked whale species are presented in more detail elsewhere (Pierpoint et al. 2021).

## Species Detection Rates

The detection outputs for each of the species of interest was analyzed offline to calculate detection positive minutes (DPM, by species-group). DPM represent the number of effective survey effort minutes in which a species or species vocalization was detected. This was expressed as a percentage of total effort minutes, either overall or per day, and per 5 x 5 km grid cell. DPM thereby describe both the spatial distribution of marine mammals, and track variation in the numbers of marine mammal acoustic detections over time.

## Humpback Whale

Humpback whales were only detected acoustically in Data Period 1, between the 25th October and 5th November. Detections were clustered in the west and south-western parts of the survey area, to the north of São Tomé (Figs. 2 and 3). Humpback whale vocalizations consisted of varied tonal sounds, mainly with the frequency

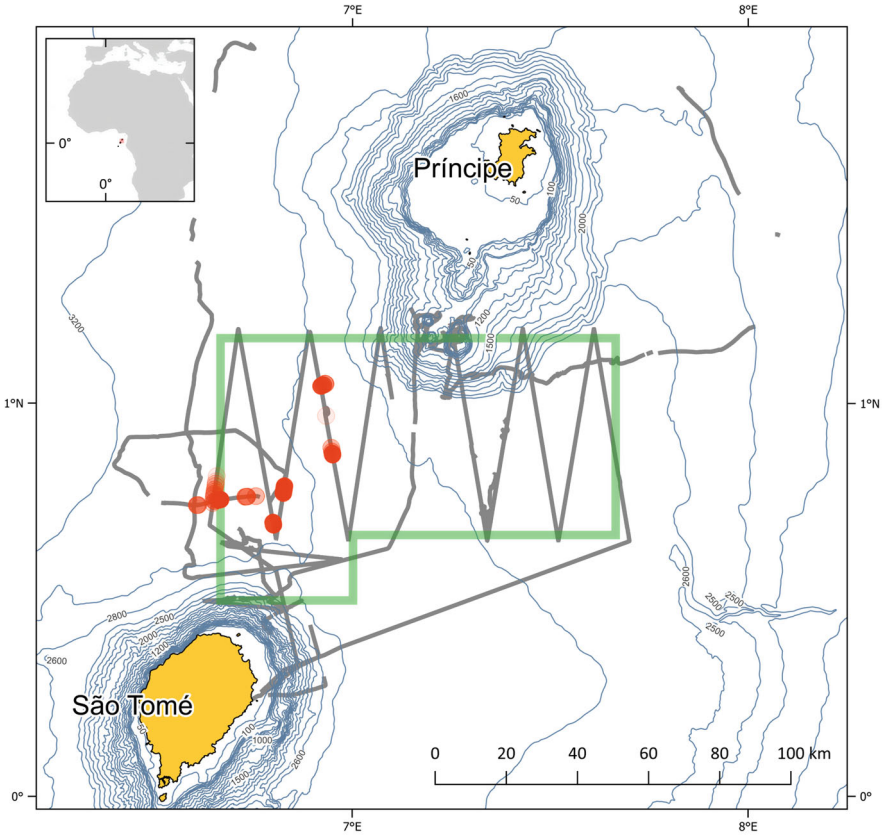

**Fig. 2** The effective survey effort track of the USV and locations from which humpback whales were detected acoustically. The green polygon delimits the core survey area. Bathymetric basemap: GEBCO (2015)

band 200–1500 Hz. Vocalizations were relatively low amplitude, with low signal-to-noise ratio and lacking overtones, suggesting they were produced by distant whales. Series of song units were recorded with repetitive phrasing, i.e., similar song units or combinations of units were repeated in sequence. From the phrasing and consistent spacing between song units, in most cases a single whale was believed to have been detected. On a few occasions, a second whale was also audible.

## Sperm Whale

The relative abundance of sperm whales appeared to increase over the course of the survey. Sperm whale vocalizations were recorded on 37% and 36% of days in Data Periods 1 and 2 respectively, and on 58% of days in Data Period 3. Sperm whale

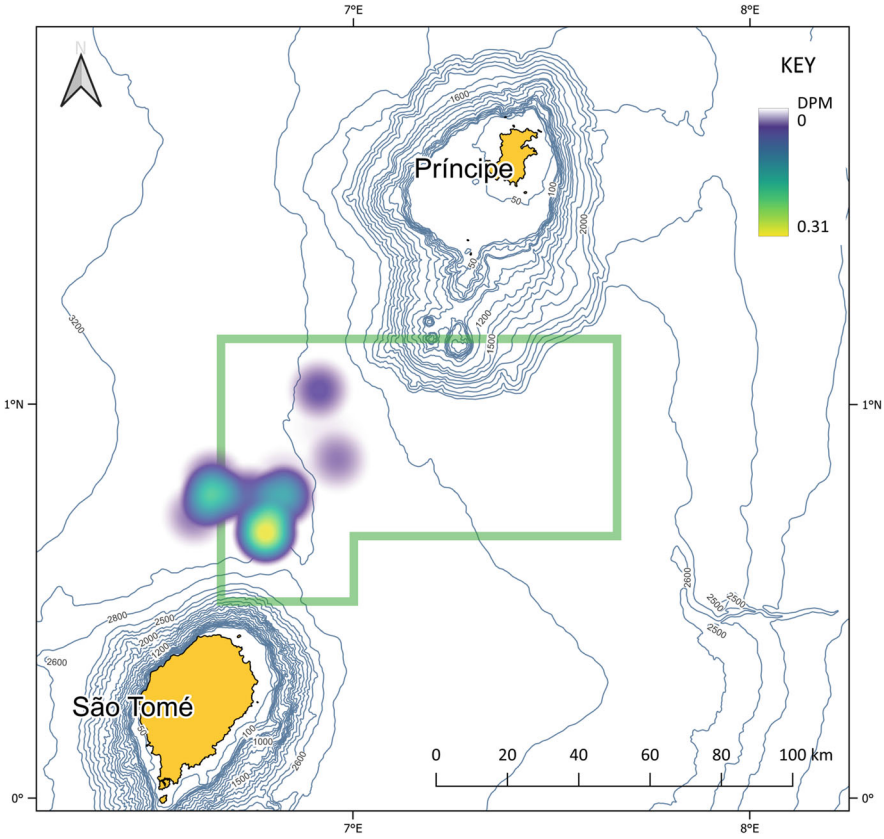

**Fig. 3** Heatmap interpolation of humpback whale detection rates within 5 x 5 km grid cells

detections were widespread and there were several parts of the survey area in which relatively high encounter rates were recorded (Figs. 4 and 5). Throughout the survey, however, extended periods with sperm whale detections were followed by periods of several days without any whales being recorded. In this respect, sperm whale detection occurrence was sporadic, and there was no evidence that aggregations of whales occupied particular areas more than others. Acoustic detections were categorized as "usual click trains," "codas," and "slow clicks" (Whitehead 2003). Usual click trains tended to be recorded for continuous periods of more than 1–2 h at a time. Multiple whales were recorded clicking simultaneously during most encounters. Some usual click trains were interspersed with "creaks," accelerated click rates that are associated with prey capture. Coda vocalizations were recorded between or concurrently with, periods of continuous clicking. "Surface creak" or "chirrup" vocalizations (i.e., "creaks" that were not the termination of a usual click train) were heard among the codas and were included in the same category. There was a

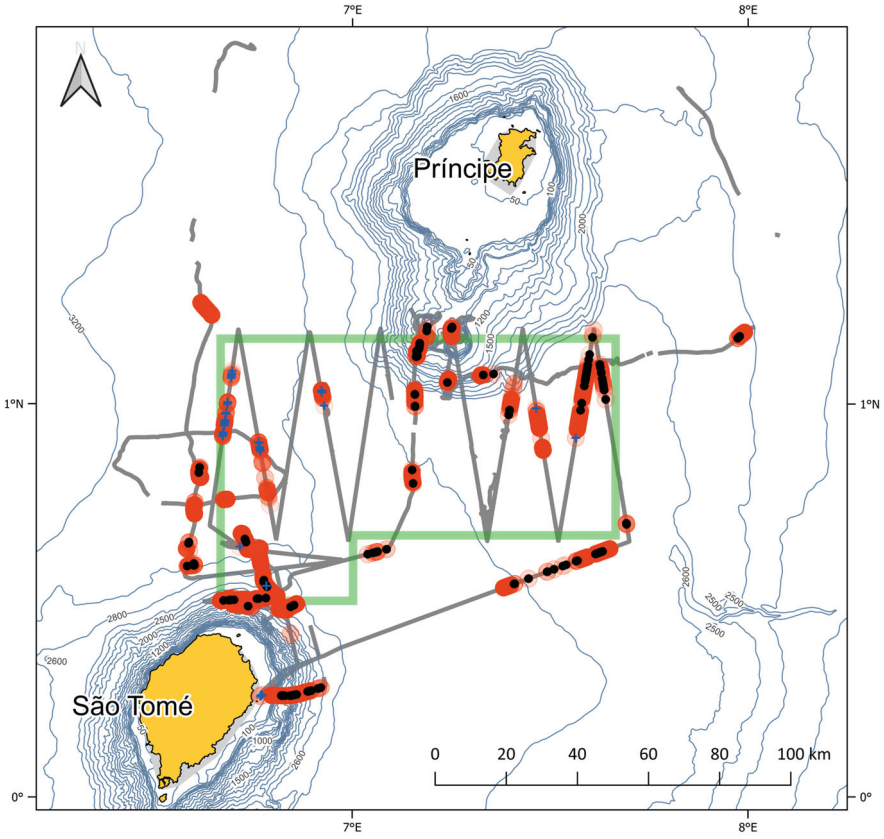

**Fig. 4** Locations from which sperm whales were detected acoustically. Black points and blue cross symbols represent detections of coda and slow click vocalizations respectively

distinct change in the proportions of different categories of vocalization during the survey period. Slow clicks were the common sperm whale sounds detected in Data Period 1 but were very rarely heard during Data Periods 2 and 3. In other studies slow clicks have been heard only in the presence of mature and maturing male sperm whales (Weilgart and Whitehead 1988). In most cases it was evident from the regularity of inter-click intervals that a single whale was slow clicking at any one time, and in a very few cases, two whales. Conversely, the incidence of both usual click trains and codas increased after Data Period 1, with the highest detection rates having been recorded in Data Period 3. Multiple whales were then recorded vocalizing simultaneously, with codas and usual click trains. Codas appear to be produced by all sex and age classes of sperm whale and are commonly recorded at low latitudes during the vocal exchanges of social units that include female and immature whales (Whitehead 2003).

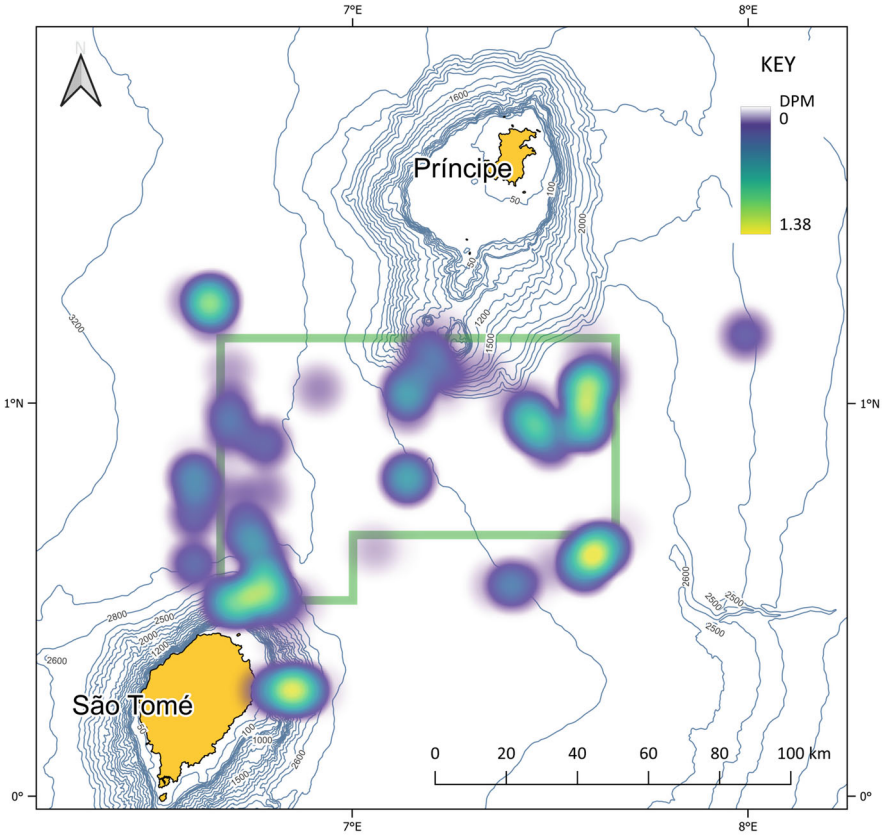

**Fig. 5** Heatmap interpolation of sperm whale detection rates

## Beaked Whale

Beaked whale detections were not uncommon and occurred on 28 of 75 survey days. Acoustic encounters were widespread on the shelf edge and in oceanic habitats above the abyssal plain (Figs. 6 and 7). The average water depth at which acoustic detections were recorded was 2519 (sd 555) m. Thirty-nine of 47 encounters that yielded a sufficient number of click measurements were attributed to Cuvier's beaked whale; the remaining eight encounters were categorized as "unidentified beaked whales." Cuvier's beaked whales were detected on four (25%), fourteen (42%), and eight (31%) survey days in data periods 1–3 respectively.

A key identification parameter was the inter-click interval (ICI). The usual foraging click trains of Cuvier's beaked whale (i.e., excluding buzz-phase clicks

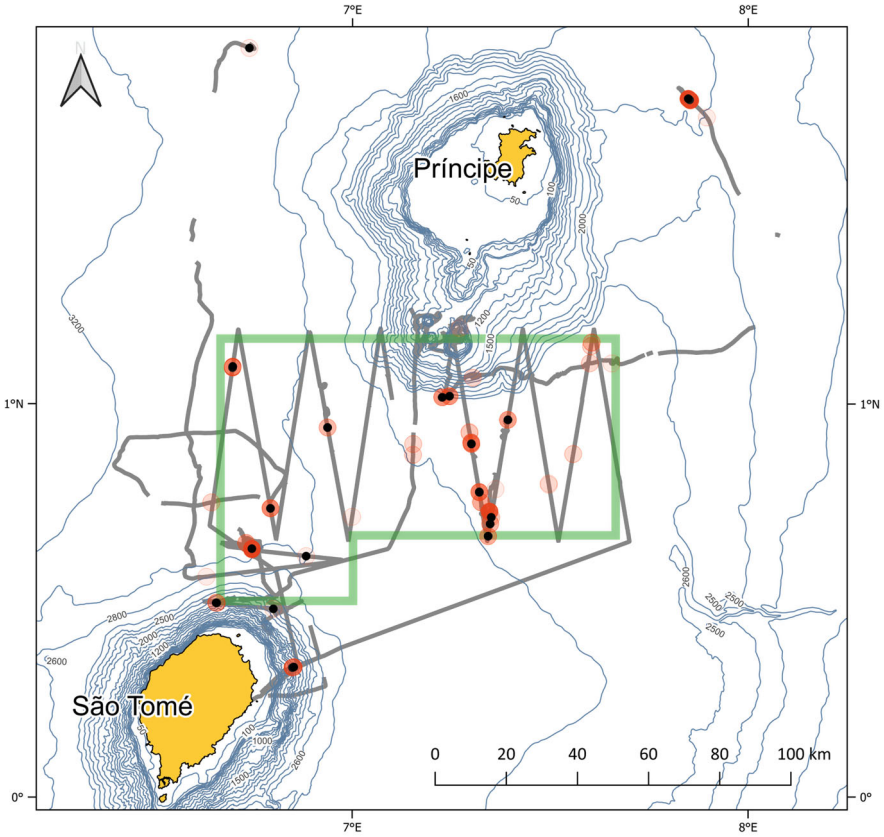

**Fig. 6** Locations from which beaked whales were detected acoustically. Black points represent detections of Cuvier's beaked whale

with increasing repetition rate) have a stable regular ICI of approximately 500 ms (Zimmer et al. 2005; Hildebrand et al. 2015). Median ICI during encounters in this survey was 537 (467–640) ms. The two *Mesoplodon* beaked whale species known to inhabit the region, Blainville's beaked whale (*M. densirostris*), and Gervais' beaked whale (*M. europaeus*) tend to produce echolocation clicks at higher repetition rates (Johnson et al. 2006; Gillespie et al. 2009). Centre and peak frequency during Cuvier's beaked whale encounters averaged 37 kHz and 39 kHz, respectively. Click waveforms during these encounters tended to have 11–15 zero-crossings and an FM sweep rate of 108 kHz $ms^{-1}$.

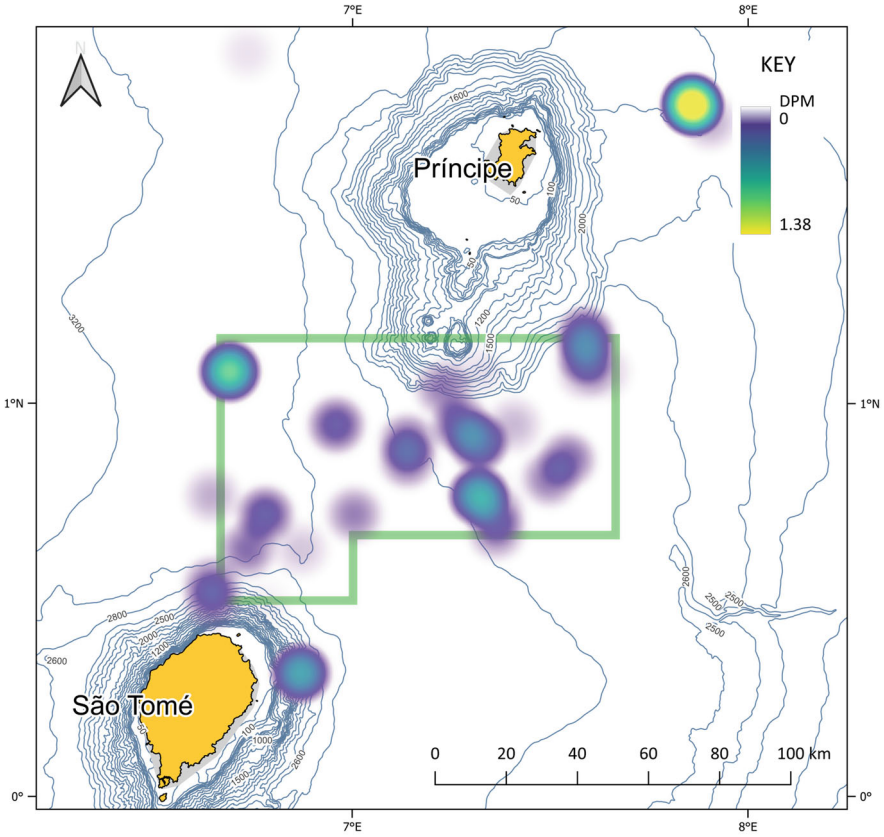

**Fig. 7** Heatmap interpolation of beaked whale detection rates

## Delphinids

Delphinids were the most frequently detected marine mammals in each data period and were recorded every day. Delphinid detection rates were higher, however, during Data Period 3 than in the previous two deployments. Vocalizations included frequency-modulated whistles, pulsed calls, and broadband echolocation click trains. Whistle calls were highly variable and occupied a frequency band from approximately 1.5 kHz to 30 kHz.

The spatial distribution of delphinid acoustic detections was widespread (Fig. 8), but when plotted as a function of survey effort in 5 x 5 km grid cells, a clustering of acoustic encounters was evident north and north-east of the island of São Tomé, including waters above the steep continental shelf break (Figs. 9 and 10).

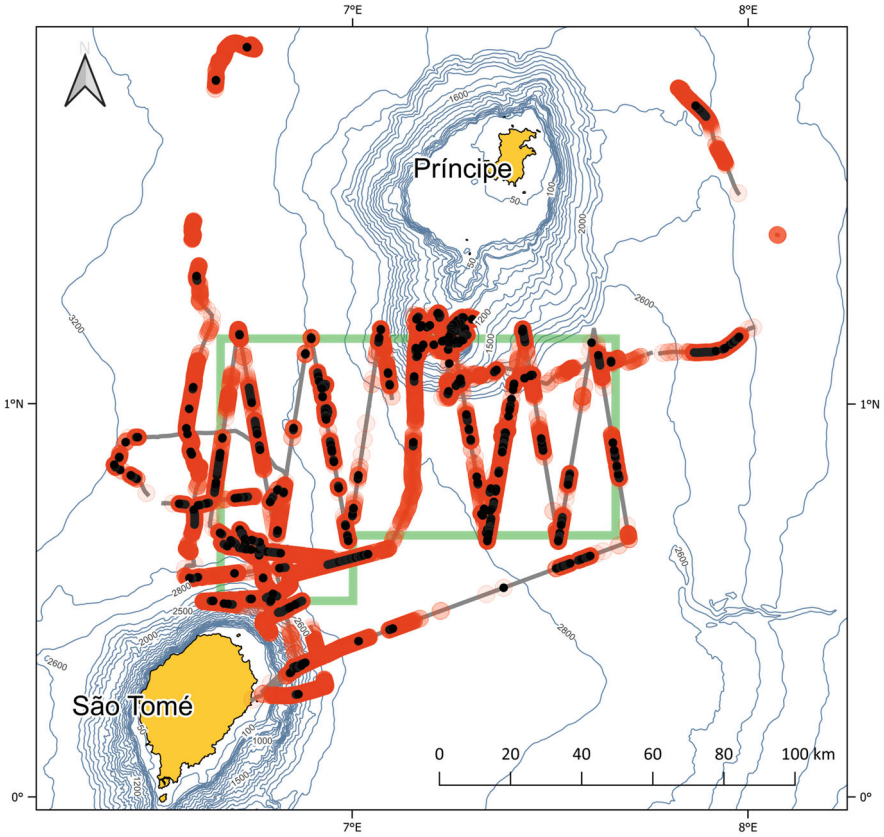

**Fig. 8** The effective survey effort track of the USV and locations at which delphinid whistles (red) and echolocation click trains (black) were detected acoustically

## Study Outcomes

This survey presented challenging conditions for a wave-propelled USV; sea conditions were often calm, oceanic currents strong and unpredictable, and overcast skies hampered solar charging of the vessel's battery power supplies. The vessel also experienced some mechanical issues that affected its propulsion, and survey transects were occasionally halted due to interference from local boat operators. None of these factors had been experienced to such an extent on previous surveys in other areas, and led to the vessel being deviated from its planned systematic survey transect lines.

Despite these challenges, the AutoNaut completed 1772 km of effective trackline effort and collected 1500 h of sound recordings. It remained at sea for 75 days, which was approximately 2/3 of the planned duration of the survey. Survey effort was fairly

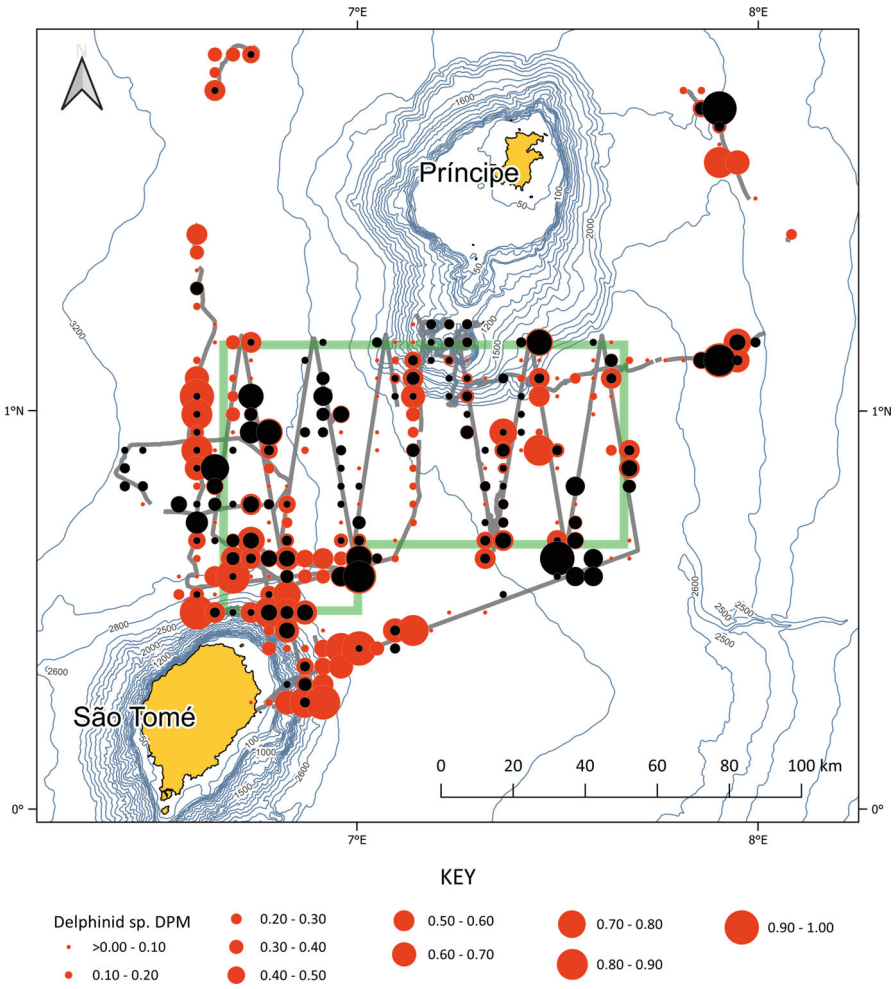

**Fig. 9** Proportional circles representing the detection rate of delphinids within 5 x 5 km grid cells. Red symbols represent whistles and black symbols click trains

evenly distributed across planned survey area, although it was not possible within the operations period to repeat the coverage of the transect lines as planned. The baseline data showed that marine mammals were regularly encountered in and around the survey area, and the following species and species-groups were recorded: humpback whale, sperm whale, beaked whales including Cuvier's beaked whale and delphinid species.

Humpback whales were only detected acoustically from late October to early November, supporting the findings of existing studies (Carvalho et al. 2005; Rosenbaum and Collins 2006). Detections were clustered in the west and south-western parts of the survey area, north of São Tomé. Sperm whales, beaked whales,

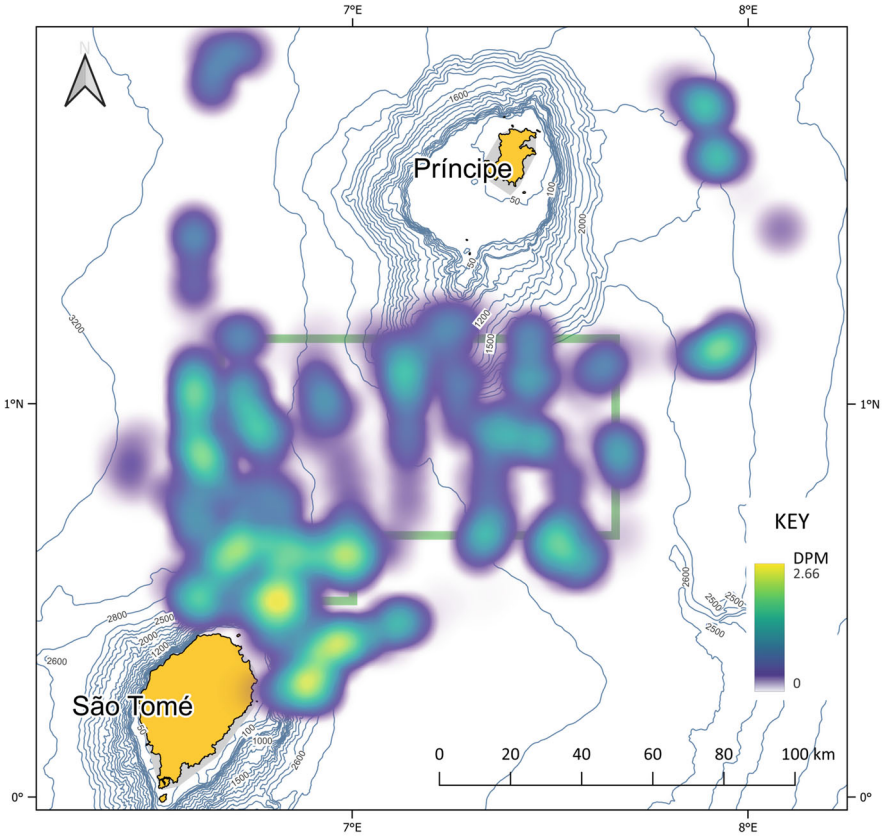

**Fig. 10** Heatmap interpolation of delphinid detection rates

and delphinid species were recorded throughout the survey and were widely distributed within the survey area. The vocalizations of sperm whales suggested that groups of female and immature animals occupied the survey area for extended periods, and that adult male sperm whales also visited the region. Beaked whale detections were not uncommon; the majority were attributed to Cuvier's beaked whale. Prior to this survey there were very few previous data on beaked whale occurrence in the region. Delphinids were recorded on a daily basis. Acoustic detections of delphinids were not differentiated by species, but likely represented encounters with a range of taxa as the Gulf of Guinea is inhabited by at least 17 species.

In conclusion, the AutoNaut baseline survey yielded a wealth of passive acoustic data and new information on marine mammals in the region. It was determined that a number of diverse species-groups inhabited the area from October 2018 to February 2019. In combination with the fixed PAM efforts, the USV contributed to achieving the overall program objectives of validating current understanding of seasonal

presence of humpback whales, confirming the presence/absence of other marine mammals and understanding the baseline soundscape characteristics. In addition, the USV study successfully demonstrated the use of uncrewed technology for marine mammal acoustic monitoring.

**Acknowledgments** We would like to acknowledge the important contribution made to this marine mammal monitoring survey by field staff based on the island of São Tomé and to BP Exploration (STP) Ltd. and partners, Kosmos Energy (STP) Ltd. and ANP-STP, for supporting this work during 2018–19.

**Abstract**

Approximately half of the North Pacific humpback whale population migrates annually to the Hawaiian Islands to breed during the winter and spring months. This Hawaii Distinct Population Segment (DPS) was removed from the US Endangered species list in 2016. Around that same time, this and other North Pacific DPSs experienced substantial climate-driven ecosystem disturbances on their Northeast Pacific feeding grounds, resulting in high mortality and disrupted migration patterns. In Hawaii, humpback whale presence has been monitored

continuously since 2014 by recording the levels of male song chorusing with acoustic moorings deployed off Maui. Changes in chorusing levels during the past eight breeding seasons indicate that humpback whale presence around Maui declined by approximately 50% between 2015 and 2018 and that the annual duration of whale presence in Hawaii across that period was reduced by up to 1 month. Chorusing levels mostly recovered in subsequent years, but the timing of the migration and the whales' residence time in Hawaii has continued to fluctuate. These results suggest that the Hawaii DPS is still adjusting to the ecosystem disturbances it experienced several years ago or may be at the beginning of a shift in migration patterns in response to climate change.

## Introduction

The Hawaiian archipelago is an important breeding ground for humpback whales in the North Pacific (Herman and Antinoja 1977; Calambokidis et al. 2008). Estimates suggest that approximately half of the North Pacific population migrates to the Main Hawaiian Islands annually during winter and spring to mate and socialize (Herman and Antinoja 1977; Calambokidis et al. 2008). This part of the population is known as the Hawaii Distinct Population Segment (DPS) and is one of nine humpback whale DPSs that was removed from the US Endangered species list in 2016 after being deemed recovered following the end of commercial whaling (NOAA 2016). Coincidentally, around that same time, humpback whales in the North Pacific experienced substantial ecosystem-wide disturbances on their Northeast Pacific feeding grounds off Alaska, Canada, and the Western USA caused by the convergence of a marine heat wave, a strong El Niño, and a warming period in the Pacific decadal oscillation (PDO) cycle that altered ocean currents and the flow of nutrients (Gentemann et al. 2017). These factors resulted in reduced prey availability on the feeding grounds that led to unusually high whale mortality (Savage 2017) and disrupted migration patterns in the population that affected whale presence on the Hawaiian breeding ground (Cartwright et al. 2019; NOAA 2019; Kügler et al. 2020; Frankel et al. 2022).

Male humpback whales produce an acoustic display of song, which forms a chorus when multiple whales sing simultaneously and becomes the dominant source of acoustic energy in the frequency band between 80 and 1500 Hz in Hawaiian waters during winter and spring, masking other biological, anthropogenic (e.g., vessel noise), and physical (e.g., wind-driven noise) sources of sound (Au et al. 2000; Au and Green 2000; Kaplan et al. 2017). The function of song remains debated but is believed to play an important role in the mating system of humpback whales by signaling to females and/or mediating male-male interactions (e.g., Darling et al. 2006; Cholewiak et al. 2018; see Herman 2017 for a comprehensive review on the function of song). Acoustic monitoring of song has been successfully

used to document trends in humpback whale presence in Hawaii and elsewhere, both temporally and spatially (Clapham and Mattila 1990; Au et al. 2000; Lammers et al. 2011; Seger et al. 2016; Noad et al. 2017; Kügler et al. 2020). Humpback whale presence in Hawaii has been monitored continuously since 2014 by recording the levels of male song chorusing on bottom-moored acoustic moorings deployed off the island of Maui (Kügler et al. 2020). Here we explore how humpback whale presence in Hawaii was affected during an 8-year period spanning the time before (2015), during (2016–2018), and after (2019–2022) the ecological disruptions experienced by the population. We examine song chorusing levels observed during each season to establish how whale presence varied between years.

## Methods

The study used data obtained from an ecological acoustic recorder (EAR) (Lammers et al. 2008) deployed at a depth of 12 m near Olowalu, Maui, to track the relative amplitude of song chorusing (Fig. 1). The EAR recorded for 30 s every 5 min at a sampling rate of either 25 or 50 kHz and was refurbished with new batteries and storage drives approximately every 6 months. The amplitude and timing of chorusing levels were used as indicators of relative whale abundance by relating measured decibel levels in the 0–1500 Hz band with visually derived whale density estimates as described in Kügler et al. (2020, 2021). In brief, a custom Matlab program (MATLAB and Statistics Toolbox Release 2015b, The MathWorks, Inc., Natick, MA, USA) downsampled 30 s recordings to 3 kHz sample rate and converted sample values to pressure, then calculated the root mean square sound pressure levels (RMS SPL) and converted the result into dB re 1 $mPa^2$ (following standards described in Ainslie et al. 2018). The data were averaged daily, and a 5-day running average was calculated for each day to smooth daily variation.

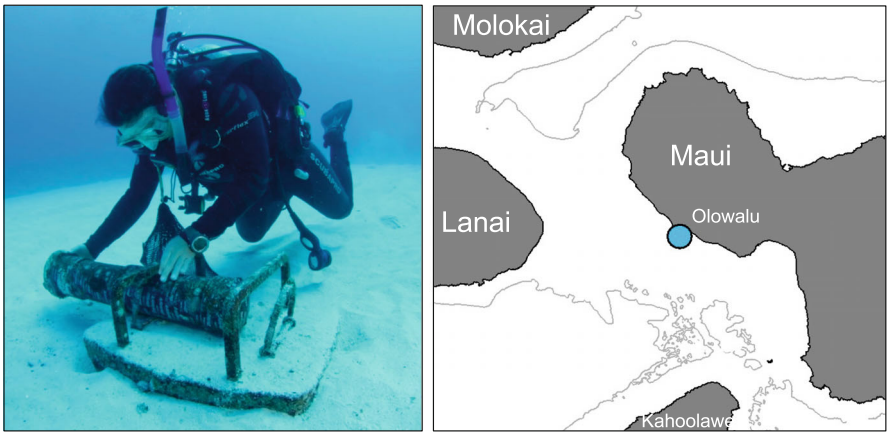

**Fig. 1** EAR deployment location off Olowalu, Maui. (Photo credit: Jason Sturgis)

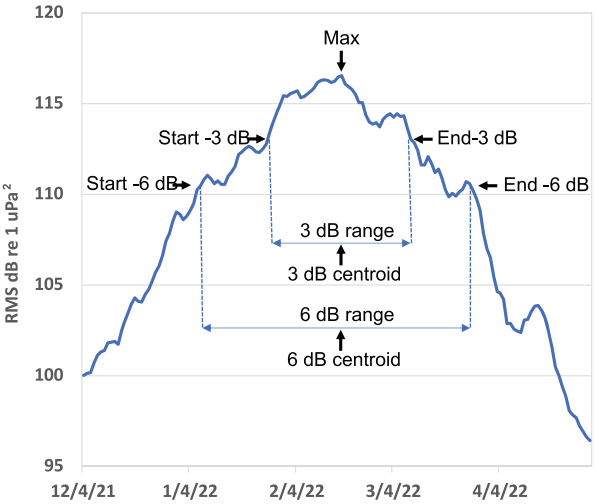

**Fig. 2** Humpback whale song chorusing decibel levels recorded between December 2021 and April 2022 off Maui showing max, −3 dB and −6 dB points

Data from each breeding season (December to April) when chorusing levels remained above other sources of ambient noise (e.g., vessel traffic, wind, etc.) were evaluated to establish: a) when peak chorusing (max) occurred; b) the number of days within 3 dB and 6 dB before and after the max; c) the total number of days within 3 dB and 6 dB of the max (range); d) the centroid of the 3 dB and 6 dB ranges; and e) the dates and number of days that chorusing levels in the 0–1500 Hz band were above 110 dB, a level reached during all 8 years (Fig. 2). These metrics were tabulated and used as a proxy for comparing the relative abundance of whales, the timing of their arrival and departure, and the relative duration of the whale season each year.

## Results

Chorusing levels varied during the eight winter breeding seasons that occurred between November 2014 and May 2022 (Fig. 3). Data from some time periods are not available because the EAR stopped recording either due to a malfunction or low batteries. The levels recorded during this period reveal that peak chorusing declined by more than 6 dB between 2015 and 2018 and that the annual duration of whale presence across that period was reduced by up to 1 month. Kügler et al. (2021) previously determined that this 6 dB decrease corresponded with an approximately 50% decrease in whale abundance, which matched with estimates obtained by other researchers for the same period (Frankel et al. 2022). Chorusing levels mostly recovered in subsequent years, but the timing of the migration continued to fluctuate annually (Fig. 3).

Annual chorusing statistics are presented in Table 1. The date of peak chorusing level varied by up to 1 month (between February 11 in 2015 and March 11 in 2020)

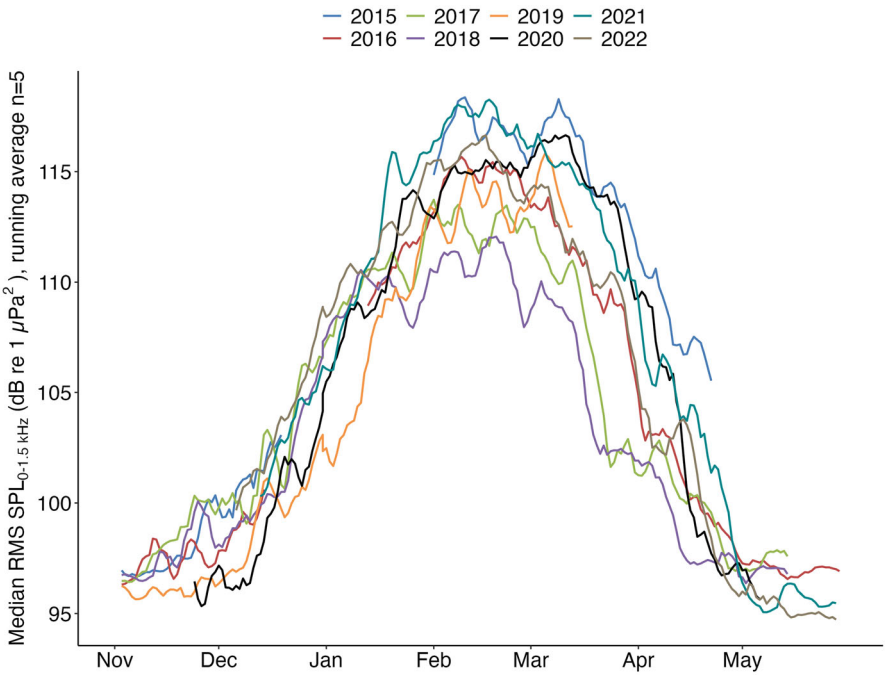

**Fig. 3** Humpback whale song chorusing decibel levels recorded during eight breeding seasons between 2014 and 2022 off Maui

during the 8-year period. The data also reveal that 2015 had the highest maximum chorusing level, which has not been surpassed since the ecosystem disruptions in the Northeast Pacific that began later that year. In addition, the 2015 season lasted longer than all subsequent seasons, with chorusing levels remaining above 110 dB until April 7, as well as 36 and 50 days lapsing between the chorusing max date and the −3 dB and −6 dB dates, respectively, which is longer than in any season since then. In 2020, the season peaked and persisted later than all other seasons, with a −3 dB end date of March 26, and both a 6 dB and 3 dB centroid date of February 23, which is later than all other years. Between 2016 and 2018, the season began progressively earlier, as revealed by the −6 dB start and 110 dB start dates. In 2019, the beginning of the season was considerably later than in 2018 and has begun progressively earlier in the following 3 years.

## Discussion

The results show that the abundance, timing, and residence period of humpback whales' seasonal migration to Hawaii have fluctuated since a marine heat wave combined with an El Niño and warming PDO event to disrupt the ecosystem in the Northeast Pacific feeding grounds between 2014 and 2017 (Gentemann et al. 2017).

These fluctuations have continued in recent years, with a general trend toward an earlier end to the breeding season in Hawaii, albeit with exceptions (e.g., 2020). This suggests that the Hawaii DPS may still be adjusting to the ecosystem disturbances it experienced several years ago (Cartwright et al. 2019; Kügler et al. 2020; Frankel et al. 2022). Alternatively, it could point to the beginning of a more long-term shift in migration patterns in response to climate change (von Hammerstein et al. 2022). Some whales may be forced to seek prey in different high latitude feeding areas, thereby affecting where, when, and/or how much time they spend on the Hawaiian breeding grounds. Lastly, it is also possible that annual fluctuations in migration could simply reflect normal variation resulting from a recovered population having reached carrying capacity (Begon et al. 2006; Kügler et al. 2020).

The extended duration of the 2020 breeding season coincided with the economic downturn that resulted from the COVID-19 pandemic. In Hawaii, Covid-related

lockdowns began in mid-March 2020, which coincided approximately with the peak of chorusing that year (March 11). Nearly all commercial vessel activity was halted temporarily by the end of March, which altered the amount of vessel traffic and noise experienced by whales during this time. This correspondence is interesting but may or may not be related. It is possible that less vessel noise prompted more whales to sing or for them to persist in Hawaii longer. Alternatively, the season may have been trending later due to factors unrelated to Covid, such as prey availability during the previous summer on the feeding grounds. Regardless, the timeline of this season's end is intriguing. If the timing of the whale's departure was indeed influenced by reduced human activity, it would be a stark indication of how vessel traffic affects whales. On the other hand, such a late departure, if driven by oceanographic/prey factors, would suggest that these are fluctuating even in the absence of a marine heat wave or an El Niño event, as was the case in 2014–2017.

The results presented indicate that continued monitoring is warranted to understand the long-term trends in this DPS, including in other parts of the Hawaiian archipelago where the population dynamics may be different. Lammers et al. (2023) recently reported the presence of a likely substantial number of humpback whales in the northwestern end of the Hawaiian archipelago. Sustained acoustic monitoring in that part of the archipelago would help determine whether whales in the Main Hawaiian Islands and Northwestern Hawaiian Islands are influenced in the same way by the climatic factors impacting North Pacific humpback whales.

**Abstract**

Passive acoustic monitoring (PAM) is instrumental to monitor marine mammals, with many applications, including impact of noise. Noise, however, also affects the ability of PAM to detect sounds of interest. The performance of a PAM algorithm was tested by feeding it recordings of ship noise merged with harbor porpoise (*Phocoena phocoena*) clicks. Three groups of porpoise clicks ("click trains") were inserted every 10 sec in files containing ship noise, one at a time (n = 1180 min). The recall (probability of detecting porpoises in 10-sec bins) was

modeled using a generalized linear model with a binomial distribution and one explanatory variable: noise in one of four frequency bands (<20 kHz, 20–80 kHz, 80–150 kHz, and the decidecade centered on 16 kHz). The best model had the 20–80 kHz band as the explanatory variable, but noise in all bands masked detections when exceeding 90 dB re. 1μPa, becoming a cofounding factor. Therefore, decreased detections at these noise levels cannot be attributed unequivocally to effects of noise on the behavior of porpoises but may be due to masking of the PAM instrument. However, PAM can be used, as long as the noise levels above 20 kHz are monitored and accounted for.

## Introduction

Monitoring wide-ranging cetaceans is a difficult task, and using traditional visual methods alone is limiting, especially for small-sized animals with cryptic behavior. The development of affordable passive acoustic monitoring (PAM) devices that can be deployed for long periods was a game changer, becoming instrumental to monitoring many cetacean species, such as the harbor porpoise (*Phocoena phocoena*). Harbor porpoises produce only one type of sound: polycyclic, narrow-band clicks. These clicks have peak and centroid frequencies between 100 and 150 kHz, with little or no spectral energy below 100 kHz, duration of about 100 μs, and − 3 dB bandwidths between 12 and 20 kHz (Hansen et al. 2008; Kyhn et al. 2013; Møhl and Andersen 1973; Villadsgaard et al. 2007). Clicks are emitted in trains in a narrow, forward-oriented beam (Au et al. 1999, 2006). A click train is a group of clicks with regular or gradually changing inter-click intervals (Koschinski et al. 2008), and the patterns in click production appears to be context dependent (Clausen et al. 2010; Sørensen et al. 2018; Verfuss et al. 2005). These characteristics make harbor porpoises' sounds well suited for PAM.

PAM systems have several advantages over visual surveys, as they can be used during bad weather conditions (e.g., high waves, fog) as well as at night. Data collection can be accomplished with no supervision, and therefore, the performance is not affected by the experience or levels of alertness of the observer. Moreover, because cetaceans spend most of their lives underwater, animals sometimes are only detected acoustically or are detected acoustically before they are detected visually (e.g., Yack et al. 2013).

Existing PAM devices that can be used specifically to study harbor porpoises can be divided into two main types: devices that only log data about acoustic events and those that record continuously. The most used data logger is the C-POD and its predecessor the T-POD (Chelonia Ltd., Cornwall, UK). T- and C-PODs have been successfully used for many applications, including understanding the impact of underwater noise (Dähne et al. 2013; Gallus et al. 2012; Koschinski et al. 2008; Kyhn et al. 2008; Tougaard et al. 2009). Wideband continuous recorders opened up

the possibility of more detailed sound analysis. Not only can the raw data be audited and reanalyzed using different parameters (e.g., detection thresholds), but it is also possible to study the temporal and spectral characteristics of the background noise. In turn, this can be used to better understand how noise impacts the target species.

Harbor porpoises are common in coastal and shelf waters (Bjørge and Øien 1995; Hammond et al. 1995), so they are regularly exposed to vessel traffic (Wisniewska et al. 2018). Ship noise is typically assessed at low frequencies (e.g., the EU descriptors for a healthy marine environment are measured at 63 and 125 Hz, Dekeling et al. 2014). This could suggest that porpoises would not be affected, as their best hearing is at high frequencies (Kastelein et al. 2010). However, recent studies carried out with devices that can record the full broadband signals from ship noise have shown that ship noise extends to much higher frequencies (Hermannsen et al. 2014) and that porpoises respond negatively, responding behaviorally or vocally, when noise exceeds certain levels (Dyndo et al. 2015; Wisniewska et al. 2018). Although high frequencies travel short distances (Urick 1983), porpoises are often close to vessels, and so it is expected that ship noise also contributes to masking porpoises' ability to detect sounds of interest (Erbe 2015).

Masking does not only affect the animals but also the PAM system itself. This phenomenon is well-known yet remains understudied (Clausen et al. 2019; Sarnocinska et al. 2016). If ship noise masks the PAM system, noise becomes a confounding factor, and reduced detections cannot be directly interpreted as reduced vocal behavior or displacement of harbor porpoises. There is, therefore, a need to further disentangle noise impact on detections and impact on the animals.

To address this, the performance of a PAM detector/classifier algorithm was investigated under different noise conditions on files containing ship noise that were merged with real harbor porpoise clicks. By doing this, the same number of porpoise detections was expected throughout the entire recording of a passing vessel. Thus, any decrease in or lack of detections would be a direct result of noise masking.

## Ship Noise and Porpoise Clicks

The data used here were obtained from five deployments carried out in Danish inner waters in 2015: four in the Great Belt area (55.3615 N, 10.9655 E) in August (n = 1), September (n = 1), and November (n = 2) and one in the Little Belt area (55.5295 N, 9.7535 E) in August (Fig. 1). The equipment used was one ST 202HF (Ocean Instruments, New Zealand), recording continuously at a sampling rate of 576 kHz. The ST hydrophone had a sensitivity of −172 dB re: 1 V/μPa.

The deployment location in the Great Belt is close to a shipping lane, so ship passages were selected to ensure only one vessel was passing at a time, assessed by the pattern of increasing and decreasing noise levels (Fig. 1). A total of 25 individual ship passages were selected, amounting to 430 min of recordings, covering different time periods in five deployment days.

Three porpoise click trains were merged with ship noise to prevent pseudo-replication. These trains were also extracted from the data and had different durations, signal-to-noise ratios, amplitude variations, repetition rates, and number of

**Fig. 1** Map of the study area. The rhomboids indicate the location of the acoustic recorders

clicks. Only one click train was merged at a time and inserted every 10 sec in each file. Periods with porpoise detections in the original files were removed to prevent errors in the interpretation of the results, which left in almost 1180 min of data.

## Noise Levels

For each 10-sec bin (n = 7076), the noise levels (dB re: 1μPa$^2$/Hz) were estimated from the power density spectrum (Welch average, 512-point FFT, Hann window, 50% overlap) for three frequency bands: 0–20 kHz, 20–80 kHz, and 80–150 kHz, as well as the decidecade centered on 16 kHz. The 16 kHz decidecade band was used because Wisniewska et al. (2018) identified it as a useful proxy for predicting porpoise reactions to ship noise, when noise in that band exceeds 96 dB re. 1 μPa$^2$/Hz.

## Porpoise Detections

The data consisted of *.wav* files of 10 or 30 min in duration, which were analyzed using D-PorCCA. D-PorCCA is a new analytical tool specifically developed for analyzing acoustic data of species that emit narrowband high-frequency clicks, like

the harbor porpoise. D-PorCCA includes a transient sound detector (adapted from Gillespie et al. 2008 by Parcerisas 2021), a porpoise click classifier (Cosentino et al. 2019), and a click train detector (Cosentino 2020). The click train detector groups clicks into acoustic events, which are then classified as either high- or low-quality porpoise click trains, based on the output of an algorithm that favors gradual changes in centroid frequency, amplitude, and inter-click intervals (Cosentino 2020).

## Noise Impact

The recall (probability of porpoise detection in a given 10-sec bin) was modeled using a generalized linear model with a binomial distribution and one explanatory variable: noise level in one of three frequency bands (<20 kHz, 20–80 kHz, or 80–150 kHz) or the decidecade centered on 16 kHz. The Akaike information criterion (AIC) value was used to compare the performance of the models with each other.

### Detections

The number of porpoise clicks detected decreased as the noise levels increased with passing vessels. The effect was visible when looking at individual vessel passages (Fig. 2), especially for increasing levels of noise in the 20–80 kHz frequency band. The models predicted reduced detections as a function of noise (Fig. 3) in all bands, and the model with the lowest AIC value (AIC = 3886.69) had noise in the 20–80 kHz frequency band as the only explanatory variable. The next best model was the one with noise in higher frequencies 80–150 kHz (AIC = 3972.76), then the decidecade centered on 16 kHz (AIC = 4070.34), and last the band <20 kHz (AIC = 4075.84).

### Disentangling Impacts

Wisniewska et al. (2018) found that the decidecade centered on 16 kHz could be used as a proxy to identify the noise levels at which porpoises respond behaviorally (by moving away from the noise) or becoming silent. The models in this study indicate that noise masks porpoise detections when it reaches about 90 dB (dB re: $1\mu Pa^2/Hz$) in all frequency bands, but especially the 20–80 kHz band (Fig. 3). This means that when noise surpasses these thresholds, masking occurs (Fig. 4).

## Conclusions

Ship noise extends far beyond the low frequencies at which it is typically monitored, reaching frequencies at which porpoises react both by changing their behavior (e.g., moving away) and also by becoming silent (Dyndo et al. 2015; Wisniewska et al. 2018). However, reduced detections (or no detections at all) during noisy periods cannot be safely explained as an effect of noise in the behavior of porpoises. At high

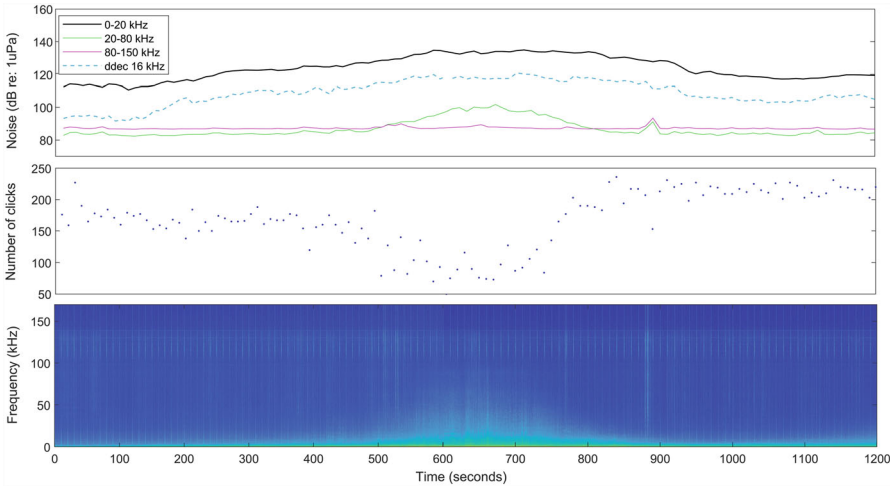

**Fig. 2** Ship noise and porpoise detections. Top panel: background noise levels (dB re: 1μPa$^2$/Hz) in three frequency bands (0–20 kHz, 20–80 kHz, and 80–150 kHz) and the decidecade centered at 16 kHz. Center panel: changes in the number of clicks detected in 10-second bins. Bottom panel: long-term spectral average of the merge files, showing the passing of an individual ship recorded on August 12, 2015, at 3.56 am in the Great Belt area. The vertical lines with energy between 100 and 150 kHz are the inserted porpoise click trains

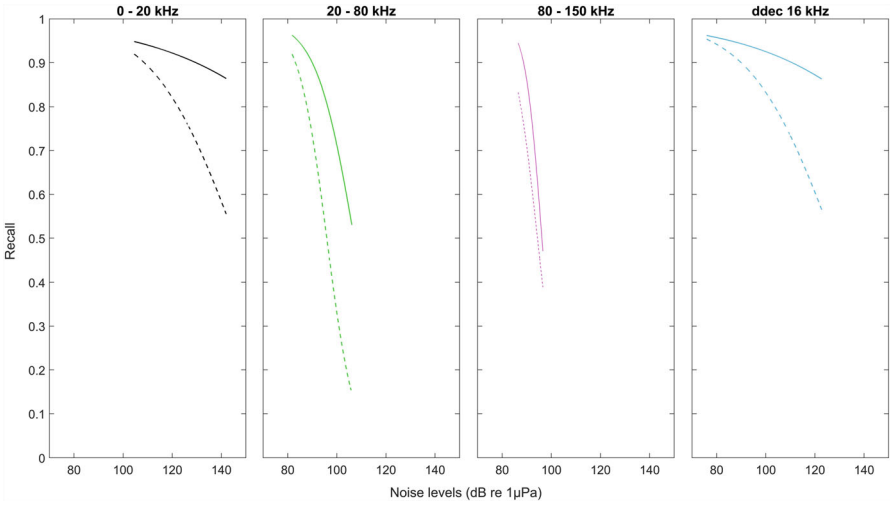

**Fig. 3** Recall (probability of detecting porpoises) as a function of ship noise. Modeled recall shows a decrease in detections as noise (dB re: 1μPa$^2$/Hz) increases in different frequency bands: <20 kHz (AIC = 4075.84), 20–80 kHz (AIC = 3886.69), 80–150 kHz (AIC = 3972.76), and the decidecade centered at 16 kHz (AIC = 4070.34). Solid lines include porpoise click trains of high and low quality. Dashed lines include only porpoise click trains of high quality

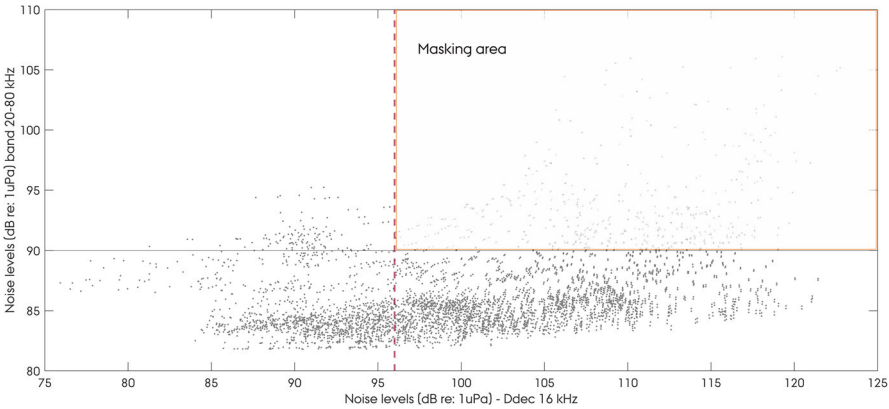

**Fig. 4** Masking. Noise levels (dB re: 1μPa$^2$/Hz) in the ddec centered at 16 kHz vs in the 20–80 kHz frequency band. The shaded area shows where noise masks the acoustic reaction of porpoises

received noise levels, the noise masks the PAM system's detectability, becoming a confounding factor.

As long as frequencies above 20 kHz are monitored and accounted for in the analysis, PAM can be used for monitoring the impact of noise on animals.

**Abstract**

In 2021, the International Association of Oil and Gas Producers (IOGP) published a report in which measurement procedures are described that enable the acoustic characterization of underwater sound sources associated with seismic acquisition, high-resolution geophysical surveys, and production of oil and gas. These procedures are designed to provide consistency and comparability of independently carried out measurements. An initial review of existing methods revealed that there was some commonality in reported measurements of airgun arrays and high-resolution geophysical sources, but very few reports or publications included all relevant parameters. Achieving comparability in measurements requires precise nomenclature and clear documentation of the various choices made concerning measurement geometry, instrumentation, and processing. The measurement procedures describe requirements and recommendations for equipment selection, calibration, placement in depth and range, sampling rates, and operational measurement procedures for the three source types. Signal analysis methods are specified, as well as reporting content and formats for the acoustic results and relevant metadata. Where possible, calculation procedures are described to determine source metrics from the measured acoustic field, which can be used as input for environmental impact assessments for future projects.

**Keywords**

Measurement procedure · Underwater sound · Sound sources · Sound measurement · Seismic exploration · Geophysical surveys · Oil and gas platforms

## Introduction

Activities related to offshore oil and gas exploration and production introduce sound into the marine environment. Since the early 1990s, there has been increasing environmental and regulatory focus on the effects on marine life of that and other man-made sound in the sea. Assessment of potential effects relies on the proper quantification of the dose of sound to which animals are exposed. Achieving consistency in measurements for underwater sound sources depends strongly on being precise with nomenclature and carefully documenting the required measurement geometries, instrumentation, and processing. Lack of standardization of terminology and of procedures for measuring or predicting and reporting of underwater sound leads to potential inconsistencies and uncertainties in the reported numbers (Ainslie et al. 2017). This hampers effective regulation and mitigation of underwater sound.

The International Association of Oil & Gas Producers (IOGP) promotes the use of standard procedures for underwater sound measurements for activities related to offshore oil and gas exploration and production (E&P). Under its Sound and Marine Life Joint Industry Programme (JIP) (http://www.soundandmarinelife.org/), a consortium consisting of TNO (Netherlands), CSA (USA), UNH (USA), and JASCO (Canada) and independent consultants produced a series of reports describing standard terminology (Ainslie et al. 2018a) and procedures for data processing (Ainslie et al. 2018b) and reporting (Ainslie and de Jong 2018). All reports are available online at http://www.soundandmarinelife.org/library.aspx.

This chapter introduces recently published measurement procedures for underwater sound sources associated with oil and gas exploration and production activities (de Jong et al. 2021). It follows ISO 18405:2017 of the International Organization for Standards (ISO) and the terminology described in (Ainslie et al. 2018a).

## Overview of Report Contents

The reported procedures provide a scientific guide on measuring underwater sound generated by oil and gas activities. Therefore, these are supported by and further support existing standards, which are referenced throughout. The final product is a report that describes all details of the procedures to be followed, with the goal of consistency and comparability across projects. The report contains the following sections:

1. Introduction (Background, Objective, and Scope).
2. Terms and definitions (Sound source types, Guidance on characterizing sound source signals, SL, SPL, PL).
3. Instrumentation (Selection of hydrophones, Preamplifiers, Filters, ADC, Recording system, Calibration).
4. Sensor deployment (Mooring geometries, Flow noise suppression, etc.)
5. Measurement procedures
   - General considerations and requirements
   - Procedure for measuring type A and B sources
   - Procedure for measuring type C sources
   - Required auxiliary measurements
6. Data processing (Received sound metrics)
7. Calculation of source output metrics
8. Uncertainties
9. Reporting

## Selection of Source Type and Source Metrics

Standard procedures are proposed for measurement of underwater sound associated with the following three types of sound sources:

1. **Type A sources**: Used for geophysical exploration surveys ("seismic acquisition"), such as airgun arrays, water guns, sparkers, boomers, some sub-bottom profilers, and marine vibrators. These typically emit most acoustic energy at frequencies below 1 kHz at a pulse repetition rate below 1 Hz. Their low frequency leads to a large beam width.
2. **Type B sources**: Used for high resolution geophysical (HRG) surveys, such as multi-beam echo-sounders, side scan sonars, and some sub-bottom profilers. These typically emit most acoustic energy at frequencies above 1 kHz at a pulse repetition rate above 10 Hz. The high frequency is typically associated with a narrow beam, which places constraints on the measurement procedure. The processing required for back-propagation to a source property also depends on frequency.
3. **Type C sources**: Associated with production platform activities. These are typically stationary sources that emit underwater sound as an unintended by-product of their activity, such as pumping and drilling. These are treated as a single composite source, similar to the ISO 8297 engineering method for measuring airborne sound power levels of multisource industrial plants.

The association of a source with one of these three types is based mainly on its frequency band and corresponding directivity. This association has implications for the selection of appropriate measurement and processing procedures. In cases where the association in uncertain, the user can make a pragmatic choice.

The measurement and analysis procedures have been developed on the basis of an initial literature review of existing methods, combined with the experience of the developers. The literature review revealed that there was a fair degree of commonality in reported measurements of airgun arrays (type A) and HRG sources (type B), but very limited commonality in reported measurements of oil and gas production activities (type C). Very few reports or publications included all relevant parameters.

The procedures are applicable for measurements of the underwater sound of these sources in or close to operational conditions, for which the measurement equipment is to be deployed in the operational area, with limited impact on operations. The measurement procedures describe requirements for selection of equipment, calibration, placement in depth and range, sampling rates, and operational measurement procedures for the three source types. Signal analysis methods are specified, as well as reporting content and formats for the acoustic results and relevant metadata.

The scope is limited to measurements of sound pressure, for the purpose of source characterization. It does not include procedures for measurement of sound particle motion. This relatively new measurement technique is addressed in the Interim Best Practice Guide for Underwater Particle Motion Measurement for Biological Applications (Nedelec et al. 2020).

Characterization of the sources in terms of a full coherent source waveform, facilitating full reconstruction of the transmitted waveform, including phase information, is considered to be achievable only under carefully controlled conditions, similar to those for the collection of the Svein Vaage data set (Vaage et al. 1983; Prior et al. 2019). Such measurements, whether for arrays or single source elements, are outside the scope of this project.

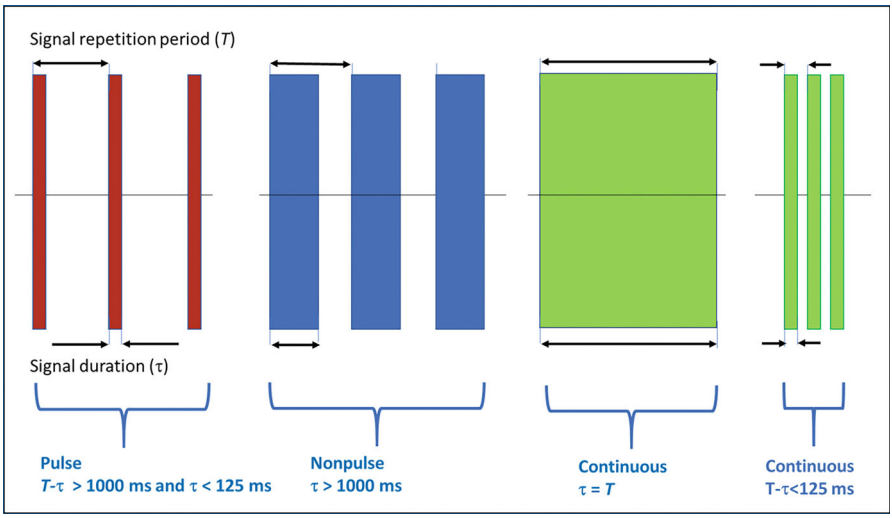

**Fig. 1** Schematic representation of signals, with different signal repetition periods ($T$) resulting in classification as either pulse, nonpulse, or continuous signal. See also Table 2

Hence, measurement procedures for underwater sound sources must collect all data that is needed to perform this calculation. The measurement geometry needs to be optimized, to limit the inherent uncertainties associated with the source calculation, and it needs to be carefully documented and the environmental acoustic parameters properly characterized.

The source characteristics based on sound pressure are expressed in different acoustic metrics, depending on the nature of the sound pressure field. Sources of type A and B often emit *pulse* or *nonpulse* sound. ISO 18405 does not define these terms, while sources of type C often emit *continuous* sound. Within this project no consensus could be achieved on a formal classification of signals as *pulse*, *nonpulse*, and *continuous*, but guidance is provided for making this characterization, according to the signal duration ($\tau$) and the silence duration ($T - \tau$), with $T$ the signal repetition period (defined as the reciprocal of the signal repetition rate), see Fig. 1 and Table 1.

## Preparation for Source Measurements

Because of the variety of sources, operational circumstances and limitations, and specific project requirements, the measurements need to be carefully prepared. Information needs to be gathered on the source to be measured, including its operational settings, and the operational environment and conditions in which the measurements are to be performed. The required information is elaborated in the following subsections. The details of the measurement plan should be determined based on this information.

**Table 1** Categorization of signals as pulses (short duration signals with a long inter-signal interval), nonpulses (long duration signals with a long inter-signal interval) and continuous signals (signals with a short or nonexistent inter-signal interval). The gray areas represent signals that are not clearly in one category or another. In these gray areas, practical considerations may determine the most appropriate choice. See also Fig. 1

| Inter-signal interval | Signal duration $\tau$ < 125 ms | 125 ms < $\tau$ < 1000 ms | Signal duration $\tau$ > 1000 ms |
|---|---|---|---|
| $T - \tau < 125$ ms | continuous | Continuous | continuous |
| 125 ms $< T - \tau <$ 1000 ms | user-defined | user-defined | user-defined |
| $T - \tau > 1000$ ms | pulse | user-defined | nonpulse |

**Table 2** Defined geometric parameters for Fig. 2 and in text

| Symbol | Description |
|---|---|
| $L_x$ | Horizontal source dimension (length) |
| $L_y$ | Horizontal source dimension (width) |
| $L_z$ | Vertical source dimension |
| $z$ | Source depth ($z \leq L_z$) |
| $H$ | Water depth |
| $r$ | Slant range (hydrophone distance) |
| $\phi$ | Vertical observation angle |
| $\theta$ | Horizontal (azimuthal) observation angle |
| $h$ | Hydrophone minimum height above sea floor |
| $R = r \cos \phi$ | Horizontal hydrophone distance (far field) |
| $D = z + r \sin \phi$ | Hydrophone depth ($D \leq H - h$) |
| $A =$ max ($L_x$, $L_y$, $L_z$) | Maximum source dimension |

## Description of the Source and Its Operational Settings

The following questions need to be answered.

- Under which of the three source types (A, B, and C) can the sound source to be measured be categorized?
- For type C sources (production facilities):
  - Which facility components and operations are to be included in the source characterization?

- What are the main geometrical dimensions of the source?
  - What are the dimensions of the smallest closed surface (rectangular box) that spatially bounds the source?
  - What are the three-dimensional coordinates of the assumed acoustic center, relative to the geometry of the actual source?
- What information is available on the underwater sound radiated by the source?
  - What is the frequency range of the source?
  - Can its radiated sound signals be classified as "pulse," "nonpulse," or "continuous"?
- At which locations and over which time durations will the source be operated?
- At which settings will the source be operated and to what extent can its operation be adapted for the measurements?
  - Sources of types A and B are controlled by an operator; thus, the vessel from which the source is deployed may have the possibility to adapt its route and timing to optimize the measurements.
  - Source of type C produce underwater sound as an unintended by-product of their activities, which may or may not be controlled by an operator, generally fixing the location and operation time.

## Description of the Operational Environment and Conditions

- At what location can the measurements be performed?
- What is the local water depth?
  - How does it vary over the operational area?
  - How is it affected by tidal variations?
- What information is available on the local sea water?
  - Acoustic models require local sound speed, as a function of depth, and absorption.
- What are the local sea floor features (are there rock outcrops or local channels)?
  - Generally, it is best to place measurement systems at locations where depth and seabed features are least variable.
- What information is available on the local sea floor composition?
  - Acoustic models require local sediment properties in terms of density, compressional (and shear) wave speed, and absorption, as a function of sediment depth, (i.e., geoacoustic profile).
- What information is available on the local weather conditions?
  - Acoustic propagation is affected by wind-generated surface waves.
  - Weather conditions may lead to practical limitations for measurements (safety and positional stability of measurement equipment).
- What information is available on other activities in and surrounding the operational environment?
  - Is it likely that the measurements are disturbed by operation of other sources in the project area or by nearby vessel traffic?

## Specification of the Requirements for Source Characterization

- Which operational conditions are of interest for the measurements?
  - The operational conditions need to be sufficiently representative in measurements to address environmental impact assessment.
- Which frequencies are of interest for the source measurements?
  - The selection of the measurement frequency range needs to match with the frequency range of interest for environmental impact assessment.
- Which source metrics are of interest?
  - Source metrics depend on the class of signals ("pulse," "nonpulse," or "continuous").
  - Source metrics depend on the metrics of interest for environmental impact assessment.
  - Local regulators may require specific metrics.
- What are the uncertainty requirements for the reported metrics?
- Which are the aspect and elevation angles at which the source characteristics are to be measured?

## Frequency Range

Since the aim is to characterize sources for environmental impact assessments, the frequency range of interest is driven by the sensitivity of marine life.

This report advises a **frequency range** for characterizing sources that at least includes the **10–50 kHz decidecade bands** (ranging from 8.91 to 56.2 kHz).

This requires a minimum sample rate above 113 kHz, which is practically achievable, because many off-the-shelf audio-recorders offer a 128 kHz sample rate.

Where possible, the acoustic frequency range should be extended up to the 160 kHz decidecade band (i.e., up to 178 kHz, which requires a minimum sample rate above 356 kHz), to cover the hearing range of high frequency marine fauna, such as the harbor porpoise.

Note that type B sources that operate at primary frequencies above 160 kHz may also radiate sound at lower frequencies, within the hearing range of marine life (Deng et al. 2014).

## Measurement Geometry

The measurement procedures focus on characterizing the far field source sound emissions rather than the effect of the operating environment on the received sound levels. The measurement distances shall be far enough from the sources that near-field effects are negligible, but also near enough to avoid poor signal-to-noise ratio (SNR) in the measurements and uncertainties associated with quantifying long-range propagation effects. A specific difficulty in dealing with long-duration signals is that source position of moving sources at the time of sound signal emission

becomes difficult to define. Nevertheless, if the source-receiver geometry variation is small over the signal repetition period, longer-duration signals can also be accommodated under the measurement procedures specified.

Figure 2 schematically illustrates the detailed measurement geometry and partners with Table 2 to define the geometric parameters.

### Measurement Distance

Ideally, source characterization measurements are made with sensors in the far field of the source, so that it can be described as a point source. As a first requirement (from ANSI/ASA S1.20:2012 developed by the Acoustical Society of America (ASA) and accredited by the American National Standards Institute (ANSI)), the minimum range $r$ that is required for measuring in the far field, should fulfil:

$$r > \pi A^2/4\lambda \tag{1}$$

with acoustic wavelength $\lambda = c/f$ (for sound speed $c$ and frequency $f$) and $A$ the maximum source dimension $A = \max(L_x, L_y, L_z)$.

In addition to the requirement to measure in the acoustic far field, there may be external requirements to maintain a safe minimum distance between source and hydrophone. For example, for the safety of personnel and equipment, or for the practicality associated with deploying and retrieving moorings near production activities.

This minimum specified distance depends on source type. For type A the recommend distance is 100 m and for type B it is 50 m. Moreover, the minimum distance of 100 m allows for the type A measurement zone to be of sufficient size to accommodate the low signal repetition rate, which is not necessary for type B sources.

The above requirement for the acoustic far field does not necessarily apply to type C sources that may contain multiple incoherent source mechanisms. The maximum dimensions associated with these source mechanisms are generally smaller than the maximum dimensions of the complete platform and unknown at the time when the measurement locations are planned. Hence, the frequency dependent minimum range for measuring in the far field (Eq. 1) is not required. For type C sources, hydrophones shall be deployed at a horizontal distance greater than or equal to 1.5 times the maximum horizontal dimension ($L_x$, $L_y$) of the surface that encloses the source, measured from the position on the contour that is closest to the hydrophone.

Hydrophone locations shall be selected such that no objects block a line-of-sight from the hydrophone to the full surface that encloses the source or affect the sound pressure measurements via acoustic reflections.

Hydrophone locations shall be selected such that the water depth along the trajectory between source and hydrophone is close to uniform or varies with a gradual slope.

### Vertical and Horizontal Observation Angles

Measuring the full directionality of source emissions is impractical and beyond the scope of the proposed measurement procedures. Instead, five main observation directions are defined, one keel and four horizontal aspects (see the plan view in Fig. 2).

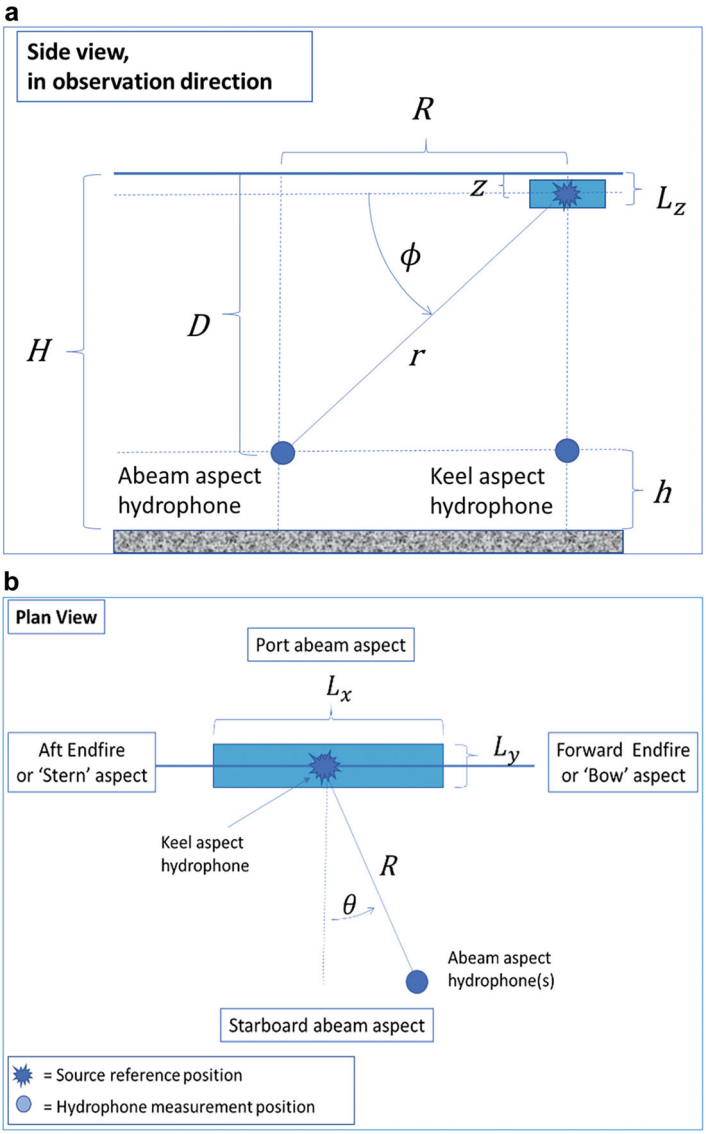

**Fig. 2** Schematic side view (top) indicating source traveling toward the reader, and plan view (bottom) of the measurement geometry indicating source traveling left to right. The sound source is contained within a (blue) bounding box (with length $L_x$, width $L_y$, and height $L_z$). Far field sound emission characteristics are determined for a hypothetical point source inside the box, which is assumed to be at a distance $z$ below the water surface. The figure parameters are defined in Table 2.

Keel aspect addresses the sound emission nominally in the vertical direction ($\phi = 90°$), directly below the source. This direction is of particular interest for type A and B sound sources because animals situated directly beneath a source will often experience the highest sound levels.

The four main horizontal aspects (bow, stern, and port and starboard abeam) are defined to characterize sound emissions mainly in horizontal directions. These measurement geometries also prescribe associated vertical angles, but the goal is to characterize sound emissions that mainly propagate horizontally to assess the exposure of animals at larger distances from the source. The bow is in front of the source and the aft is behind the source. Looking to the bow, port is to the left and starboard is to the right of the source, both "abeam" aspects (port and starboard) are perpendicular to the source track. For ships, abeam aspect is the direction in which the radiated noise level measurements of ships are made, according to the ISO 17208-1 standard. For the type A and B sources, the abeam definition is adapted to indicate the bearing projected at right-angles from the bow and aft line, outward from the center of the source. For type C sources, the horizontal directionality needs to be specified case-by-case.

Sound source measurements are to be taken from different aspects:

- For type A sources from at least three aspects: either the bow or stern aspect, either the port or starboard abeam aspect, and the keel aspect.
- For type B sources the procedure requires measurements from at least two aspects: either the port or starboard abeam aspect, and the keel aspect.
- For type C sources the user should define the aspects.

The vertical observation angle ($\phi$), see Fig. 2, needs to be representative of sound emission angles that lead to long-range propagation. Those propagation paths are relatively shallow, but to obtain reliable measurements it is necessary to maintain a minimum $\phi$ to avoid excessive surface interference effects that occur at very shallow angles.

Therefore, in *deep* water (see section "Water depth") the following three abeam measurement angles are to be selected: $\phi = 15°$, $30°$ , and $45°$, which are based on ISO 17208-1 geometry specified for radiated noise level measurements of ships.

The opportunity to measure the abeam aspect source emissions at these three angles is limited by the minimum measurement distance ($R$) necessary to be in the acoustic far field of the source, the water depth ($H$), the distance between the hydrophone and the sea floor ($h$), and the source depth ($z$).

The hydrophone geometry for abeam aspect measurements in *shallow* water (see section "Water depth") uses a single hydrophone positioned at horizontal distance $R$ off the source track and at depth as close as possible to the seabed to maximize the angle $\phi$ of the direct acoustic path.

There is no general standard for selecting a minimum height ($h$) of the lowest hydrophone above the sea floor. Proximity of the hydrophone to the sea floor may affect the measurements due to contributions of bottom-reflected sound, interface waves, and other sea floor vibrations that can cause hydrophone accelerations leading to unwanted noise. Alternatively, flow noise on hydrophones close to the sea floor can be reduced because water currents there are often lower. Hence, the effects of hydrophone position relative to the sea floor will need to be evaluated for each project to ensure they are accounted for appropriately.

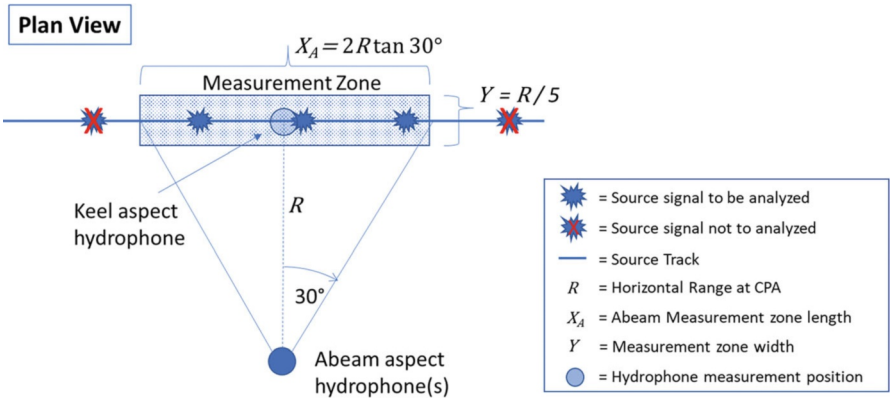

**Fig. 3** Plan view of abeam and keel aspect measurement zone relative to hydrophone locations

For moving sources (types A and B), a measurement zone is defined along the portion of the track subtending an angle of $\pm 30°$ relative to line segment between the abeam hydrophone position and the source's CPA position, as shown in Fig. 3. The measurement zone is centered on the source track and is given a width of $Y = R/5$ to accommodate up to $\pm 10\%$ range deviation that might result from the source being towed slightly off-track. This allowance is expected to result in maximum measurement errors less than 1 dB. However, when measuring type B sources with narrow cross-track beam widths, the off-track deviation may have to be smaller to ensure the keel hydrophone samples the beam.

### Water Depth

This report defines minimum water depths for both *deep water* and *shallow water* measurement geometries.

The minimum water depth allowed for the *deep water* geometry is required to obtain measurements of at least $\phi = 45°$ vertical angle (see Fig. 2) when the source reaches its closest point of approach (CPA), corresponding with horizontal distance $R$, to the abeam hydrophones. This means that the water is *shallow* when the water depth is less than the horizontal measurement distance $R$ plus the source depth ($z$), plus the distance of the hydrophone above the sea floor ($h$).

The minimum water depth allowed for the *shallow water* geometry is defined to obtain measurements of at least $\phi = 15°$ vertical angle (ref Fig. 2) when the source reaches its CPA.

## Requirements for Statistical Analysis of Source Output

Multiple measurements over time are required to evaluate statistical variations caused by:

- Variations of the source signal (a sensor at a fixed distance from a type C source can be useful to provide information on source signal variations over time).
- Geometry variations (for type A and B sources that are generally towed or mounted on a moving platform), including variations due to small-scale seabed features and geoacoustic parameter differences that affect seabed reflectivity.
- Variations in environmental conditions (wind, currents, etc.)

Multiple sensors are required to evaluate statistical variations caused by:

- Evaluating the source metrics in different aspects and frequency bands.
- Statistical uncertainties in propagation loss estimation.

## Data Processing (Received Sound Metrics)

The term "data processing" is used here to mean the conversion from recorded sound signals to processed metrics of received sound at the position of each hydrophone. The focus is on metrics for describing sound pressure signals that are suitable for the quantification of their possible biological impact, and for conversion to source output metrics. Both applications are topics of scientific investigation. Future updates of this report may include additional metrics. Specification of the time period and the frequency range over which these metrics are calculated depends on the signal type (*pulse*, *nonpulse*, or *continuous*, see Table 1), as well as on whether the source is moving (type A and B) or stationary (type C) during the measurements.

The report specifies the data processing steps that are required to quantify these metrics, starting from the digitized representation of the measured sound pressure at the output of the ADC at the end of the measurement chain.

### Metrics for Pulse and Nonpulse Signals

The main received sound metric to be calculated for pulse and nonpulse signals is sound exposure level ($L_{E,\,p}$).

The *temporal analysis window* (TAW) is a time window corresponding with signals captured while the source was within the spatial measurement zone (Fig. 3). The TAW may include multiple pulse or nonpulse signals, as illustrated within the blue box of Fig. 4.

The *temporal observation window* (TOW) is a time window that contains a complete received signal of a *single* pulse, as illustrated within the green boxes of Fig. 4, or the full sequence of signals of interest for a single nonpulse transmission nonpulse. The reported statistics are calculated from the metrics of multiple individual TOWs.

Other metrics such as sound pressure level ($L_{p,\mathrm{rms}}$), peak sound pressure level ($L_{p,\mathrm{pk}}$), or SEL with a specified (auditory) frequency weighting ($L_{E,p,\mathrm{w}}$) may be

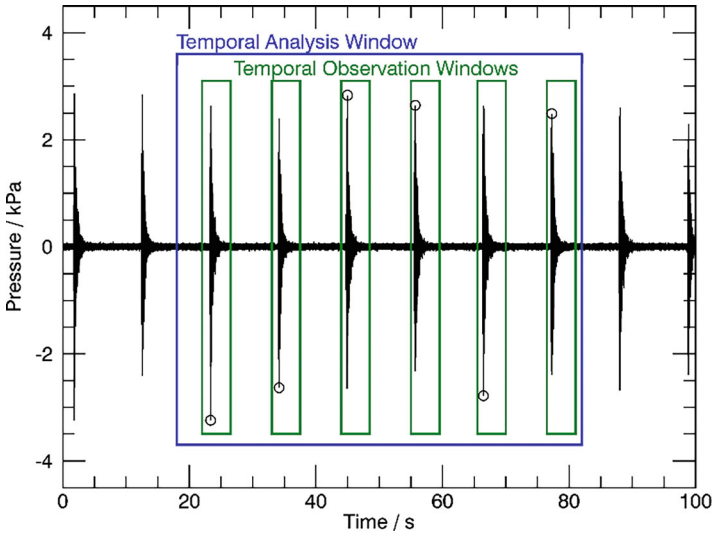

**Fig. 4** Illustration of time windows for pulse and nonpulse signals (example for a sequence of airgun pulses). Black curve: sound pressure time series; the black circles indicate the (compressional or rarefactional) peak sound pressures of single pulses within each individual pulse's respective TOW. Green boxes: TOW for $L_{E,\,p}$ for six complete pulses. The blue box spanning the six pulses represents the selected TAW, during which the source was within the spatial Measurement Zone

required. It may also be of interest to determine additional metrics such as, e.g., kurtosis, see (Prior et al. 2019; Martin et al. 2020; Müller et al. 2020).

## Metrics for Continuous Signals

The main received sound metric to be calculated for continuous signals is sound pressure level ($L_{p,\mathrm{rms}}$).

For continuous signals from stationary sources (type C), $L_{p,\mathrm{rms},60\ \mathrm{s}}(t)$ shall be calculated over a series of time intervals (TOW) $T = 60$ s. The TOW duration is selected in correspondence with the guidelines for observation of ocean sound proposed by the International Quiet Ocean Experiment (IQOE 2019).

## Calculation of Source Output Metrics

Underwater sound sources are typically quantified in terms of their source level. Since 2017 the term source level has been defined in an international standard for underwater acoustic terminology [ISO 18405]. This defines source level ($L_S$) in terms of the product of the square of the distance and the mean-square sound

pressure at that distance in the acoustic far field of the sound source "if placed in a hypothetical infinite uniform lossless medium of the same density and sound speed as the real medium at the location of the source, with identical motion of all acoustically active surfaces as the true source in the true medium." This cannot be measured in practice, but it can be calculated from measurements of sound pressure level ($L_p$) in a real environment. If there is one and only one sound source contributing to the sound field, source level can be calculated by adding the propagation loss ($N_{\mathrm{PL}}$) between the source and receiver locations in that environment to the measured sound pressure level

$$L_S = L_p + N_{\mathrm{PL}}. \tag{2}$$

The main sound source metric to be calculated for pulse and nonpulse signals is "energy source level" ($L_{S,E}$), equal to the sum of sound exposure level ($L_E$) and propagation loss ($N_{\mathrm{PL},E}$) for the measurement environment and geometry (ISO 18405)

$$L_{S,E} = L_E + N_{\mathrm{PL},E} \tag{3}$$

Propagation loss is usually assumed to be a frequency-dependent, time-invariant property of the environment and geometry over the duration of the measurement period. Frequency domain representations of $N_{\mathrm{PL}}$ and $N_{\mathrm{PL},E}$ for the same measurement geometry and environment are equal ($N_{\mathrm{PL}} = N_{\mathrm{PL},E}$) and can be determined from:

- Measurements on a source with a known source level, in the same environment with the same measurement geometry. Note: In an environment with multipath propagation, the three-dimensional directionality of this source needs to reproduce the directionality of the actual source.
- An appropriate numerical propagation model that accounts for source and receiver geometry, sea surface and seabed reflections, and acoustic absorption, where possible validated (or calibrated) for the measurement environment.
- An appropriate semiempirical ("practical spreading law" (Ainslie et al. 2014)) model, calibrated by measurements at multiple distances from the source. This approach is considered suitable for measurements of type B (HRG) source measurements in which propagation loss is dominated by spherical spreading and absorption in sea water.

Note that ISO 18405 provides no definition for source metrics resulting from measurements of zero-to-peak sound pressure level, hence these are not included.

Two different type C source configurations are considered:

(a) Floating platforms in deep water (Fig. 2, top).
(b) Bottom mounted platforms that extend over the water depth.

The source level of a *floating platform* can be determined following the approach for measuring ship source level (ISO 17208-1 and 17208-2) when measured in deep water. The source level can be defined in shallow water as well; however, a standard procedure for measuring ship source level in shallow water is still under development (ISO 17208-3).

For *bottom-mounted platforms* in shallow water, calculation of source metrics faces the same problems as observed for offshore pile driving. The scope of the ISO standard for measuring radiated underwater sound from percussive pile driving (ISO 18406) does not include the calculation of source level metrics. The Annex to ISO 18046 explains that it is not yet clear how to provide an entirely robust definition of source level for percussive pile driving. Sound sources that penetrate both the water surface and the seabed are intimately connected to the environment. This means that if the environment changes, so does the source output. Hence these sources cannot be properly characterized independent of the environment in which they operate. Nevertheless, source characterization may be required to map the sound distribution around their operational location. In that case, it is advised to adopt an approach based on inter- and extrapolation of the received sound metrics at the measurement locations to the sound map of the environment.

## Conclusions

- Reports describing standard procedures for characterizing underwater sound sources associated with oil and gas exploration and production activities are available online from http://www.soundandmarinelife.org/library.aspx.
- Regular maintenance of these standards is recommended. ISO standards are reviewed every 5 years. Therefore, feedback from users of these standards is appreciated, to support future updates, incorporating lessons learned.
- In the event that procedures cannot be precisely followed, it is imperative that all deviations from the standard procedures be thoroughly documented and reported. The importance of following these standard procedures is the provision of comparability between studies and results.

**Acknowledgments** This work was sponsored by the E&P Sound and Marine Life Joint Industry Programme under the auspices of the International Association of Oil and Gas Producers (IOGP). In particular we thank Mr. Michael Jenkerson for recognizing the need for inter-project alignment and for his continuing support throughout this standards project. We thank the members of the project steering group for their constructive comments after reviewing versions of the report. We thank TNO for the permission to publish material from report TNO 2021 R11210-A in this chapter. And we thank Darlene Ketten, Mark Prior, Erwin Jansen, and Roberto Racca for their valuable contributions to various stages of development of the standard procedures.

**Abstract**

Aquatic ecosystems contain some of the world's most diverse environments, and their soundscapes are often teeming with sounds from a wealth of biological sources. Passive acoustic monitoring (PAM) is an increasingly accessible technique that offers an unprecedented, non-extractive means to "observe" these habitats, many of which are too deep, dark, turbid, or remote to sample easily with other methods. Applications to assist analysis of PAM data already exist (e.g., reference libraries, data portals, discussion forums), machine learning code is increasingly more available, and citizen science programs are broadening public interest in underwater sound. However, individually, these resources do not realize their full potential. To help address this limitation, a working group for a Global Library of Underwater Biological Sounds (GLUBS) has proposed an open-access web-based single-point-of-contact platform to integrate and expand these applications to help broaden and standardize scientific and community knowledge of underwater soundscapes and their contributing sources. This paper presents a summary of a meeting of the GLUBS working group that was

of local habitat at the recording site (e.g., Greenhalgh et al. 2020; Linke et al. 2018; Mooney et al. 2020; Rountree et al. 2020b; Williams et al. 2022). However, the world's aquatic ecosystems are experiencing rapid changes as our planet progresses through the Anthropocene epoch, and in response, their inhabitants are changing their distribution, behavior, and contributions to the soundscape (Duarte et al. 2021). Passive acoustic monitoring (PAM) is a technique for sampling aquatic systems that can be particularly effective in deep, dark, turbid, and rapidly changing or remote locations (ACT 2007; Bolgan and Parmentier 2020; Gordon et al. 2018; Lin et al. 2019; Mellinger et al. 2007; Van Parijs et al. 2009). Technological developments of the last two decades have significantly advanced the logistical, acquisitional, analytical, and economic facets of PAM (Chapuis et al. 2021; Lindseth and Lobel 2018; Waddell et al. 2021; Wall et al. 2021), and as a result, collection of PAM data has increased dramatically in both deployment number and data volume, to a point that traditional acoustic data processing techniques are becoming ineffective (Mooney et al. 2020; Parsons et al. 2022). The recent increased volume of data and focus on aquatic ecoacoustics have also led to the discovery of many undescribed sounds from unknown sources that contribute to underwater acoustic diversity, particularly in coastal environments, the sources of which remain largely unknown (e.g., Bolgan and Parmentier 2020; Di Iorio et al. 2021; Rountree et al. 2020a). There is much space for collaboration among the growing research community asking questions in this area; the co-creation of a Global Library of Underwater Biological Sounds by this community could potentially serve to facilitate many of the goals of PAM scientists.

New methods of processing aquatic PAM data are continually being developed and multiple applications have recently been published: Reference libraries that document groups of taxa are increasingly being created (e.g., Looby et al. 2023a; Mellinger and Clark 2006; Ocean Networks Canada 2021; Sayigh et al. 2016; Vigness-Raposa et al. 2012); focus groups have developed event extraction, detection, characterization, localization, and density estimation machine learning algorithms (e.g., Frazao et al. 2020; Lin et al. 2021b; Shiu et al. 2020; Sun et al. 2022); data portals to upload long-term and short-term recordings are online (e.g., Darras et al. 2022; OPUS 2022); software to extract soundscape characteristics from long-term recordings are becoming standardized (e.g., Merchant et al. 2015; Miksis-Olds et al. 2021); and forums are being created to encourage discussions about PAM analysis (e.g., https://bioacoustics.stackexchange.com/).

At the same time as these PAM advances, some wider-reaching ecological tools now have the potential to include acoustic information. The World Register of Marine Species (WoRMS; Costello et al. 2013), for example, provides a list of all aquatic and semiaquatic species, including a selection of their characteristics or "traits," the Ocean Biodiversity Information System (OBIS; Fornwall 2000) can map the regional or global distribution of these species, and Fishbase (Froese and Pauly 2022) provides biological and ecological information on adult finfishes around the world. A web portal that keeps an up-to-date set of links to tools demonstrating the latest best practice in PAM data processing and sharing could be of great value to the research community.

Individually, all these applications offer a wealth of information to better understand aquatic soundscapes and the soniferous species that contribute to them. However, to maximize their use and streamline analysis processes, these tools need to be integrated on a cohesive platform (Parsons et al. 2022). Previous efforts to create enduring PAM-related applications, such as acoustic libraries, have often been unable to secure sufficient ongoing funding to continue updates and maintenance once the initiator departs the host institute and therefore become outdated or without license (Bianco et al. 2019; Frasier 2021). To overcome these issues requires significant initial and long-term investment, driven by substantial user endorsement and uptake, stakeholder engagement, appropriate governance on national and international levels, and scalable infrastructure to cope with the expansion of PAM (Parsons et al. 2022).

A working group for the Global Library of Underwater Biological Sounds (GLUBS), initiated by the International Quiet Ocean Experiment (IQOE; Tyack et al. 2015), has proposed the development of a web-based platform to bring these applications together in a single point-of-contact interface and to facilitate the integration of a new wave of PAM data mining, extraction, and artificial intelligence (AI) techniques (Parsons et al. 2022). A similar approach is underway to collate museum collections and allow the querying of their data for characteristics and specimens of individual species (vertnet.org). For PAM, GLUBS would be a critical step forward in collating, documenting, understanding, and mapping the world's underwater soundscapes and their sources, as they respond to increasing pressure from climate change, fishing, aquatic resources development, and various pollutants (e.g., plastics and anthropogenic noise). For individual researchers that lack data storage support, such as the servers of large institutions, this platform will provide a much-needed avenue to ensure the longevity of samples of biological sounds. GLUBS will also facilitate growth in knowledge and understanding of aquatic soundscapes among the potential stakeholders through sharing soundscape data and the sounds that contribute to them, sharing the algorithms that can analyze the data, and open discussions about issues, new developments, and the ever-occurring question, "What's that sound?".

The following discussion summarizes the focus points discussed at a GLUBS workshop on July 16, 2022, following "The Effects of Noise on Aquatic Life, 2022" conference in Berlin, Germany. This 1-day GLUBS meeting was attended by 20 partners (7 in person, 13 online). The authors of this report comprise the attendees, plus several contributors to specific subgroup discussions included below.

## GLUBS Vision and Framework

The overarching GLUBS objective is to provide a holistic approach to PAM that is as useful for as many stakeholder sectors as possible. This includes, for example, processing and analysis packages for researchers of varying experience and disciplines, application-based information to assist management decisions, knowledge, and the opportunity to contribute for citizen scientists and soundbites for musicians and artists. To do this, GLUBS will be a web-based application programming

interface (API), serving as an umbrella platform that links external software applications and purpose-built GLUBS software packages that perform multiple complementary functions. It will host dedicated GLUBS data storage and links to external databanks, such as existing sound libraries and national sound repositories, from which it would have the functionality to record metadata, extract data from long-term recordings, and store "snippets" (i.e., relatively short-term recordings of individual sounds, such as a fish sound or humpback whale song). The GLUBS framework will also include software to fill functionality gaps left between the integrated applications.

Approaching such a multidisciplinary objective from an individualistic or discipline-focused approach may not unveil the functionality required by all users and thus could limit stakeholder uptake needed to ensure enduring support. Therefore, a decision was made to achieve community consensus on the structure and scope of such a platform, prior to implementing any design. To achieve this, a bioacoustic community appraisal was designed to collate the experiences, knowledge, and needs of stakeholders and will develop the GLUBS structure with consideration of the community's views. Therefore, GLUBS will be a product, designed by a consortium of bioacousticians and implemented under the auspices of the IQOE.

## Core Values

To ensure outcomes are as equitable and valuable as possible, the platform will be based on open-science principles and follow a series of core values and endorsed/standardized principles, essential to modern research. The GLUBS platform would therefore:

- Follow FAIR (Findability, Accessibility, Interoperability, and Reusability of digital assets) principles (The Turing Way 2021; Wilkinson et al. 2016).
- Be as inclusive and transparent in its design and implementation as feasible.
- Ensure identifiers are used to track usage and provide recognition for contributors.
- Minimize national bias (e.g., incorporate multiple languages, wherever possible).
- Prioritize net environmental benefit, which may include being carbon neutral, and ensure outputs follow standardized and community-endorsed processes, where possible. For example, GLUBS would follow International Standards Organization (ISO) definitions (International Organization for Standardization 2014) and use IQOE-endorsed applications.

## Framework

The final platform design, contributing applications, and how they can be integrated into the platform are part of the engagement process and will be chosen and defined over the coming year. However, GLUBS will be structured and written in a programming language that facilitates integration with external applications and not necessarily exclusive to individual packages (e.g., this would allow potential data

portals to connect to GLUBS and their users could interact with GLUBS). There is no intention to supersede existing applications, but, where possible, GLUBS will help enhance or expand them, typically to include functionality required to produce desired outputs of GLUBS. For example, this could include supplying libraries with new sounds; highlighting target (data-limited) "wanted" species; developing soundscape analysis tools for processing software to include novel, established metrics; creating generalized analysis tools that can visualize acoustic data from different databases; or providing AI groups with training datasets to test and evaluate and benchmark their new algorithms.

The framework will be categorized into essential and preferential functions and applications. Different levels of implementation will match stage-gated funding to ensure that, if initial funds were limited, the core structure is in place and will have the technical capacity to be expanded to include additional, predesigned levels, when sufficient funds are secured. This will ensure core functionality is available to as many users as quickly as possible. Core features have been broadly identified as:

1. User front-end interface with query structure (to identify user objectives) and metadata forms
2. Data portal(s) potentially being different for sounds and soundscapes
3. Links to external databases that can interactively improve the observation of marine biodiversity and ecosystems, such as WoRMS, Fishbase, and OBIS
4. Integrated internal and external reference libraries
5. Training datasets for AI algorithm development
6. Event extraction/machine learning software and links to external AI groups
7. Graphical interface(s) for scientists/public/artists to visualize and download information
8. Software package for soundscape analysis to produce data products (e.g., sound levels, acoustic indices, visualizations)
9. Forum (internal or external) for bioacoustics discussion

## Initial Targets: Collating Information on Known Soniferous Species and Unidentified Sounds

To assist the goal of documenting as many biological aquatic sounds as possible, the GLUBS working group (WG) set two initial targets. The first was to produce and maintain a list of all aquatic species confirmed or anticipated to produce sound underwater. The WoRMS comprises a searchable database of selected characteristics (known as "traits") for all extant and extinct aquatic and semiaquatic species, for which the distribution of species with this trait can be mapped through OBIS. Including underwater sound production as a searchable trait would facilitate distribution mapping of soniferous species for a specific region or globally. One could also choose a location and extract a list of all confirmed or likely soniferous species known to occur there or choose a species and investigate how their sounds vary through space and time. Integrating this information with a reference library of

sounds would present all the sounds that one might expect to be present in a recording at a given location and time. To begin to achieve this objective, a GLUBS sub-working group has produced a database of the extent to which all known aquatic species produce sound (Looby et al. 2023b). To achieve this, each species was assessed to determine in what way they answer the question "Does the species actively or passively produce sound under natural conditions while submerged in water?" following set definitions of active and passive sound production in natural and unnatural conditions (see Looby et al. 2022 for definitions). The trait has six categories according to whether a species has been confirmed or is considered likely to produce sound (Table 1). This database can be updated on WoRMS as reports of new species confirmed to exhibit soniferous behavior are released and later incorporated with sound recordings.

The second initial target is to promote the reporting of sounds from unknown sources. Unidentified sounds can provide valuable information on the richness of the soundscape, the acoustic communities that contribute to it, and behavioral interactions among acoustic groups (Bolgan et al. 2020; Di Iorio et al. 2021; Sun et al. 2022). However, unknown, cryptic, and rare sounds are rarely target signals for research and monitoring projects and are, therefore, largely unreported (Parsons et al. 2022). To address this knowledge gap, GLUBS will facilitate a series of forums to promote research of such signals, make knowledge of their characteristics more accessible, and increase awareness of their occurrence. The first of these forums is a special issue on unidentified underwater biological sounds that is being developed for the journal *Frontiers in Remote Sensing* (https://www.frontiersin.org/journals/remote-sensing).

## Ongoing Design, Development, and Implementation Discussions

### The Snippet, the Snapshot, and the Soundscape

Passive acoustic monitoring encompasses the assessment of individual sounds and the soundscape through time and space. Short acoustic recordings (here called "snippets") may record individual sounds, while a longer recording (e.g., minutes, hours, days) can provide a "snapshot" of a soundscape and include numerous sounds, and recordings that extend into months or years provide the opportunity to capture all the cycles (e.g., naturel diel, tidal, lunar, seasonal patterns in biological noise) and other fluctuations (e.g., passing vessels, earthquakes, cyclones, seismic surveys) in the soundscape, across many time frames. In its simplest context, the soundscape is defined as a sound or combination of sounds that forms or arises from an immersive environment (International Organization for Standardization 2014). It is important to note that characteristics of the soundscape vary with time and so the length of the recording may affect whether the recording captures all the potential variation and sounds that naturally occur at the recording site (Parsons et al. 2016). In contrast, soundscapes are degrading due to human influence over timescales of months to years (Gordon et al. 2018), and the PAM community is currently

addressing the challenge to develop rapid assessment tools that can detect both anthropogenic impacts to soundscapes and the "sound of recovery" to healthy soundscapes (Lamont et al. 2022a).

**Table 1** Trait and category definitions for species sound production characteristics in the World Register of Marine Species, based on our current state of knowledge regarding sound production

| Identifier | Presented information/field | Definition |
|---|---|---|
| Trait | Species exhibits underwater soniferous behavior | Does the species actively[a] or passively[b] produce sound under natural conditions[c] while submerged in water? |
| Category 1 | Unknown or undetermined | There is no known acoustic[d], morphological, or physiological[e] study of sound production for this species, and its likelihood of soniferous behavior based on an ancestral state reconstruction analysis[f], lineage, or evolutionary records has not been assessed, or this species has yet to be categorized by an expert source |
| Category 2 | Does not or is unlikely to produce sound under natural conditions | Species has been the subject of one or more studies to assess its acoustic behavior[d] morphology and/or physiology[e], none of which have provided evidence of sound production either actively[a] or passively[b], and/or species does not have a likelihood of soniferous behavior based on an ancestral state reconstruction analysis that results in a probability below 0.5[f], lineage, or evolutionary records |
| Category 3 | Likely to produce sound under natural conditions but unconfirmed | There is no known acoustic documentation[d] to confidently validate sound production under natural conditions[c] by this species, but it is likely to exhibit natural soniferous behavior based on an ancestral state reconstruction analysis that results in a probability of 0.5 or higher[f], lineage, evolutionary records, morphological characteristics, physiological characteristics[e], documented sound production behavior under artificial conditions[g], and/or documented sound production behavior with some uncertainty[h] |
| Category 4 | Produces passive sound under natural conditions | There is validated[i] acoustic documentation[d] that this species produces passive[b] sound under natural conditions[c], but no validated documentation to confirm that it actively[a] produces sound |
| Category 5 | Produces active sound under natural conditions | There is validated[i] acoustic documentation[d] that this species produces active[a] sound under natural conditions[c], but no validated documentation to confirm that it passively[b] produces sound |

(continued)

**Table 1** (continued)

| Identifier | Presented information/field | Definition |
|---|---|---|
| Category 6 | Produces active and passive sound under natural conditions | There is validated[i] acoustic documentation[d] that this species produces active[a] and passive[b] sound under natural conditions[c] |

[a]Active sound: produced deliberately in association with a particular behavior or situation, frequently with specialized sonic organs or structures, and are generally used for communication; also referred to as intentional, deliberate, or specialized sounds (Looby et al. 2022)
[b]Passive sound: may not be associated with specialized sound-producing structures nor with specific behaviors or situations, though they may still serve some signal function; also referred to as incidental, unspecialized, or mechanical sounds (Looby et al. 2022)
[c]Natural conditions: in the absence of artificial manipulation, such as an electrical current or direct handling
[d]Acoustic study or documentation: documentation in the peer-reviewed or gray scientific literature of the presence or absence of audible sounds through listening live or on a recording in captivity or the field (Looby et al. 2022)
[e]Morphological or physiological study or documentation: documentation in the peer-reviewed or gray scientific literature of the presence or absence of morphological and/or physiological structures with sound production functions (Looby et al. 2022)
[f]Ancestral state reconstruction analysis: the extrapolation back in time from measured characteristics of individuals to their common ancestors using statistical techniques to, in this case, recover information on the likelihood of soniferous behavior (https://doi.org/10.1371/journal.pcbi.1004763 Joy et al. 2016; https://doi.org/10.1643/i2020172 Rice et al. 2022)
[g]Artificial conditions: involving human intervention or manipulation, such as an electrical current or direct handling
[h]Uncertainty: doubt or uncertainty expressed by researchers conducting examinations for sound production about their conclusions (e.g., that the species they examined was correctly identified, that they correctly identified active versus passive sounds; https://doi.org/10.1007/s11160-022-09702-1 Looby et al. 2022)
[i]Validated: The researchers' conclusions have no associated uncertainty in the documentation (see above)

Although all these recording durations provide valuable information, the primary initial function of GLUBS is as a global library of biological sounds, created both through the integration of existing libraries and from new dynamic contributions. The library thus has a focus of separating and presenting individual sounds to assist in source allocation. The individual sounds may then be used to analyze the components of soundscapes in recordings of varying duration. Further, although the focus of GLUBS is on biological sounds (or "biophony"), soundscape analysis is also often conducted with the consideration of geophony and anthropophony (Lin et al. 2021a; b; Pijanowski et al. 2011). For algorithms to be able to recognize biophony in soundscapes among background sounds, geophony and anthropophony will also need to be considered. As the future goal, the platform may extend to the collection and analysis of long-term soundscapes and the associated metadata; however, for the immediate future, GLUBS will aim to focus on snippets of individual sounds while bearing in mind their context in soundscapes.

The assessment of biodiversity, habitat type, and condition are novel and complex issues in the underwater environment. Ecoacoustics is the investigation of the natural

and anthropogenic sounds that shape a location's soundscape and the physical environment and species assemblage at that location, across multiple spatial and temporal scales. While numerous terrestrial PAM "ecoacoustic" techniques have been applied successfully (Farina et al. 2018; Kahl et al. 2021; Potamitis 2014; Sueur and Farina 2015), the results have been mixed when applied to aquatic recordings (► Chap. 37, "Anthropophony Effects on Acoustic Metrics in a Marine Soundscape"). Complexity, spectral and temporal variation, and various metrics of sound levels can contribute to what may be a site-specific reflection of physical biodiversity and condition. Therefore, GLUBS must hold the ability to assess and potentially incorporate new methods, as they become available, and their utility is evaluated.

Calibration of equipment is critical if sound levels are to be evaluated and environmental metadata is also required if source levels are to be calculated. Uncalibrated equipment has valid applications for detecting acoustic events or changes in soundscape characteristics over time within a single recording. How the functionality of GLUBS is applied to the assessment of biodiversity and the quantification of sound levels will be decided during the design process, with the inclusion of soundscapes potentially held as a future ambition of GLUBS. There may also be the need to attach provisos with any outputs to identify their limitations and avoid misinterpretation. At this stage therefore, the intention for the design of GLUBS is that it will have gated input options, so that calibrated and uncalibrated data can be included, and there will be the option to input metadata if it is available. This will maximize the accessibility and utility of the platform.

## Sound Categorization

Recent advances in technology have increased accessibility of underwater PAM to a variety of scientists (with different fields of expertise), managers, citizen scientists, artists, and the general public. As a result, reports of sounds may originate from physicists, biologists, ecologists, managers, or musicians, each of whom is recording for their own objectives and reporting using their own experience. There are currently no standards for classifying or reporting sounds and so these may be categorized onomatopoeically, from spectral or temporal components of the sound, or simply using the common name of the source species (Parsons et al. 2022; Looby et al. 2023c). However, while categories related to species' common names can resonate among local communities, common names and onomatopoeic names can be too subjective, are not widely applicable, and are sometimes meaningless to non-English speakers. While in some countries such names have had success for birds and amphibians (e.g., see online use of BirdNet and FrogID), it has not been successfully realized for mammals and even less so for fishes and invertebrates. To be able to systematically include sounds into GLUBS, a standardized method of sound categorization is needed, preferably based on a statistical method. It is anticipated this will use a multitiered naming system, similar to scientific naming of species (i.e., a decision tree process), which is based on the sound rather than the source. Common or colloquial names could then be applied as secondary levels of

naming to maintain public engagement and understanding, in the same way as with Latin and common species names.

## Data Storage, Management, and Governance

As individual PAM datasets approach volumes of terabytes per site, per year, the potential for collection to outweigh storage capacity at a single node or databank is high, if not already occurring. Data storage capacity is also growing rapidly, and volume may not be a long-term future issue, but it is currently a major consideration (Havlik et al. 2022; Wall et al. 2021). However, PAM data are also transient and cannot be recollected in the true sense, and soundscape characteristics (such as ambient sound levels) are difficult to hindcast without the data. Thus, from an information perspective, to ensure their reusability, all raw data need to be appropriately archived in highly durable storage. The cost of data collection often outweighs that of storage, so there is a trade-off between minimizing replication of data to save storage space (and minimize environmental impact) and maximizing the retention and availability of information. Additionally, minimizing restrictions on contributors is one of the best ways to promote user uptake and endorsement. Some national governments have realized this and already ensure that sufficient space is allocated for important PAM data, such as the US National Centers for Environmental Information (within the United States' National Oceanic and Atmospheric Administration) for ongoing programs that acquire significant data volumes (Wall et al. 2021). It is important for GLUBS to be able to access these data sources and potentially add value to them.

Data managers often recommend one server (on a cloud or hosted server) and one hard copy backup of a dataset, with a web-based copy available for sharing. Although cloud data storage is relatively inexpensive, there is a cost each time the data are retrieved for analysis and this increases with the speed at which data are downloaded. The cost versus benefit of data accessibility should be analyzed and this cost/benefit ratio is currently unknown. Such an analysis may suggest an approach of processing as much data as possible at the outset, before uploading to the cloud, and storing the resulting metadata and outputs on the GLUBS platform. An additional and possibly more advantageous option is to exploit various levels of data storage and archival processes and tailor these to the types of data sources GLUBS will encounter. For example, remote links to national databanks may make it possible to process datasets without downloading and extract required metrics and sound snippets directly, depending on the respective storage method. This type of access could be key to minimizing time and data replication. Software links could be provided to research institutes to process their data in-house and upload the outputs. This would potentially limit GLUBS server requirements to include the reference library sound snippets, and eventually metadata, and soundscape metrics from these two sectors (national data collection programs and research institutes) of large-scale data collectors. Additional data contributors will be individual researchers, hobbyists, and citizen scientists who lack resources for data storage themselves. GLUBS

would need to store what is currently a nebulous, but fast-growing data stream. Developing a strategy to address these points is nontrivial and identifying the full needs is problematic until a full design of the GLUBS structure has been finalized. However, ongoing system maintenance and data management (excluding future expansions and developments) clearly require full-time staff.

The proposed level of data sharing and reporting on the web – across multiple regional, national, and community boundaries – necessitates an understanding of the licensing and sovereignty requirements. When sharing and publishing on this scale, it is important to note that all agreements are not created equal and the authority of some licenses is not applicable outside of its region of copyright origins. To avoid bespoke data-sharing agreements, GLUBS will rely on existing licensing frameworks that provide a level of international compatibility, such as the Creative Commons (CC) suite. No single CC license or waiver will be made mandatory as a data owner's legal jurisdiction may prohibit their involvement in the platform. For example, the "CC0" license waiver is not legal in Australia. It is therefore important to produce a table of different agreements and uses of data across all participating communities or countries to develop a flow process outlining the authority and governance and a "user-friendly" way to identify the possible avenues a stakeholder could contribute to the platform.

From an environmental perspective, the GLUBS core values require its designers, developers, and contributors be aware of the environmental cost of data collection and attempt to minimize the platform's impact. This could be achieved through optimizing face-to-face/online meetings, translating recordings of meetings into multiple languages and storing them to enhance inclusivity, sharing recording equipment, engaging local collaborators to conduct deployments (rather than sending researchers long distance), assessing and minimizing the environmental cost of data storage, and minimizing use of disposable items (e.g., batteries, mooring systems). The environmental aspirations of GLUBS and documenting emissions related to platform development and ongoing data collection will be considered on an iterative basis to maintain the platform is of net environmental benefit. Any environmental data and archived recordings of meetings will be stored and made publicly available via the GLUBS platform.

## Artificial Intelligence Needs

Serving as a platform for developing AI algorithms has been identified as a key feature of GLUBS. This requires the creation of manually annotated datasets from diverse marine environments that can serve as training and testing data of AI-based sound detection, classification, and separation applications. Many automated detectors for particular sound sources have been successfully developed. However, although one detector that works in one place has significant value, for single sound detection and species identification, to date, multiple research studies have shown that there is no single detector solution for all sources and locations. Recently, BirdNet (Kahl et al. 2021) and the LIFEPLAN project (https://www.helsinki.fi/en/

projects/lifeplan) have made significant advances in this area, for bird calls. Lauha et al. (2022) describe the development of a pipeline for a global identification model that can be adjusted to detect local calls when supplemented with annotated local recordings.

To develop this field in the aquatic environment, there is therefore a need to identify the various objectives of acoustic signal processing within GLUBS; to engage multiple AI groups in aquatic, terrestrial, and avian research; and potentially to leverage the state-of-the-art AI tools used in music and speech information retrieval. Such data sharing has previously proven successful as evidenced by open competitions for developing algorithms (e.g., Frazao et al. 2020, www.dcase.community/challenge2022/index) and the software applications already available in this field (e.g., Bird Sounds Global, Wikiaves, OrcaSound, etc.). As with open forums and competitions, such engagement is conducted with the ethos that GLUBS outputs provide mutual benefit to the AI groups.

Although data from different contributors will hold characteristics (e.g., sampling frequency, system frequency response) that may affect algorithm performance and compatibility, it is possible to create benchmark AI datasets. These will require samples from all potential environments (e.g., with different background noise, habitat, propagation characteristics from multiple geographical areas), must be carefully identified, and ideally meet as many criteria from an AI developer's wish list of characteristics as possible. To this end, any GLUBS AI dataset should include the following:

- Clear objectives of audio signal processing and suggested metrics to assess performance
- Many (i.e. potentially tens of thousands) examples of the target signals
- Many examples of context (backgrounds, other sounds such as those produced by nontarget species)
- Representative scenarios in which the model will be used (noise, seasonal changes, etc.)
- Comprehensive, validated (false and missed detections) test sets that also reflect the expected usage scenarios
- Annotation (start/end times, lower- and upper-frequency limits) throughout the training data that can include mixture of strong and weak labeling
- An annotation style that generally matches the expected output of the machine learning model

There are several avenues through which datasets can be annotated: by those that created the dataset, by the GLUBS network, or even by citizen scientists. It will be important to develop a roadmap to identify how each of these options can contribute to the datasets and engage contributors.

Sounds of rare, data-deficient species can provide key ecological information and should not be ignored or overlooked. Data augmentation methods will be trialed for such species, noting that few-shot learning and unsupervised learning methods are available. Automatic clustering techniques like scikit-maad (Ulloa et al. 2021) can

be used to identify and group (or "cluster") matching rare sounds and can be used as a first step to build machine learning detectors of rare sounds. Further, it may be necessary to develop and compare AI algorithms that can account for these data-deficient sounds in the assessment of soundscapes, with those that do not. However, as confidence in AI detections improves with the size and quality of the training dataset, it may be necessary to tier databases to highlight and potentially target such sounds for ongoing development.

## Stakeholder Engagement

Historically, several applications and acoustic programs have fallen by the wayside because of lack of user and broader stakeholder uptake (Parsons et al. 2022). However, some platforms remain successful, providing valuable lessons on community engagement and potential partners for moving forward (e.g., DOSITS.org). As GLUBS is planned to be a multidisciplinary and multi-sector platform and therefore requires continued engagement at multiple levels, it is also important to not only engage but to provide recognition to those who contribute data and information. This practice will promote confidence in the platform and potentially improve user opportunities (e.g., citations of contributors' sounds to improve their chances of winning grants).

### National PAM Strategies

Multi-decadal long-term, non-military PAM datasets are few (Caiger et al. 2020, www.acoustic.aodn.org.au/acoustic/); however, several national government departments are dedicating resources toward ensuring that these types of programs can be set up, maintained, and even expanded into the future (e.g., Wall et al. 2021), highlighting the increasing acceptance of ocean sound as an Essential Ocean Variable (EOV; Tyack et al., in prep.), increasing the provision of baseline or reference soundscape data, and advancing this notion to freshwater and brackish environments. The development of national strategies in collaboration with a standardized global platform like GLUBS could increase user uptake.

### Scientists

As stated above, the decision has been made to engage the broader bioacoustics community to ensure the core element of the platform (acoustics research) meets their needs, and the best way to achieve this is through a co-design and endorsement process. However, this needs to be an ongoing ethos and the best way to ensure this is through providing recognition and credit, where appropriate. For example, persistent identifiers (PIDs), digital object identifiers (DOIs), open researcher and

contributor identifiers (ORCIDs), and Research Organization Registry (ROR) tags can be added to contributed recordings, metadata, or algorithms, with the agreement that anyone using the data associated with these identifiers is required to cite their origins whenever published.

## Citizen Science

There are several different levels at which public engagement can occur (e.g., data collection and analysis, individual citizen science, passive consumption, artistic and science communication projects), and there are many members of the public that can be involved for these processes. In the underwater PAM realm, this has most recently been achieved through the Google Arts "Calling in our Corals" project, presented recently at COP 27 (www.unfccc-events.azureedge.net/COP27_87813/agenda). There are also multiple ways to incentivize citizen scientists/public users. Virtual community competitions with points rankings, or online rewards (e.g., virtual toys that increase in size with contribution), for example, have already been shown to thrive to increase validation datasets. Additionally, citizen scientists, keen to become fully engaged with PAM programs, could contribute sound recordings with access to low-cost recording systems (e.g., Hydromoths, GoPros) that are being assessed to identify their potential level of scientific contribution (e.g., Chapuis et al. 2021; Lamont et al. 2022b).

The capacity to crowdsource the transcription of GLUBS text into multiple languages as has been successful elsewhere is highly appealing and, similar to other aspects of GLUBS, such as data collection, could be achieved through social media (Hirschberg and Manning 2015). At the community level, sound is a highly engaging medium and holds potential for successful outreach projects, such as educational presentations with area-specific themes (Scowcroft 2021) and presentations on sound produced in the local language, potentially for specific indigenous communities (Ocean Networks Canada 2021). Such presentations could be provided to local institutions, schools, or libraries to increase engagement. Coordinated media and online outreach efforts could also lead to higher user engagement and extent (Looby et al. 2023c). Collectively, these aspects highlight a need to discuss the level at which these stakeholder groups wish to be engaged and what would they want in the final product.

## Case Studies to Demonstrate Utility

To provide examples of the potential utilities of the planned GLUBS system and to assist end users in understanding the platform's process management, a series of case studies were developed that also fit within the PESTEL (Political, Economic, Social, Legal, Environmental, Technological) framework (Richardson 2006). One such objective is delineating essential fish habitat and estimating biomass of a spawning

aggregation of a commercially or recreationally important soniferous species, which is presented below. These case studies were designed to provide a broad overview of the flow process that highlights how GLUBS might link existing and new applications. For brevity, they do not detail all the methodological subtleties and additional validation data that users may collect.

For example, in the case study below, relative and absolute abundance estimation of "calling" fishes using PAM is a complex and nuanced problem that is dependent on numerous behavioral, physiological, and environmental factors that are species and site specific. As such, methodological detail for abundance estimation techniques (e.g., call counting, fish chorus sound levels, combining threshold limits with chorus sound levels), and validation studies needed to support the transfer between call detections or chorus levels to abundance estimates (e.g., source level, caller spatial distribution, call rates, signal duration, propagation losses, ratio of calling: non-calling fish based on age and gender), can be found elsewhere (e.g., Erisman and Rowell 2017; Parsons 2010; Parsons et al. 2009, 2010, 2012, 2013; Rowell et al. 2017, 2020; Sprague and Luczkovich 2011). For clarity, here, a "call" is defined as being an acoustic advertisement signal related to spawning behavior (e.g., Parsons et al. 2013), and a "chorus" follows the definition of continuous or discontinuous choruses by Cato (1978) and McCauley (2001), respectively.

## Case Study – Fisheries – Identifying Essential Fish Habitat and Estimating Biomass

The following case study assumes a researcher has collected one or more, long-term, calibrated recordings from one or more sites within an estuary that holds a spawning aggregation of a known soniferous species, with some reported acoustic characteristics. GLUBS would utilize multiple applications within the platform to provide information that assists in producing either a relative or absolute estimate of the numbers of fish(es) at the recording sites based on their calls, and this changes through the spawning season. The flow process for this procedure would be as follows (steps below are visualized in Fig. 1):

1. User inputs metadata information and selects query topic (GLUBS stores metadata).
2. GLUBS automatically links to WoRMS/OBIS to query all soniferous species expected at the location and time of the recording.
3. WoRMS/OBIS sends a list of all known and likely soniferous species reported that could be contributing to sounds in the recording to GLUBS portal.
4. GLUBS portal queries internal and external reference libraries for known acoustic characteristics of known and likely sound-producing fish species (as well as other sounds).
5. Libraries produce details on all reported sounds of known soniferous species likely present and the user selects which of these species they are interested in, i.e., species that produce sounds similar to those in the user's recordings.

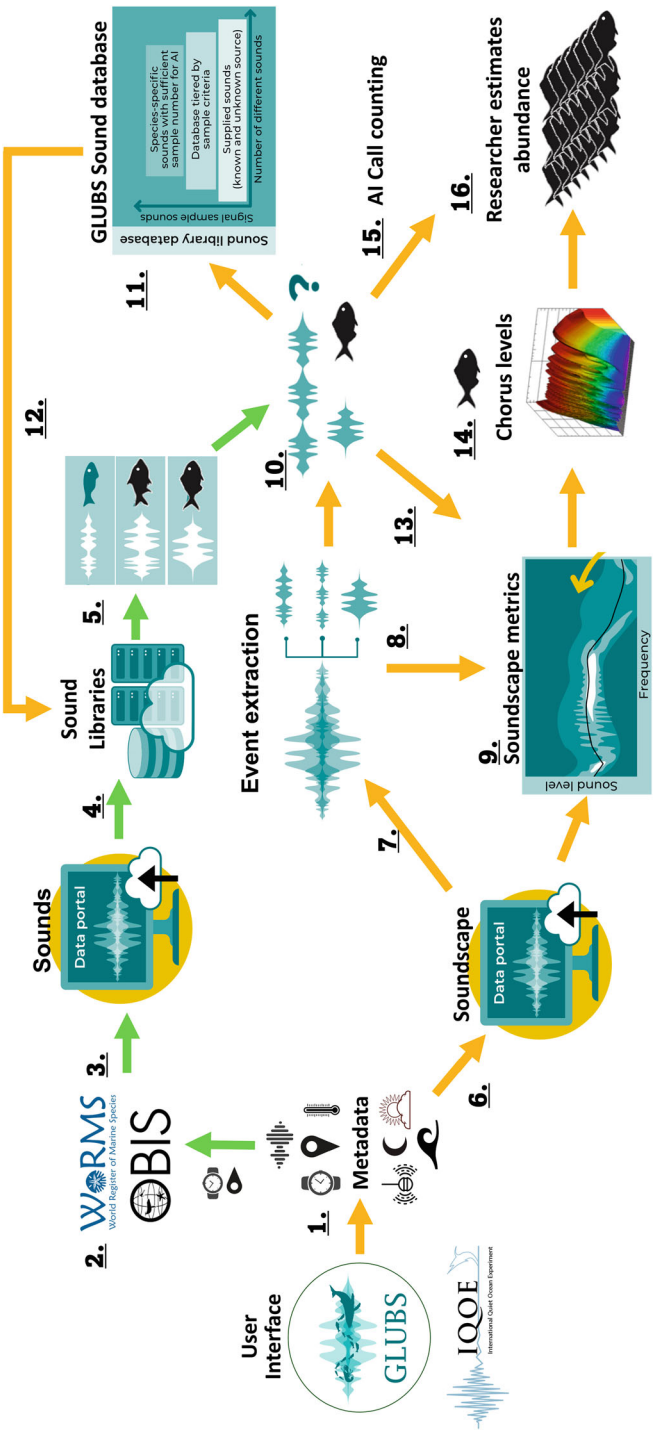

**Fig. 1** Broad GLUBS workflow for a case study (outlined in numerical steps in section 6.1) on estimating fish essential habitat and biomass. Further species-specific research may be required by the researcher between steps 14 and 16

At the same time:

6. The user is forwarded to a soundscape data portal to upload the entire dataset.
7. For all sound types detected in the recordings:
   - Event extraction algorithms identify time periods when mass phenomena (fish choruses) occur and the frequency band of the chorus that contain 90% of the energy.
   - Integrated external AI algorithms pull individual sounds (fish calls) from the dataset.
8. These times and frequency bands are inserted into a soundscape analysis tool to assist processing of the entire dataset.
9. Initial soundscape data products are exported from software, such as percentile plots of sound levels through time and sound levels within the frequency bands and times denoted by the event extraction algorithms.

Combining the reference data and the snippets extracted from the uploaded dataset:

10. Known sources of the individual sounds and choruses are identified by the user either through personal knowledge or from the information provided by the reference libraries.
11. User either (a) validates the fish in the recording or (b) deems sounds to be of unknown origin and examples of both types of calls are forwarded to the GLUBS sound database to begin/expand AI dataset.
12. Selected reference sounds for known and unknown sources are forwarded to GLUBS and external libraries.

Analysis of fish calls:

13. Source identified as the fish species queried by the user is forwarded to GLUBS software.
14. Daily chorus sound pressure levels (over the time and frequency band determined in 7 and 9) are then exported.
15. AI software runs an automated detector through the recording to count the number of fish calls and the estimated call rates (for periods when individual calls can be discriminated).
16. Daily call detection rates and chorus levels are exported for analysis outside GLUBS, and the two methods are compared to investigate the relative change of fish acoustic activity through time, noting the species- and site-specific constraints, nuances, and validation data, described above.

## Financial Support

There are three tiers of activities that require funding: (1) implementation, (2) ongoing maintenance and platform development, and (3) stakeholder engagement and user uptake. These costs (e.g., salary for dedicated and contracted staff, data storage,

and infrastructure) would initially be administered through the IQOE and, in some cases, founding partner institutes, ensuring it is not the responsibility of a sole institute. Funding for associated research and development may be administered through any partner within the GLUBS consortium to work toward a mutual goal. It would comprise three types of team members, supported through multiple institutions and funding mechanisms: (1) dedicated full-time staff to implement and maintain GLUBS (e.g., curator, systems manager/developer/web designer), (2) contracted part-time staff to implement GLUBS (e.g., web designer, maintenance manager), and (3) collaborative researchers/developers co-funded from one or more of a consortium of partner institutions to research and develop GLUBS (some of which operate associated applications).

The costs could be met by one or more of three envisaged dominant sources of funding: industry partners and regulators, philanthropic interests, and government support. In essence, it is expected that the GLUBS WG would provide mission documents and members could seek grants and funding from stakeholders in their region. Once the GLUBS system is operational, commercial avenues of funding could be accessed to cover ongoing costs. Commercial sources of funding could include advertising space within the interfaces, royalties from aspects of the platform used for commercial gain, income from commercial products developed through GLUBS, and, although the intention is for this platform to be open access, subscription fees to use one or more aspects of the platform. There is also the possibility that industry partners, who typically hold large datasets of PAM data, may be interested in funding the assessment of historic datasets via data mining for individual target species. Industry partners may also be able to engage regulators to push for funding to implement GLUBS. Industry and regulators have shared interest in better understanding factors such as impacts of noise, the distribution and migratory pathways of key species, or increasing baseline datasets on sound levels, and funding to help achieve these with GLUBS could be sought through industry programs, such as carbon offsets or Good Standing Agreements that have funded research in Australia (e.g., AIMS 2023).

## Working Subgroups

Finally, the GLUBS WG determined that several working subgroups (WSG) would be required to deliver a complete plan for such an ambitious platform. The WSGs that have been identified to date are species list and reference libraries, sound categorization, PAM applications, cyberinfrastructure design, AI needs, funding, and stakeholder engagement.

**Acknowledgments** The IQOE Science Committee provided financial support to hold the GLUBS workshop at the Effects of Noise on Aquatic Life 2022 conference and facilitated the attendance of some members. The Richard Lounsbery Foundation has provided financial support for the continued development of this working group. Support for the group was provided by the Scientific Committee on Oceanic Research, Monmouth University Urban Coast Institute, and Rockefeller Program for the Human Environment. Jesse Ausubel of the Rockefeller Institute has provided valuable insights to the working group. We thank them for their initiative and support.

**Conflict of Interest** The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

# Correction to: Anthropophony Effects on Acoustic Metrics in a Marine Soundscape

Lara C. Lopes, Eliziane G. Oliveira, Christopher W. Clark, and Renata S. Sousa-Lima

**Correction to: Chapter 156, "Anthropophony Effects on Acoustic Metrics in a Marine Soundscape" in: A. N. Popper et al. (eds.), *The Effects of Noise on Aquatic Life*, https://doi.org/10.1007/978-3-031-50256-9_156**

The chapter was inadvertently published with incorrect name of the first author and this is now corrected as Lara C. Lopes.

The updated version of this chapter can be found at https://doi.org/10.1007/978-3-031-50256-9_156
